PREFACE

TO THE 36TH EDITION

We have retained the Preface and Introduction to the 35th edition, because they record events leading to a new editorship and extensive alterations in format and contents; and they also state our conviction that anatomy is a continuum of study from the biochemics of the cell to the whole organism. It would be unnecessary to re-state this attitude, especially since our convictions remain unaltered and indeed strengthened. This does not imply, however, that we have become 'fixed in our ways'; our very policy of revision precludes that, entailing as it does the formidable task of keeping abreast of advances in a wide field. In this we have been stimulated and sustained not only by the apparent success of the 35th edition (which has been twice reprinted, with translations into Italian, Dutch, and Spanish), but perhaps even more by the spate of correspondence, from many countries, containing criticisms, corrections, suggestions and sometimes, encouragement. To these correspondents, from the most junior student to the most eminent specialist, we are grateful, trusting that they will be equally unrestrained in their reception of this new edition. While it is impossible to mention the many hundreds involved by name, we must acknowledge in particular the students and teachers of the Indian and North American continents, who have been specially helpful in their comments. Many colleagues must, however, receive more formal expression of our debt to them, in addition to those already named in the 35th edition. These include: Doctor R. McN. Alexander (Department of Pure and Applied Zoology, University of Leeds), Doctor Sally P. Allwork (Department of Surgery, Royal Postgraduate Medical School, London), Doctor Robert H. Anderson (Cardiothoracic Institute, London), Doctor Caroline A. Berry (Paediatric Research Unit, Guy's Hospital, London), Doctor F. Bojsen-Møller (Department of Biological Structure, University of Washington, Seattle), Professor Ruth E. M. Bowden (Department of Anatomy, Royal Free Hospital Medical School, University of London), Professor A. J. E. Cave (Professor Emeritus, University of London), Professor R. Čihák (Department of Anatomy, Charles University Medical Faculty, Prague), Doctor Yves Clermont (Department of Anatomy, McGill University, Montreal), Doctor Julian Dussek (Cardiothoracic Unit, Guy's Hospital, London), Doctor Walter R. Dyson (British Leather Manufacturers' Research Association), Doctor D. W. Fawcett (Department of Anatomy, University of Harvard Medical School, Boston), Professor B. Raymond Fink (Department of Anaesthiology, University of Washington), Professor D. B. Fry (c/o Department of Phonetics, University College, London), Doctor G. Gabella (Department of Cytology, University College, London), Doctor John R. Garrett (Department of Oral Pathology, Dental School of King's College Hospital Medical School, London), Doctor D. W. Grieve (Biomechanics Laboratory, Department of Anatomy, Royal Free Hospital Medical School, London), Doctor Juliet Heaton (Department of Histopathology, Guy's Hospital Medical School, London), Doctor Karen Hiiemae (Department of Anatomy, University of Illinois, Chicago), Doctor Anthony Huson (Anatomisch Embryolisch Laboratorium der Rjksuniversiteit te Leiden), Doctor Peter Isaacs (Gastro-enterology Unit, Guy's Hospital, London), Doctor Jean M. Jacobs (Department of Neuropathology, National Hospital of Nervous Diseases, London), Doctor Klaus Jacobsen (Department of Orthopaedic Surgery, Geritofte Hospital, Copenhagen), Professor Indar Jit (Department of Anatomy, Postgraduate Institute of Medical Education and Research, Chandigarh), Professor Jack Joseph (Department of Anatomy, Guy's Hospital Medical School, London), Professor J. M. F. Landsmeer (Anatomisch Embryolisch Laboratorium der Rjksuniversiteit te Leiden), Doctor Niels A. Lassen (Department of Clinical Physiology, Bispedjerg Hospital, Copenhagen), Doctor N. Lockett (Institute of Ophthalmology, University of London), Doctor John Marshall (Institute of Ophthalmology, University of London), Doctor David M. Maurice (Department of Surgery, Stanford University Medical Center, California), Doctor N. J. Mizeres (Department of Anatomy, Wane State University College of Medicine, Detroit), Professor David B. Moffat (Department of Anatomy, University College, Cardiff), Doctors Linda Ziemer (Uniform Services University, Bethesda) and John Palfrey (Charing Cross Hospital Medical School, London), Doctor Dwight Parkinson (Department of Surgery, University of Manitoba), Doctor Christopher Piasecki (Department of Anatomy, Royal Free Hospital Medical School, London), Doctor D. Rampton (Gastro-enterology Unit, Guy's Hospital, London), Professor Lynne M. Reid (Children's Hospital Medical Center, Harvard Medical School, Boston), Doctor Eva L. Saha (Calcutta), Doctor Gordon Sladen (Gastro-enterology Unit, Guy's Hospital, London), Professor R. W. Sperry (Division of Biology, California Institute of Technology), Mr. Graham Stack (Essex Nuffield Hospital, Brentwood), Professor R. B. Symington (Department of Anatomy, University of Rhodesia), Professor Colin P. Wendell-Smith (Department of Anatomy, University of Tasmania), and Doctors W. J. Whitehouse and E. D. Dyson (Medical Research Council Radiobiology Unit, Harwell). Some of these authorities, as is recorded in appropriate captions, have generously allowed us to use or adapt their original illustrations. For this we are indebted to them and also to the publishers and editors of many journals and books, as we have duly acknowledged. We are grateful in particular to the Cambridge University Press, publishers of *The Journal of Anatomy*, and to its late editor, Professor J. J. Pritchard, of The Queen's University of Belfast, whose death during this revision we note with much regret.

Textually, this revision embodies at least as much new writing as the 35th edition, partly in replacement but more often as additions. In the many tasks involved we have been greatly assisted by our two new Associate Editors, Doctor Lawrence H. Bannister (also involved in the 35th edition) and Doctor Mary Dyson, whom we welcome with pleasure. Owing to the fact that we are all colleagues in the same department, we have been able to enjoy almost daily discussions on a host of matters of revision; every new illustration, for example, has been seen, criticized and amended by all four of us, and it is therefore not always possible to indicate the prime mover in any particular innovation. In this connexion we have also to acknowledge the continued support of our illustrator, Mr. Richard Moore, whose services are sometimes

as much intellectual as graphical. He has been joined by Mrs. Jennifer Halstead, whom we also welcome as a most talented and fortunate addition to our team. Between them they have added about 200 new illustrations; and for their skill and patience in producing these in a friendly but arduous environment of criticism, repeated revisions, and constant pressure, we are indeed grateful to them. While a few unsatisfactory photographs have been deleted or replaced, a much larger number have been added. For much loyal aid in this respect we continue in our indebtedness to Mr. Kevin Fitzpatrick our Departmental photographer, and we must also thank his assistant Miss Marina Morris. Our thanks are also due to Messrs. David Ristow and Stephen Sitch for histological preparations. For the large number of new electron micrographs (transmission and scanning) introduced in this edition we acknowledge the expertise of Messrs. Derek Lovell and Michael Crowder and Mrs. Susan Smith, who are responsible for technical services in our Electron Microscopy Unit. In connexion with illustrations and much expert advice, it is a pleasure to record our appreciation of the assistance of our colleague, Doctor Michael C. E. Hutchinson, whose outstanding ability and willingness in the preparation of special dissections and of osteological and corrosion cast specimens, has greatly assisted us. Doctor Susan M. Standring, the recipient of the Symington Memorial Prize of the Anatomical Society of Great Britain and Ireland in 1974, has again demonstrated her breadth of knowledge and efficiency in preparing the bibliography, and Doctor E. Lowell Rees has, once more, faced the rigours of the seemingly endless and demanding task of formulating the index with great care and discrimination. Doctor Christopher Buckland-Wright has kindly prepared a number of micro-focus radiographs and we have had the advantage of his skilled advice regarding the trabecular patterns of bone. We are, indeed, much indebted to all our departmental colleagues for their endless and patient support. We record our debt with respect and affection.

With this support a multitude of minor and many major improvements have been made, and it is not possible to note more than a few special topics which have received particular attention beyond the general revision of the text. These include: in Cytology, cell surface specializations, intracellular organelles, intercellular materials, the cellular elements of blood, haemopoiesis and cellular aspects of immunity; in Embryology, the general introduction, which has been completely re-written, now embodies applications ranging from modern theories of cell differentiation, pattern formation, to 'field' and 'catastrophe' theory. In Osteology, bone growth and vascularization have been extensively revised, with special emphasis on new theories of ossification. In Arthrology and Myology the chief changes are an expansion of kinesiology to include more recent concepts and a wider application of these principles to individual joints and muscles. Masticatory, respiratory, and hand movements have also been further analysed and corrected in some descriptive details; and the section on walking has been expanded. In Angiology the entire section on the heart and coronary vessels has been replaced and expanded to bring it closer to current physiological, clinical and surgical views and practices, and briefly to equate cardiac structure with the events of the cardiac cycle. The sections on cardiac muscle, structure of blood vessels, and those on the thymus, spleen, other lymphoid tissues and lymphocytes have been extensively improved. Apart from many minor corrections and additions in respect of individual vessels, the intracranial venous sinuses have been much revised. In Splanchnology all sub-sections have been considerably re-written, often with many new illustrations. In the Respiratory System the functions of the larynx and especially phonation have been re-written; and the micro-anatomy, histology and cytology of the bronchial tree and lungs have been re-described in the light of the most recent work, with particular emphasis upon the varieties of epithelial cell. Similarly, the Alimentary System has been the subject of much revision in connexion with its epithelial and glandular structures, including the liver and pancreas. The article on teeth has been revised by our former colleague, Professor Jeffrey W. Osborn (now in the Department of Oral Biology, University of Alberta, Edmonton). In the Urinary System the structure and ultrastructure of the kidney have been described in greater detail and briefly associated with current concepts of renal function. The gametes and gametogenesis have also been updated. The Endocrine Glands have been completely re-written in the light of the most recent work concerning their structure, synthetic and secretory pathways, and the control systems and target tissues involved. All the major glands have received such treatment, but special mention should, perhaps, be made of the pineal body, the paraganglia, and the endocrine and paracrine functions of many types of cell in autonomic ganglia and epithelia, particularly in the alimentary tract. General discussion on concepts such as the 'APUD cell system', the 'GEP cell system', the 'diffuse neuroendrocrine system', and the varied usages of the term 'chromaffin system' are included. The Nervous System, central and peripheral (and some aspects of the special senses), have also received much attention, including such topics as the structure and classification of peripheral nerve fibres and sensory endings, the classification of synapses and synaptic groups, the cells of sensory and autonomic ganglia, the peripheral distribution of autonomic nerve fibres, the mapping of the central nervous system according to the distribution of known and putative neurotransmitter substances, especially biogenic amines, and the modes of analysis of the reticular system. The latter topics, which have attracted much recent research, have been described in considerable detail. Like so many aspects of central nervous structure they now present such ramifications, especially in their functional connotations, that little more can be done in a volume of this size beyond reference to appropriate monographs.

All these changes, which would have materially increased the size of this volume to an inconvenient bulk, have been countered in this respect by a complete re-setting of the text in slightly smaller type. We hope that this will be found acceptable, although the change introduces the possibility of an entirely new crop of typographical errors, some of which may have eluded repeated proof-reading, and for this we ask forbearance. As a second means of saving space the footnote references have been deleted and the so-called Harvard System introduced, to obviate unnecessary repetition of citational detail, all of which is now concentrated in the Bibliography. We hope that this change will be approved, although it has entailed considerable encumbrance of the text with citational concatenations in some places. It has not impeded the inclusion of new references, and in fact the Bibliography has increased by about 1,000 items. We hope that the altered style of quotation of journals will be regarded as an improvement, and that the omission of page references for each item cited will also be acceptable.

Despite the many difficulties and delays inseparable from the preparation of a new edition of so large a volume, committed as we are to ideals of revision—most trying to our publishers—our relations with them and our printers have remained most cordial.

Miss Margaret Collins has continued to aid us with secretarial tasks, handling not only extensive correspondence and many sporadic items of typescript, but also the hospitality occasioned by rather frequent visitors.

Mrs. Irene Williams, undeterred by the experience of preparing all the typescript for the 35th edition, has repeated the task in her own patient and impeccable manner, for which we—and doubtless our printers—are again most warmly grateful.

As before, we end our long task with a sense of profound gratitude to the many friends and colleagues who have helped in many different ways to sustain the enthusiasm of ourselves and our small team through a long period of effort. Especially to our wives, for their unending encouragement and support through our long years of preoccupation, we offer our gratefulness.

Summer 1980 R.W. and P.L.W.

PREFACE

TO THE 35TH EDITION

When our predecessor, Professor David Vaughan Davies, began his preface to the last edition, his first words were to regret the death of his co-editor (Professor Francis Davies) and to acknowledge, with characteristic generosity, the latter's editorial virtues. It is now our equally saddening task to record the death of an editor and friend for whom we shared, with so many others throughout and beyond the confines of human anatomy and medicine, a deep respect both as a scientist and teacher, and as a man of many accomplishments outside his profession. During a period of fifteen years he brought to this editorship the same unyielding standards of scholarship which he applied so outstandingly in his own discipline and school. For both of us his death had also immediate personal associations, for one (P.L.W.) had enjoyed twenty-five years as his student, colleague and companion, and for a number of years acted as his indexer, while the other (R.W.)—frequently a co-examiner—was expecting him on the second day of an examination of our own students when he was so suddenly stricken. We both regard it as an honour to carry forward his editorial obligations.

At the time of his death Professor Davies had completed a small number of revision notes, and these and his collection of references have been valuable to us. However, the decision had already been taken to modernize the format of this volume, with a complete resetting of the text; and it was therefore opportune to undertake a more extensive revision than would have been otherwise possible. The original role of *Gray's Anatomy* as a treasury of 'descriptive and applied' systematic human topography has become amplified through more than a century of usefulness by the early addition of histology and embryology, and by the gradual development of introductory sections to the various 'systems'. To many readers, both graduate and undergraduate, this elder textbook has, however, represented *in excelsis* the field of naked-eye or *dissectional* anatomy. We have neither disturbed nor curtailed this aspect of the volume: rather have we added to it—by the correction of errors, the addition of a host of new observations, the inclusion of hundreds of new references to cover details beyond the scope of even a large textbook, and by reinstatement of variations in respect of many structures. On the other hand we have endeavoured to reduce prolixities of language, as far as the shortened period of revision remaining to us has permitted; no page has escaped such attention, frequently extensive in degree. A considerable saving of space has been thus effected—to offset large additions of new writing and to keep this new edition within a single volume. To rewrite the whole text would have been an impossibly lengthy task, and there has inevitably resulted an increase in size. Subsequently we hope and intend to render all of the established text in a simpler and more succinct style, but to do this throughout with no loss of factual detail is a massive undertaking, and for our limited success in this regard we ask our readers' forbearance. Moreover, we were convinced that other tasks were more urgent and important.

Particularly in this century, the conviction has increased amongst anatomists that isolated observation and description is not enough, and that an experimental approach to problems of structure is as necessary as in other biological sciences. In addition, the greater advances in technique—especially in the study of finer detail, in living and developing organs, tissues and cells—have enlarged the scope of anatomy far beyond the parent stem of macroscopic structure. These advances have engendered a spate of new specialities, such as histology, cytology, ultrastructure, embryology, neurology, electromyography, kinesiology, ergonomics, and so on, to a degree dependent only upon the choice of individual minds and the canalization of techniques. The expanding scope of structural knowledge and the exacting demands of more elaborate techniques do indeed dictate such specialization; but all such knowledge remains a continuum—except insofar as extensive gaps of ignorance and uncertainty persist. Unfortunately, and perhaps particularly in the medical sphere, the compartmentalization of anatomy into several disciplines or subjects—with attendant titles, individual chairs, and even separated departments—tends towards disintegration. To study some such region as a limb, in all its proportions, activities, and even evolution, and then its major structures—bones, joints, muscles, vessels and so forth—and to proceed to the microscopic, ultrastructural and ultimately biochemical details of its tissues and cells, appears to us a continuous process, and most desirably so to a balanced education for medicine, however elementary the standard. Unfortunately, these different levels of organization and function are perforce usually considered in separate laboratories, departments, lectures and books.

The defects of this compartmentalization are widely recognized, and have resulted in much effort to 'integrate' teaching. In this persuasion we have re-arranged certain contents of this volume, and in particular have transferred most of the existing section of histology to the appropriate systems. Hence, in *Myology* will be found not only a systematic description of the muscles of the human body, but also of muscle as a tissue. Moreover, there are certain general considerations such as, in this instance, the variable form and the mode of action of muscles and accessory structures—tendons, aponeuroses, bursae, and the like—which have already in recent editions been set out in introductory sections. It is precisely in these generalized aspects of human anatomy that the greatest interest often lies, attracting the major volume of research. We have concentrated special attention upon these sections, which are the more difficult to keep in accord with current progress in research. For this reason, and because the *significance* of structural data is more apparent in generalizations, we have found it necessary to rewrite all such introductory sections and to extend them—to a marked degree in most instances.

The accelerating tempo of enquiry in all respects of structure has a dual effect: there is not only a continuous correction and, more especially, accumulation of data, but also in the main a sharpening awareness of defects in knowledge and deficiences in its interpretation. It is our belief that ignorance and uncertainty should be more prominently stated in textbooks than they usually are. We have tried to imbue this new edition with rather more of this attitude, not merely in introductory sections, but throughout the systematic text. Where the actions of a muscle are not

convincingly demonstrable by direct observation or experiment, we believe uncertainty should be admitted; and where, for example, intricate central nervous organization has been investigated in another animal—perhaps quite remote from man—we consider that the need for caution in extrapolation to mankind should, in a textbook of human anatomy, be clearly appreciated.

It would be burdensome to categorize the changes and additions in this edition; approximately seven hundred pages of completely new writing have been contributed, covering all systems and a wide spectrum of topics. Doubtless our efforts have been uneven; we have, for example, not been able to revise some aspects of cardiac anatomy as thoroughly as we wished, but these and other defects will be remedied in the next edition. While hoping that many will welcome the substantial changes and additions in histology (and especially ultrastructure), in the sections on the teeth (completely rewritten), joints, muscles, lymphatic system, nervous system, special senses and endocrine organs, we also hope that our readers will freely and constructively criticize our mistakes, excesses and deficiencies. To keep abreast of all the new work reported is a formidable undertaking, and we trust that no one will hesitate to inform us of our shortcomings in this or any other regard.

In one particular this edition is unique; for the first time since the first edition, in 1858, this, the *direct* descendant of the original '*Gray*', will be available in the United States side by side with the American scion, which has also persisted through almost an equal period, having begun in 1859 as a reprint of the first edition, but having diverged markedly in its evolution from the direct British descendant. The American parallel version ceased to refer to the British senior heir as long ago as 1896, though preserving the name of Henry Gray on its title-page. With subsequent editions, and particularly this, the divergence has become so great that the two books cannot be regarded as parallel versions; each has its own character.

Our editorial labours have been lightened by much help from others. Doctor Lawrence H. Bannister has contributed the new section on cytology and many of the histological and ultrastructural passages in the sections devoted to myology, neurology, and splanchnology. Doctor Jeffrey W. Osborn has recast the section on dental anatomy. Doctor Susan M. Standring has prepared the bibliography, which appears as a new feature at the end of the text, and has meticulously supervised all reference material. Doctor E. Lowell Rees has not only undertaken the complex revision of an expanded index, but has also provided many special dissections, histological preparations and advice. However, the majority of the revision remains the work of the editors, who are wholly responsible for any errors of judgment, incorrect terminology, omissions, misquotations, or lack of clarity throughout the volume. With the complete resetting of the text, index, illustration captions and tabbing, and the addition of a new bibliography, it is inevitable that, despite prolonged and repeated proof reading, some typographical errors will have eluded us; for these we apologize.

In accord with the comprehensive textual changes in this edition, the illustrations have also received much attention. More than 200 of the 1,305 figures of the 34th edition have been removed, with the addition of over 600 new items; thus, in this 35th edition almost a third of the illustrations are new. Moreover, new blocks have been prepared for all illustrations retained—from the original artwork wherever possible. Apart from those radiographs and reproductions from external sources, acknowledged below, all new illustrations have been prepared in our Medical Centre. We are much indebted to Doctor Aszal Riaz and Doctor John D. Dow (Department of Diagnostic Radiology) and to Mr. Kenneth Twinn and Mrs. Joy Taylor (Department of Physics) for much help with radiographs. In our own department Doctors E. Lowell Rees and Michael C. E. Hutchinson have produced many special dissections and other preparations, assisted in this by Doctors Andrew M. Seal and William J. Owen. Most of these have been photographed by Mr. Kevin Fitzpatrick, our photographer, to whom we are much indebted. Mr. Derek Lovell and Mr. David Ristow have provided skilled technical assistance in respect of electron microscopy and histology. Many other workers on our staff, past and present, have also helped with illustration material, including Doctors Mary Dyson, Murray Brookes, Karen Hiiemae, Wimal Jayaratnam and Kenneth J. W. Taylor; Doctors David R. Turner and Roy O. Weller (now in Pathology), Doctor David N. Landon (now in the Department of Neurobiology, National Hospital for Nervous Diseases, London), Doctor Eric W. Baxter, Mr. Eric C. Tatchell and Miss Hilary Phillip (Department of Biology) and Doctors J. P. Black and P. Barkhan (Department of Haematology) have all afforded us generous aid with preparations for photography. We also gratefully record the expert help of our School's Librarian, Miss Jean M. Farmer and her willing staff.

Mr. S. W. Woods had already prepared six new illustrations (chiefly in embryology), with the same high standards with which he embellished several previous editions while serving Professor Davies. Most of the new artwork, however—amounting to about 210 items—has been carried out by our colleague, Mr. Richard E. M. Moore, D.F.A.Lond., M.M.A.A., member of l'Association Internationale pour l'Etude de la Mosaique Antique, and Fellow of the Royal Society of Arts. His combination of meticulous draughtsmanship, a most unusual ability to comprehend the scientific intent of projected illustrations, and his extraordinary patience and stamina throughout two and a half years of continuous effort, have made our collaboration most fruitful and enjoyable.

Many other authorities in various fields have allowed us to reproduce, copy or adapt illustrations from papers and monographs, or have special materials available for photography. It is a pleasure to acknowledge the generosity of Professor Janos Szentágothai (University of Budapest), Doctor Elizabeth Crosby (University of Michigan), Doctor W. J. W. Sharrard (University of Sheffield), Doctor Michael J. Hogan, Doctor Jorge J. Alvarado and Mrs. Joan E. Weddell (University of California), Doctor Alan M. Laties (University of Pennsylvania Medical School), Mr. Emanuel Rosen (Royal Eye Hospital, Manchester), Doctor N. A. Locket (Institute of Opththalmology, London), Professor Alf Brodal (University of Oslo), Professor William J. Hamilton (Professor Emeritus, University of London), Professor Peter M. Daniel (Institute of Psychiatry, University of London), Professor J. André-Balisaux (University of Brussels), Doctors Keith E. Webster and A. Robert Lieberman (University College, London), Professor Don Fawcett (Harvard University Medical School), Professor N. Cauna (University of Pittsburgh), Professor Yves Clermont (McGill University), Doctor Max Levene and Mr. Emrys Turner (St. Helier Hospital, Surrey), Doctor Charles Levene (Sir William Dunn Department of Cellular Pathology, University of Cambridge), Doctor R. C. Edwards (University of Cambridge), Doctor A. F. Holstein (University of Hamburg), Doctor L. M. Franks (Imperial Cancer Research Fund, London), Doctor Don H. Tompsett (Royal College of Surgeons of England), Doctor M. A. Sleigh (University of Bristol), Professor Sir John O. Eccles (Laboratory of Neurobiology, State University of New York), Doctor Berta Scharrer (Albert Einstein College of Medicine, New York), Professor Paul D. Maclean (National Institute of Mental Health, Maryland), Doctor Walle J. H. Nauta (Massachusetts Institute of Technology), Doctor Webb Haymaker (Ames Research Center, N.A.S.A., California), Doctor Bror Rexed (Socialstyrelsen, Stockholm), Professor James M. Sprague (University of Pennsylvania), Doctor Ray S. Snider (University of Rochester, New York), Professor Clinton N. Woolsey (University of Wisconsin), Doctor Julia Fourman (University of Leeds), Professor David B. Moffat (University College, Cardiff), Doctor Alexander Barry (University of California), Professor Viktor Hamburger (Washington University, Missouri), Professor Setsuya Fujita (Prefectural University Medical School, Kyoto), Doctor Douglas R. Anderson (University of Miami), Professor Koji Uchizono (University of Tokyo).

We have had the benefit of special advice from many of the authorities acknowledged above, and in addition from Professor M. A. MacConaill (University College, Cork), Professor Jack J. Pritchard and the late Doctor James H. Scott (University of Belfast), Doctor F. Torrent Guasp (University of Barcelona), Professor John Z. Young (University College, London), Mr. D.

G. Wilson Clyne, Professor Patrick D. Wall (University College, London), Professor J. V. Basmajian (Emory University, Atlanta), and Doctor Keith Jones (Keeper of the Jodrell Laboratory, Royal Botanic Gardens, Kew, Surrey). Among colleagues in other departments in our centre we are especially indebted to Doctor R. T. Grant (late of the Department of Experimental Medicine) and Professor Paul E. Polani and his staff (Department of Paediatric Research) for much help respectively in regard to arteriovenous anastomoses and genetics. Similarly we have had the advantage of advice from many other colleagues in their own specialities, including Doctor Sidney Liebowitz (Immunological Pathology), Doctor John R. Henderson (Physiology) and Doctor David Watts (Biochemistry).

Although we have striven to acknowledge with punctilo the many publishers of scientific journals and books who have allowed us, with customary generosity, to use copyright material, we trust that any neglect in this respect of which we may have been guilty will be forgiven in the same generous spirit.

Throughout the ardours and pressures of this ambitious revision we have enjoyed the most cordial relationship with our publishers and printers, who have both given us the greatest freedom and encouragement. In particular we wish to mention Mr. John A. Rivers of Churchill, and Mr. William G. Henderson, Mr. Gerald J. Hooton and Mr. Alfred S. Knightley, of Churchill Livingstone, who have been our companions in many anxious, sometimes convivial, and always protracted discussions.

We are most grateful to our departmental secretaries, Miss Margaret Collins and Mrs Patricia Elson, for much sporadic and demanding help, and to our official secretarial assistant, Mrs. Irene Williams, who has patiently translated innumerable notes and drafts into immaculate typescript for the printers.

It is customary to eulogize the patience of wives—faint praise which is scarcely *galante*. Far from tolerating our preoccupation, our wives have supported us unfailingly with a true and critical interest and sympathy in our labours. To them and all our friends and colleagues, who have helped more than they know to sustain our enthusiasm, we remain profoundly grateful.

1973 P.L.W. and R.W.

HENRY GRAY, F.R.S., F.R.C.S.

Since readers of *Gray's Anatomy* will be interested to learn something of the original author, Henry Gray, the following information as to his career has been extracted from an article which appeared in the *St. George's Hospital Gazette* of 21 May 1908.

Gray, whose father was private messenger to George IV, and also to William IV, was born in 1827, but of his childhood and early education nothing is known.

On 6 May 1845, he entered as a perpetual student at St. George's Hospital, London, and he is described by those who knew him as 'a most painstaking and methodical worker, and one who learnt his anatomy by the slow but invaluable method of making dissections for himself'.

While still a student he secured, in 1848, the triennial prize of the Royal College of Surgeons for an essay entitled, 'The origin, connexions and distribution of the nerves to the human eye and its appendages, illustrated by comparative dissections of the eye in other vertebrate animals'.

At the early age of twenty-five he was, in 1852, elected a Fellow of the Royal Society, and in the following year he obtained the Astley Cooper prize of three hundred guineas for a dissertation 'On the structure and use of the spleen'.

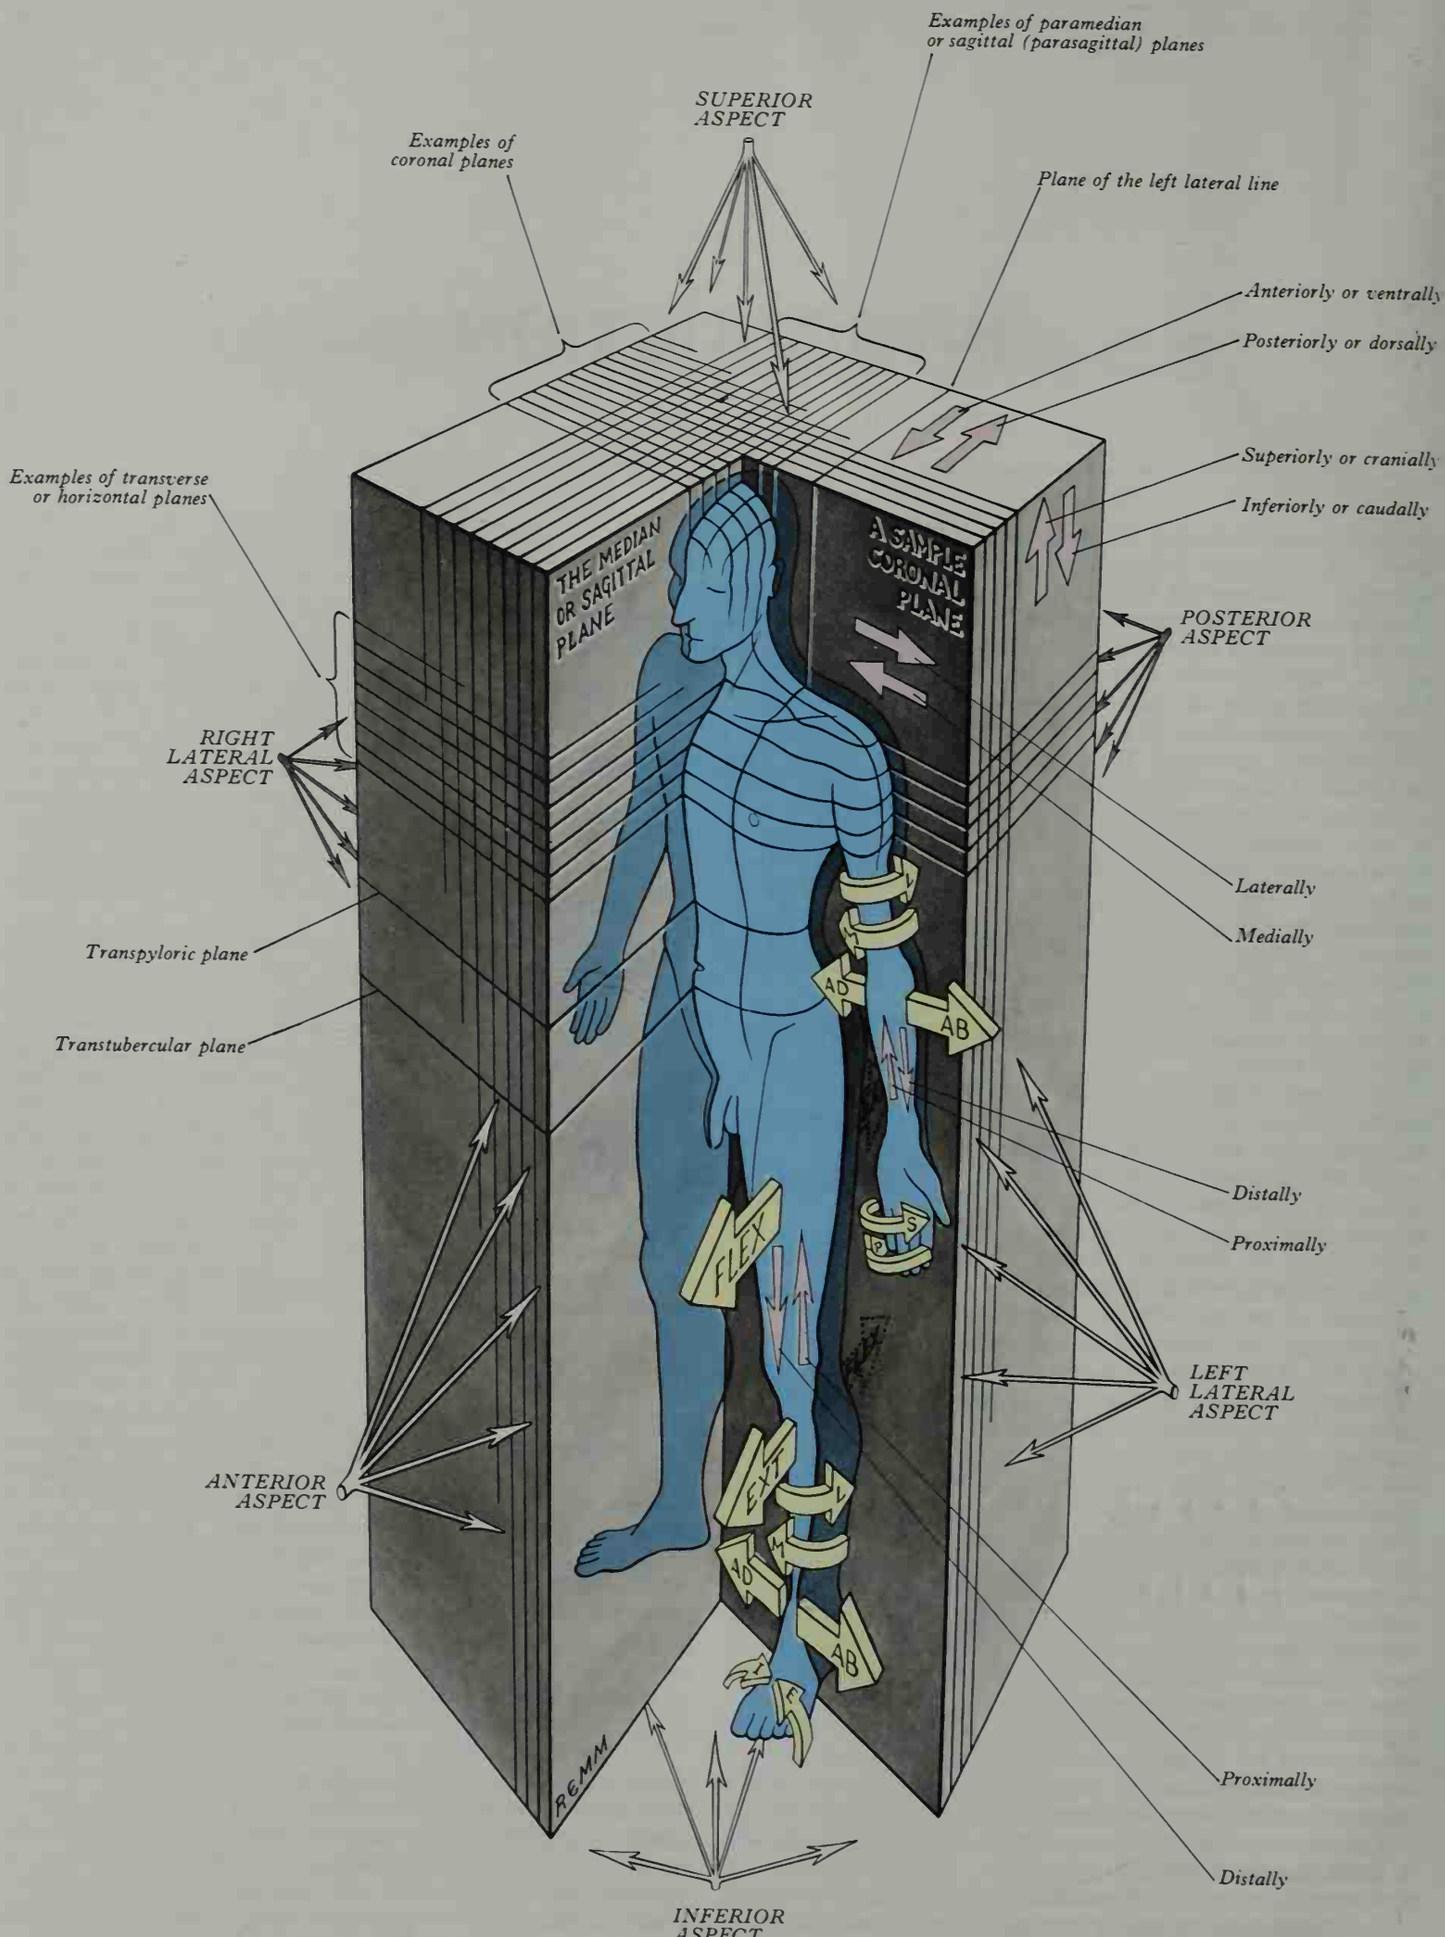
He held successively the posts of demonstrator of anatomy, curator of the museum, and Lecturer on anatomy at St. George's Hospital, and was in 1861 a candidate for the post of assistant surgeon. Unfortunately he was struck down by an attack of confluent smallpox, which he contracted while looking after a nephew who was suffering from that disease, and died at the early age of thirty-four. A career of great promise was thus untimely cut short. Writing on 15 June 1861, Sir Benjamin Brodie said, 'His death, just as he was on the point of obtaining the reward of his labours . . . is a great loss to the Hospital and School.'

In 1858 Gray published the first edition of his *Anatomy*, which covered 750 pages and contained 363 figures. He had the good fortune to secure the help of his friend, Dr. H. Vandyke Carter, a skilled draughtsman and formerly a demonstrator of anatomy at St. George's Hospital. Carter made the drawings from which the engravings were executed, and the success of the book was, in the first instance, undoubtedly due in no small measure to the excellence of its illustrations. This edition was dedicated to Sir Benjamin Collins Brodie, Bart., F.R.S., D.C.L. A second edition was prepared by Gray and published in 1860.

The portrait of Gray published in the present section is a reproduction of one which appeared in the *St. George's Hospital Gazette* of 21 May 1908, where the original is described as being 'a very faded photograph taken by Mr. Henry Pollock, second son of the late Lord Chief Baron Sir Frederick Pollock, and one of the earliest members of the photographic society of London'.

INTRODUCTION

To perform an 'anatomy' was to make a 'dissection'; the two words are no longer synonymous. *Dissection* has remained a technique; *Anatomy* has become a field of study—a corpus of observations, still dependent upon technique, but capable of rational correlation among themselves and with other biological studies. Most narrowly, anatomy may be the investigation of biological structure—in plants or animals—with no other motive than description of form. Even so, such *topographical anatomy* has not remained insulated from technological progress; the usefulness of direct visual dissection persists, but its relatively crude results have become incalculably augmented by the advent of light microscopy, micro-dissection, electron microscopy, histochemistry, radiology, autoradiography, and many other techniques. The application of these, with ever-growing modifications and extensions, has revealed great new fields of discovery. Some, such as *histology* and *cytology*, the study of tissues and cells, are true extensions of the parent discipline; others—*electron microscopy, histochemistry* and *autoradiography*—are merely techniques capable of providing particular types of data.



The theme of growth and differentiation, both in individual development or *ontogeny* and in that of the species or kind—*phylogeny*—has led to the particular studies of *embryology*, *comparative anatomy* and *morphology*. Embryology, the study of individual development, also embraces problems of gametogenesis, fertilization and embryonic nutrition, and in the investigation of these in relation to mankind, *comparative embryology* has proved invaluable.

Studies of growth, whether upon the epochal time-scale of evolution or the rapid cycles of ontogeny, emphasize the mutability of structures; and the dynamic nature of all *living* structures entails an inescapable relation between form and function. It is, of course, possible to consider form in isolation, an exercise of most limited value, though the data of pure description may have particular applications. Such *applied anatomy* is usually concerned with human structural observations which are useful in medicine, especially in surgical technique, but also in clinical diagnosis. Descriptive anatomy, however, has a far more extensive application in relation to function. Few biological structures can be regarded as functionless, and no biological function is known to occur outside living fabric, which includes, it must be noted, everything from the whole creature to its molecular structure. In human considerations of nature it is possible to divorce structure from function (though not the reverse); but few structuralists are disinterested in function. The mere fact that topography can be described upon a *regional* or *systematic* basis necessarily entails functional considerations, for while the former is of particular vocational interest in medicine, *systematic anatomy* is based upon recognition of function. The *locomotor system* embraces structures directly concerned with movement—skeletal elements, articulations and ligaments, and muscles, the study of which may be formalized as *osteology*, *arthrology* and *myology*. Similarly, *neurology*, which treats of the nervous sytem, including its sensory organs, and *angiology*, the study of cardiovascular arrangements of organs and tissues, are correlated as much by function as by structure. It is equally clear that the *respiratory, alimentary, urogenital* and *endocrine systems* (though often grouped under the unilluminating anatomical term *splanchnology*), are clearly functional as well as anatomical fields of study.

All such 'systems' are investigated at macroscopic, histological, cytological, ultrastructural and biochemical levels. Furthermore, experimentation upon structures—classically illustrated by early work on the circulation, reflex behaviour and endocrine influences—has formed the vanguard of anatomical research, with increasing momentum in this century. *Experimental anatomy, experimental cytology* and *experimental embryology*, have contributed greatly to the advancement of knowledge in the field of human anatomy. Throughout the following sections, where relevant, numerous allusions will be made to the results of such experimental studies.

Descriptive anatomy obviously demands an internationally acceptable repertoire of names for structures, and there is also a need for an agreed convention upon terms for their spatial relationships (*see* accompanying figure). For this purpose the human body is assumed to be in its usual bipedal or erect position with the arms pendent and eyes and hands facing forwards. This position is open to certain objections; for example, the arms are rotated laterally at the shoulder joints and the forearms are fully supinated and are thus not in their usual position of rest (*see* p. 350). Moreover, comparisons of human anatomy with that of other animals, which are mostly quadrupedal in habit, are confronted with some difficulties. Nevertheless, the erect 'anatomical position' does provide an unambiguous system of correlation for man. In this posture the *median plane* divides the body vertically into right and left halves which are approximately symmetrical, apart from certain visceral details. The superficial contours of this plane form *anterior* and *posterior median lines* on the surface of the body. The median plane is also frequently called the *sagittal plane* (after the cranial suture of that name), but this term is also sometimes applied to any vertical plane parallel to the median, and hence the latter may be termed *paramedian* or *parasagittal planes*. To avoid confusion and to maintain simplicity, it is perhaps best to reserve the term *median* for the single *median plane* defined above, and to regard all other planes parallel to this as *sagittal*. Vertical planes at right angles to the median plane are usually described as *coronal planes*, after the coronal suture (p. 298). To complete the three-dimensional reference grid, *horizontal planes* are those which traverse the body at right angles to both the median and coronal planes.

The adjectives *anterior* and *posterior* are applied to the front or back surfaces of the body, including the limbs. Synonyms for these are *ventral* and *dorsal*, which, since they can be applied equally to quadrupeds, are sometimes preferable. All these terms are in fact used more extensively to specify the aspects or surfaces of individual structures *within* the body, and often to denote their relative positions. Thus—the heart is posterior (or dorsal) to the sternum, the posterior surface of which is close to the anterior (or ventral) aspect of the heart. Similarly, *superior* (or *cranial*) and *inferior* (or *caudal*) are adjectives qualifying the positions of structures in the vertical sense. Of the two venae cavae one is

The terminology widely used in descriptive anatomy is illustrated in the figure above. The abbreviations on the solid arrows: AD—adduction, AB—abduction, FLEX—flexion (of the thigh at the hip joint), EXT—extension (of the leg at the knee joint), M and L—medial and lateral rotation, P and S—pronation and supination, I and E—inversion and eversion.

superior, *cranial* (headward) with respect to the other which is *inferior*, *caudal* (tailward) in position. (Incidentally, the *superior* and *inferior* venae cavae are *anterior* and *posterior* in the quadruped, but the terms cranial and caudal, which obviate this confusion, have not been adopted in this instance in mankind.) In describing structures within the cranium, the term *cranial* is obviously unsatisfactory. Particularly in describing positional terms to cerebral structures it is more appropriate to employ the term *rostral*, which indicates that a particular entity is nearer the *rostrum* (beak or nose). Thus, the cerebrum is *rostral* to the cerebellum, which is *caudal* to the former. To define the relation of structures to the median plane the terms *medial* and *lateral* are employed: the heart is *medial* to the lungs, which are *lateral* to it, and so on.

Any number of oblique planes can be imagined, and likewise the spatial relations of structures are not always so orthogonally simple as anterior, posterior, superior, medial, and so forth. Combined terms are therefore sometimes used for intermediate positional arrangements, such as anterolateral (ventrolateral), postero-inferior (dorsocaudal), etc., and these are self-explanatory. In the limbs certain variant terms are current—and since these do not involve reference to the 'anatomical position', they have some value in obviating confusion. Thus, structures which are superior, and hence nearer the limb root, are dubbed *proximal*; those relatively inferior in position are clearly more *distal*. Anterior and posterior aspects or regions may be described respectively as *flexor* or *extensor* in upper limbs, but the terms do not correspond in the lower limbs, which have undergone a contrasting form of morphological rotation (pp. 150, 350), such that the primitively extensor or dorsal aspect is now anterior. In the forearm, the terms *radial* and *ulnar* are occasional synonyms for lateral and medial, as are *fibular* (peroneal) and *tibial* in the lower limb. *Palmar* and *plantar* are variants for the flexor surface of the hand and foot. Finally, *superficial* and *deep* specify distance from the surface of the body; the somewhat similar terms, *external* and *internal*, are usually applied to the walls of hollow structures such as the head, thorax and abdomen and various viscera, including vessels and ducts.

It will be noted that throughout the text, the units of linear measurement are those of the Système Internationale (S.I.). These include the *micrometre* (micron, μm) 1 μm = 1×10^{-6} metre; 1000μm = 1 mm), and the *nanometre* (nm) 1nm = 1×10^{-9} metre; 1000 nm = 1 μm). Accordingly the use of Ångstrom unit (Å = 1×10^{-10} metre; 10Å = 1 nm) has been discontinued.

We have, in the main, continued the policy of adherence to *Nomina Anatomica* (3rd ed., by G. A. G. Mitchell, Excerpta Medica Foundation, 1968). Familiar variants and some eponyms have also been included where deemed advisable. We have also attempted to follow the proposed *Nomina Histologica* and *Nomina Embryologica*, prepared by the subcommittee of the International Anatomical Nomenclature Committee and presented to the Eleventh International Congress of Anatomists held in Leningrad in August 1970, at a plenary session at which these two drafts were approved. Unfortunately, both contain many common terms at variance with each other, important omissions, and some terms which have aroused belated dissatisfaction. Moreover, some ultrastructural details were overlooked, often obliging us to follow current practice, itself confused by synonyms and vernacular jargon. Therefore, we have regarded the recommendations of *Nomina Histologica* and *Nomina Embryologica* as less obligatory than *Nomina Anatomica*, which has been exposed to much more critical revision. Nevertheless, the latter does not meet all contingencies, especially in the central nervous system; it also still retains some intrinsically unsatisfactory terms. Notwithstanding, we have continued to adhere to most of these, though we have preferred not to handicap a whole section with the title of 'Syndesmology', for which 'Arthrology' has priority in time and in clarity of communication. We have also disregarded official disapproval of the hyphen, employing it frequently, though not perhaps consistently, to separate vowels likely to be compounded as diphthongs. (Since these remarks were written a 4th Edition of *Nomina Anatomica* (Ed. Roger Warwick, 1977) has appeared from the same publisher, and some of the difficulties referred to have been resolved. We have also had the advantage of consulting revisional proposals for a 5th Edition, which will be published shortly after the Twelfth International Congress of Anatomists, which is to take place in Mexico in 1980. The 4th Edition contains *Nomina Histologica* and *Nomina Embriologica*, which have therefore now been available for assessment for three years. It is to be hoped that active workers, especially in the fields of Cytology and Histology, will collaborate adequately with the I.A.N.C. to elaborate acceptable compromises between the jargon of the former and the sometimes impractical Latinity of the latter.) Even in Europe and the Americas, most university students, however, fall short of even 'a little Latin and no Greek', and this takes no account of the large numbers of schools outside these continents. Consequently, it must be assumed that a large majority of undergraduates and younger postgraduates find words of Greek and Latin derivation unfamiliar, and that this difficulty will increase in the future. Even the Latinist may find *bulbourethral* bothersome; *ou* is a diphthong not only in English but in other European languages; similarly, *sacro-iliac* aids in both pronunciation and understanding. The diaeresis is often frowned upon these days: but while *cooperate* perhaps no longer requires hyphen or diaeresis, *spermatozoön* and oöcyte are awkward words. We believe that an increasing number of readers need this help if unfamiliar words are to be pronounced with confidence, to the betterment of international communication. Officially, all anatomical terms are expressed entirely in Latin; but there is little objection to translating *flexor digitorum superficialis* into 'the superficial flexor of the digits', and this kind of vernacularization is practised in many countries, especially in Europe. Human anatomy, however, is a worldwide science, and the Latin terms are recognizable everywhere. A little effort with the first few pages of an elementary Latin grammar will quickly unveil the mysteries of masculine and feminine plurals, genitives and so on—a small personal concession to international understanding, in a world which must surely welcome unequivocal terms, even if based on a 'dead' language—perhaps all the more acceptable because no longer a contender in petty national rivalries.

1

CYTOLOGY

Introduction

All living organisms show distinctive patterns of organization with respect to time and space. Temporally, these involve orderly sequences of physical and chemical events which are conventionally described in terms of movement, metabolism, growth, differentiation, reproduction, reactivity to external change, and evolutionary progression (see also pp. 72–78). Spatially, these sequences are not haphazard, but arranged in a complex structural framework which determines their direction and their coordination. The integration of these phenomena, and their dependency upon environmental energy sources, constitutes what we call 'life' in the biological sense.

The microscopic study of living things concerns such intimate organization of their life processes, and since their ultimate structure is on a molecular scale, various special means have to be used to analyse them.

The *biological molecules* are arranged in complex aggregations playing specific roles in the living process; these aggregations are the *organelles*; multiples of different types of organelles are further combined in specific membrane-bound units, or *cells*. The cell is an important unit, since it is the smallest aggregation to show all the major features of living organisms mentioned above. In some simple organisms, e.g. bacteria, protozoa, the cell is also the whole organism, and capable of an independent existence. In more complex organisms, multiples of cells are grouped together, with spatial differentiation of various regions to perform particular roles, such as digestion, reproduction, and so forth. These may have the form of simple co-operative layers of cells, or *tissues* (a term introduced by Bichat (1771–1802) for the different groups of cells, muscular, nervous, and so on, in post-mortem man). Multiples of tissue layers are further grouped together to carry out more complicated co-operative actions; these constitute the *organs* of the body. Finally, the whole consortium of organs, co-ordinated and unified by specialized communication systems, is capable of the activities which characterize human life. To analyse adequately the biological basis of such activities, it is necessary to understand its parts, and the subjects of *cytology* and *histology* have as their aim the clarification of these at the microscopic level.

Advances in cytology, as in all scientific pursuits, have awaited technical progress (Singer 1931; Taton 1966). The early microscopes of the sixteenth and seventeenth centuries only allowed examination of large cells, such as those of protozoa and plants, and the English microscopist Robert Hooke (1665) was the first to use the term *'cell'*, which was applied by him to the compartments of cork wood. With the refinement of the optical microscope by Abbé and Leitz, and the introduction of staining and sectioning techniques in the late nineteenth century, the field was set for the rapid expansion of cytology and histology as a serious discipline. The further introduction of bright field, phase contrast, and interference microscopy in the 1930–50 period allowed direct detailed observation of living cells. By this time histology had lost some of its initial impetus, but the growth of electron microscopy, increasing resolution by three orders of magnitude, together with the development in biochemistry of cell-fractionation techniques, and of methods of biophysical analysis of molecules, allowed observation and interpretation at the molecular as well as the cellular level.

The concept of the cell is a convenient starting point; each cell comprises a discrete unit enclosed by a membrane which is interposed between it and its micro-environment, and envelops the living material or *protoplasm*, included in which is one or more *nuclei*. The protoplasm is a heterogeneous aqueous phase in which is the chemical machinery for metabolic processes, and the material of heredity, which specifies the character of the cell from one generation to the next. In some very primitive cells (*prokaryotes*) such as bacteria and actinomycetes, the hereditary and metabolic materials are not separated from each other; in more complex cells (*eukaryotes*) the hereditary instructions are almost entirely sequestered in a special membrane-bound region, the *nucleus* (*karyon*), which is distinct from the remainder of the cell, the *cytoplasm*.

The protoplasm of cells consists chemically of large and small organic molecules, and inorganic ions in aqueous solution (DeRobertis *et al.* 1975); water comprises about 70 per cent of the total cell volume. Of the large organic molecules, the most abundant are those of carbohydrates, lipids, and proteins which provide important structural materials and metabolic machinery in the form of enzymes. Nucleic acids are also important in directing the activities of the cell. The cytoplasm of each cell is relatively unstable in its composition, and must be held ionically and osmotically within a narrow range for the effective functioning of its metabolic apparatus. However, each cell is also in a constant dynamic interchange with its external environment (p. 72), including other cells, and the continuous expenditure of metabolic energy is needed for a cell to maintain its steady state. If this is lost, the cell dies.

Most mammalian cells lie within the size range of 5–50 μm in diameter. Although many cells possess only one nucleus, some, formed either by fusion of uninucleate cells (*syncytia*), or by nuclear division without corresponding cytoplasmic division (*plasmodia*), are multinucleate. The latter may achieve a much larger volume than a uninucleate cell, although the *ratio* of nuclear to cytoplasmic volume is similar.

One great advantage of cellularity is that diffusion of materials between and within the living units is relatively rapid, so that control systems can operate rapidly within a mass of cells, and also that gaseous, nutritive, and excretory exchange processes can keep pace with the high demands of active cells. In this regard it should be noted that as a cell increases in size, its surface area (available for diffusion) increases by the square of the diameter, whereas the volume of protoplasm increases by the cube; this relationship puts a limit on the maximum size a cell can attain (D'Arcy Thompson 1942; see also p. 78). Preservation of cellularity also allows the emergence of different cell types joined together into functionally distinct tissues.

In the living state most individual cells are greyish in appearance when examined by transmitted light, and each is bounded by a deformable elastic membrane. Physical measurements of protoplasmic viscosity (DeRobertis *et al.* 1975) indicate that it is a heterogeneous material which can be highly viscous (the *gel* state), or relatively non-viscous (the *sol* state), or both states may coexist and interchange. Metabolic processes can profoundly alter these physical characteristics.

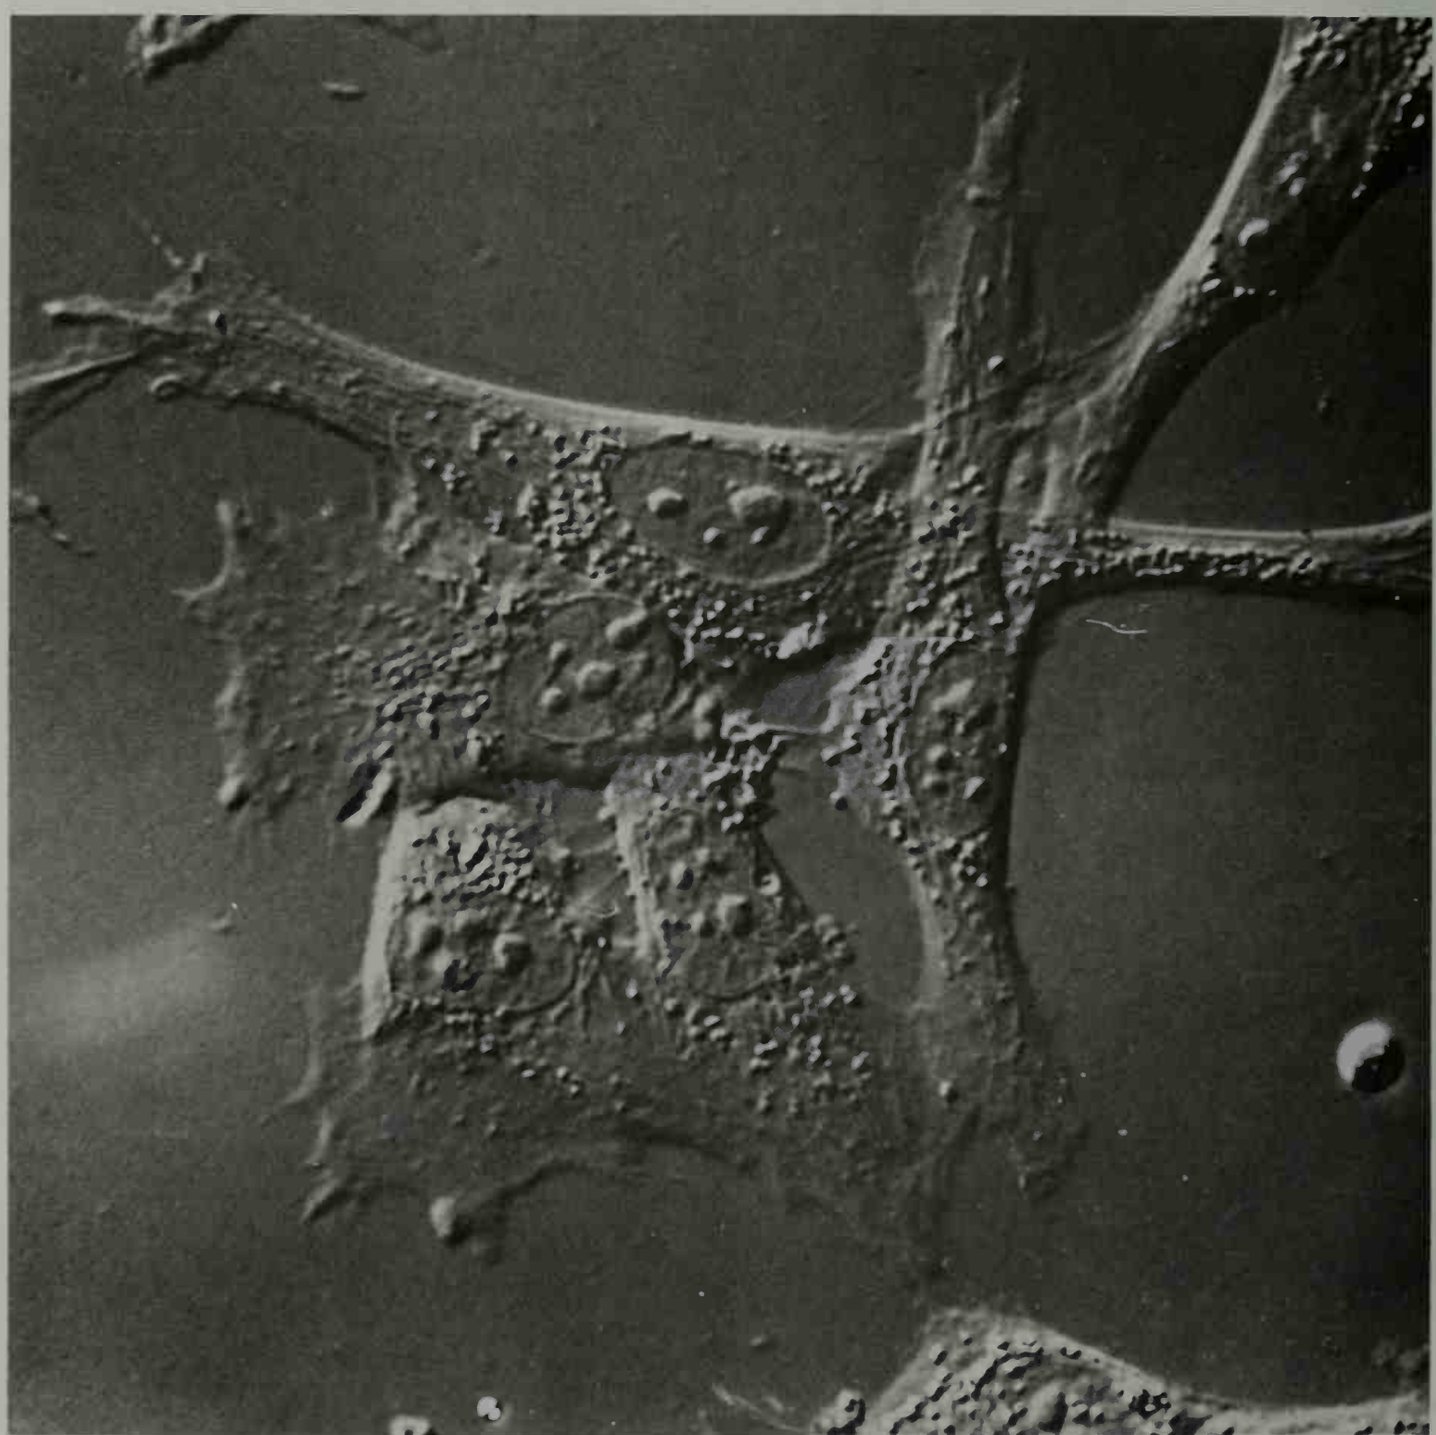
Motility is also a characteristic of most cells. This may take the form of intracellular streaming, with the movement of materials within the cell, or may produce movement of the whole cell by the progressive formation of finger-like projections (*pseudopodia*), or other extensions, of the cell surface (p. 35). Cell movements are also involved in the multiplication of cells by division to form two—*binary fission*—and in the uptake of extracellular materials such as solid particles (*phagocytosis*) or fluids (*pinocytosis*).

Cells in many situations form aggregates by reciprocal adhesion, and the cell surfaces behave as though sticky. Small differences in ionic composition can alter this aggregation, e.g. the presence of calcium ions is necessary for cell adhesion. When similar motile cells growing in nutrient media outside the body (i.e. *in vitro*) come into contact, movement normally ceases, a phenomenon termed *contact inhibition* (p. 91). Such a process is believed to govern the aggregation of cells into stable tissues in the body. These activities of the cell will be examined further in subsequent sections of this chapter.

1.1 A three-dimensional reconstruction of some of the principal architectural features of an absorptive cell lying in the simple columnar epithelium of the small intestine. Part of the cell is cut away to expose the nuclear envelope (green); nuclear contents are the nucleolus (red) and chromosomes (black). Outside in the cytoplasm lie the endoplasmic reticulum (yellow) with ribosomes (red) in clusters; the Golgi apparatus (pink) is shown in a supranuclear position, various cytoplasmic vesicles including lysosomes, microtubules (blue), microfilaments, and a centriole pair (grey) are also shown. The apical surface of the cell is covered with microvilli supported by microfilaments which are inserted into a filamentous terminal web. Junctional complexes are seen at the lateral borders of cells apically. A lamina basalis (purple) forms the boundary of the epithelium basally, and lies in close relation to the underlying reticulin and collagen.

CELL STRUCTURE

Electron microscopy has had a great impact on our understanding of cell structure; although no two types of cell are identical, there is a common pattern of organization, so that some generalizations can be made. In describing their internal structure, it is convenient to divide the cell into cytoplasmic and nuclear divisions (Bloom and Fawcett 1975; Ham 1974; Junquiera *et al.* 1975).



In the cytoplasm several distinct systems of organelles are discernible, comprising the external and internal cytoplasmic membranes, membrane-bound bodies such as mitochondria, lysosomes, lipid vacuoles and the Golgi complex; ribosomes, the microtubules, microfilaments, centrioles, cilia and flagella, and microvilli; also the proteins in suspension, termed collectively the *cytosol*.

The nucleus is made up of the nuclear membranes with nuclear pores, the nucleoplasm (nuclear sap), chromosomes (chromatin), nucleoli, and intranuclear bodies of various kinds. These structures will now be described in some detail (1.1, 2, 3, 4, 5).

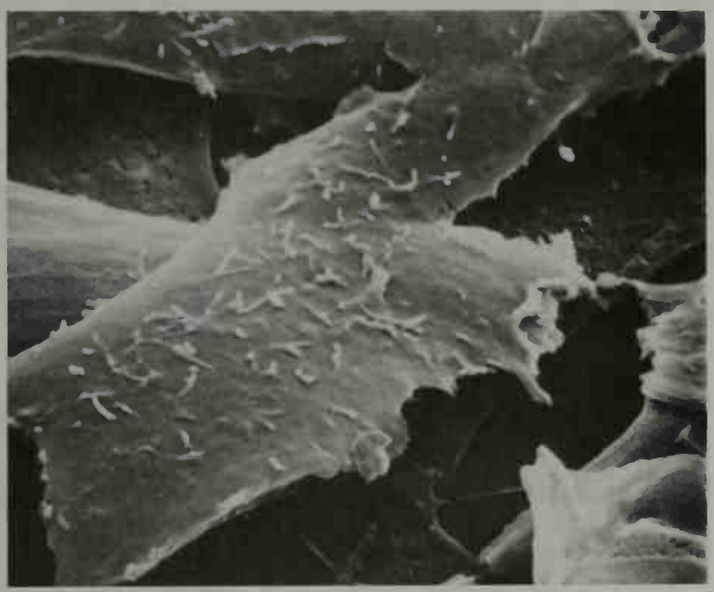
Cytoplasm

THE MEMBRANE SYSTEMS OF THE CELL

With the advent of electron microscopy, it was confirmed that cells are bounded by a distinct membrane, and internally are permeated by membrane-lined vacuoles and channels. Both external and internal membranes (*cytomembranes*) have many

1.2 A high-power micrograph of living cells (fibroblasts in tissue culture), viewed by Normarski interference microscopy. Kindly provided by the Paediatric Research Unit, Guy's Hospital Medical School. Magnification × 2,000.

features in common. They are all composed chemically of phospholipids and proteins, usually in an approximately 3:2 ratio, with a small amount of carbohydrate. The amount of lipid in an external membrane is enough to give a layer two molecules thick over the cell surface, so it was proposed as long ago as 1925 by Gorter and Grendel that cell membranes are bilayers of lipid, with the hydrophobic ends of each lipid molecule pointing towards the interior of the membrane, and the hydrophilic ends pointing outwards. Later, Davson and Danielli (1935) suggested that the protein might be situated on both sides of the lipid to form a protein/lipid sandwich, but more recently a 'fluid mosaic' model has been proposed (Singer and Nicolson 1972), in which the proteins are envisaged as embedded, or floating, in the lipid bilayer (1.6A). Some proteins, by virtue of extensive hydrophobic portions of their polypeptide chains, appear deeply embedded in the lipid, spanning its entire width (*intrinsic proteins*) whilst others are only superficially embedded and can be more easily detached by mild treatment (*extrinsic proteins*). Carbohydrates in the form of oligosaccharides and polysaccharides are attached either to proteins (glycoproteins) or to lipids (glycolipids), projecting outwards from the surface of the membrane (Nicolson and Poste 1976).



These features, deduced partly from biochemical and biophysical data, can be correlated with appearances in the electron microscope. Membranes when suitably fixed and stained with heavy metals show, in section, two densely stained layers separated by an electron-translucent zone, the total thickness being about 8 nm (the classical *'unit membrane'* of Robertson 1959), probably reflecting the binding of stain by the 'heads' of the phospholipid molecules. Freeze-fractured and/or etched specimens (Branton 1971; Stolinsky and Breathnach 1975), in which the deeply frozen sample is cleaved to expose membrane interiors, and of which a metal-shadowed carbon replica is then made and viewed in the electron microscope (1.8, 9), have also demonstrated a bilaminar structure in membranes. The cleavage planes usually pass along the midline of each membrane where the hydrophobic 'tails' of the phospholipids meet. This method has also demonstrated protein 'particles' embedded in the lipid layers; these particles are in the 5–15 nm range and may represent large protein molecules or assemblies of several smaller protein molecules. It is interesting that the particles are distributed asymmetrically between the two half-membranes, usually adhering more to one face than the other. In plasma membranes (which form the cell surface), the *inner* or protoplasmic half-membrane carries most of the particles, exposed at its externally-facing (P or A) surface, whilst the internally-facing (E or B) surface of the *external* half-membrane usually shows pits into which the particles fit (1.8, 9). Not all the proteins of membranes are *visible* as particles, however; some are either too small or not compact enough to appear in this form, and have, as yet, only been demonstrated biochemically.

Biophysical measurements have shown the phospholipid bilayer to be a highly fluid structure, allowing diffusion *along the plane* of the membrane at rates as high as 2 μm/sec. Thus some proteins are able to move freely along the membrane plane unless there are special attachment devices within the cell preventing this, and aggregates of proteins are thus able to form (*see* p. 7). Some internal membranes possess much higher amounts of protein than the external cell membrane, for example, the inner mitochondrial membrane which is rich in enzyme activity, and the fluidity of such membranes is correspondingly much reduced.

The functions of cell membranes are many; they form boundaries which selectively limit diffusion, separate different phases inside the cell—dividing, in general terms, those regions within the channel system (*vacuoplasm*) from those outside it (*hyaloplasm*). Membranes actively control the passage of electrolytes and small organic molecules, generate bioelectric potentials, and they act as surfaces for the attachment of enzymes and other metabolic systems, often associated with the movement of reaction products from one side of the membrane to the other (*vectorial metabolism*). Membranes also serve as sites for the reception of external stimuli including hormones and other chemical agents, and for the recognition and attachment of other cells. Lastly, they can themselves act as points of attachment of intracellular structures, thus providing the basis for locomotor activity and for cytoskeletal stability.

The membranous elements of a cell can, on occasion, fuse with each other and so form a potentially continuous system. However, there are severe restrictions on the fusion of different types of membrane so that each maintains its unique chemical and functional features distinct from those of others. How the cell is able to prevent the indiscriminate mixing of membranes when they do fuse, for example, in the passage of metabolites within vacuoles from one organelle to another, is not known. So although the membrane systems of the cell can be viewed as a single entity, they are also highly distinctive and localized in their activities.

Cell membranes are synthesized by the granular endoplasmic reticulum (p. 12), usually in collaboration with the Golgi apparatus (Poste and Nicolson 1977).

PLASMA MEMBRANE (PLASMALEMMA OR CELL MEMBRANE)

This constitutes the external boundary of the cell, and differs from the other membranes in that it bears a diffuse carbohydrate-rich coat, the *cell coat*, or *glycocalyx*, on its external surface. The cell coat varies in composition from cell to cell, but usually contains much sialic acid; it confers on the cell surface a net negative electrostatic charge. Disturbances in the cell coat and surface charge are associated with neoplastic transformations, and may play a part in the failure of some malignant cells to adhere to one another, with their consequent metastasis to other sites. Many tissue and blood *antigens* are also located in the coat in its glycoproteins and glycolipids.

The plasma membrane is capable of active transport of small molecules without any apparent structural change, but the uptake of larger molecules is associated with the invagination and rounding up of the plasma membrane to form small vacuoles termed *endocytic vesicles* (1.1, 4), which are transported to other regions within the cell. The reverse process—the extrusion of organic molecules—is achieved by *exocytic vesicles* which fuse with the plasma membrane and release their contents to the exterior.

Although the plasma membrane carries out the functions common to all membranes, it has especial importance as the boundary of the whole cell, in co-ordinating many of its activities, by mediating changes in the cell's environment to the cell interior, and in maintaining the cell's shape and coherence (De Pierre and Karnovsky 1973). The plasma membrane, therefore, acts as a

1.4 A composite diagram showing the principal structures found within tissue cells. Only a proportion of the features illustrated will be present in any specific cell type.

sensory surface, and possesses a wide variety of special receptor molecules, some responding only to a narrow range of stimuli, as for example the receptors for specific steroid hormones, whilst others are perhaps activated by more general factors such as the contact with other cells or inorganic surfaces. Stimulation of the cell surface may result in changes in the bioelectric transmembrane potential which accompany fluxes of inorganic ions; this is most striking in the *excitable* plasma membranes of nerve and muscle cells in which the 'resting' voltage can change transiently from as much as 100 mV (negative on the inside) to one of 50 mV (positive on the inside) when suitably stimulated, a phenomenon which results from the opening and subsequent closure of channels selectively permeable to sodium and potassium and other ions (*see* pp. 9, 824).

Stimulation of receptors at the cell surface also often results in the activation of a chemical 'second order messenger' which may cause profound changes in the metabolism or motility of the whole cell (Weissmann and Claiborne 1975). Adenylate cyclase, an enzyme associated with the plasma membrane of probably all nucleated cells, is an important element in this process; activation of this enzyme results in changes in concentrations of cyclic AMP (cyclic adenosine monophosphate) within the cell, in turn leading to alterations in, for example, metabolic pathways, DNA synthesis, gene expression, protein synthesis, actin and myosin interactions, and many other intracellular events. Cyclic GMP (cyclic guanidine monophosphate) is likewise controlled by similar enzyme systems, and may have effects antagonistic to those of cyclic AMP. Some hormones and neutrotransmitters have been shown to act on the cell in this manner, and it is probable that many types of intercellular communication use the same or similar systems (p. 830).

Maintenance of cell shape by the plasma membrane is largely brought about by filamentous proteins, including microfilaments, which are attached to it; the same structures may also be responsible for changes in shape such as those associated with cell motility (for a fuller discussion *see* p. 35).

Although these considerations apply to the plasma membranes of all cells, those of specialized cells are often highly developed in some particular respect. Thus, sensory membranes derived from the plasma membrane, for example those of the retinal photoreceptors, have numerous photoreceptive proteins embedded in their surfaces; the acetylcholine-receptive sole plate membranes of skeletal muscle cells likewise are studded with protein particles capable of binding the transmitter. Other specialized cell membranes, such as that of the erythrocyte, have important metabolic and cell shape-determining components. This area of research is indeed of great potential, since we may learn much about cellular functions in general by first understanding the cell surface which is responsible for co-ordinating so many cellular activities. We may also gain a deeper understanding of the actions of drugs on cells since the cell membrane is undoubtedly the primary target of a wide variety of chemotherapeutic agents, anaesthetics, and other substances of medical importance.

As mentioned above, *the cell coat* forms an integral part of the plasma membrane, projecting 2–20 nm, or perhaps more from the lipoprotein elements considered above. It is composed of the carbohydrate portions of glycoproteins and glycolipids embedded in the plasma membrane (1.6A), often consisting of highly branched oligosaccharides and polysaccharides, the terminal residues of which are usually negatively charged sialic acids such as n-acetyl neuraminic acid, but are also often rich in galactose residues. These and other carbohydrates can be readily demonstrated with plant-derived chemical probes termed *lectins* (e.g. concanavalin A, wheat germ agglutinin, phytohaemagglutinin) which bind specifically to particular carbohydrate groups. By conjugating lectins with fluorescent molecules, or with an electron microscopic tracer such as ferritin or horseradish peroxidase, the surface carbohydrates can readily be visualized (1.6B) and even measured (Nicolson 1974, 1976). Since the glycoproteins and glycolipids are usually free to move in the plane of the membrane, addition of lectins can cause the aggregation of these carbohydrate-rich membrane molecules which become cross-linked to form raft-like groups or 'patches'. If these are further aggregated by motile activities of the cell, they merge to form a 'cap' at one pole of the cell (p. 36). In other cells (e.g. erythrocytes) the carbohydrate-rich molecules are prevented from wandering or forming patches by internal anchoring proteins.

The plasma membrane itself, like other cytomembranes, is in a constant state of flux, the whole surface being regularly renewed by addition from exocytic vesicles, by subtraction and degradation in the lysosomal system of the cell, or by the loss of components into the surrounding micro-environment.

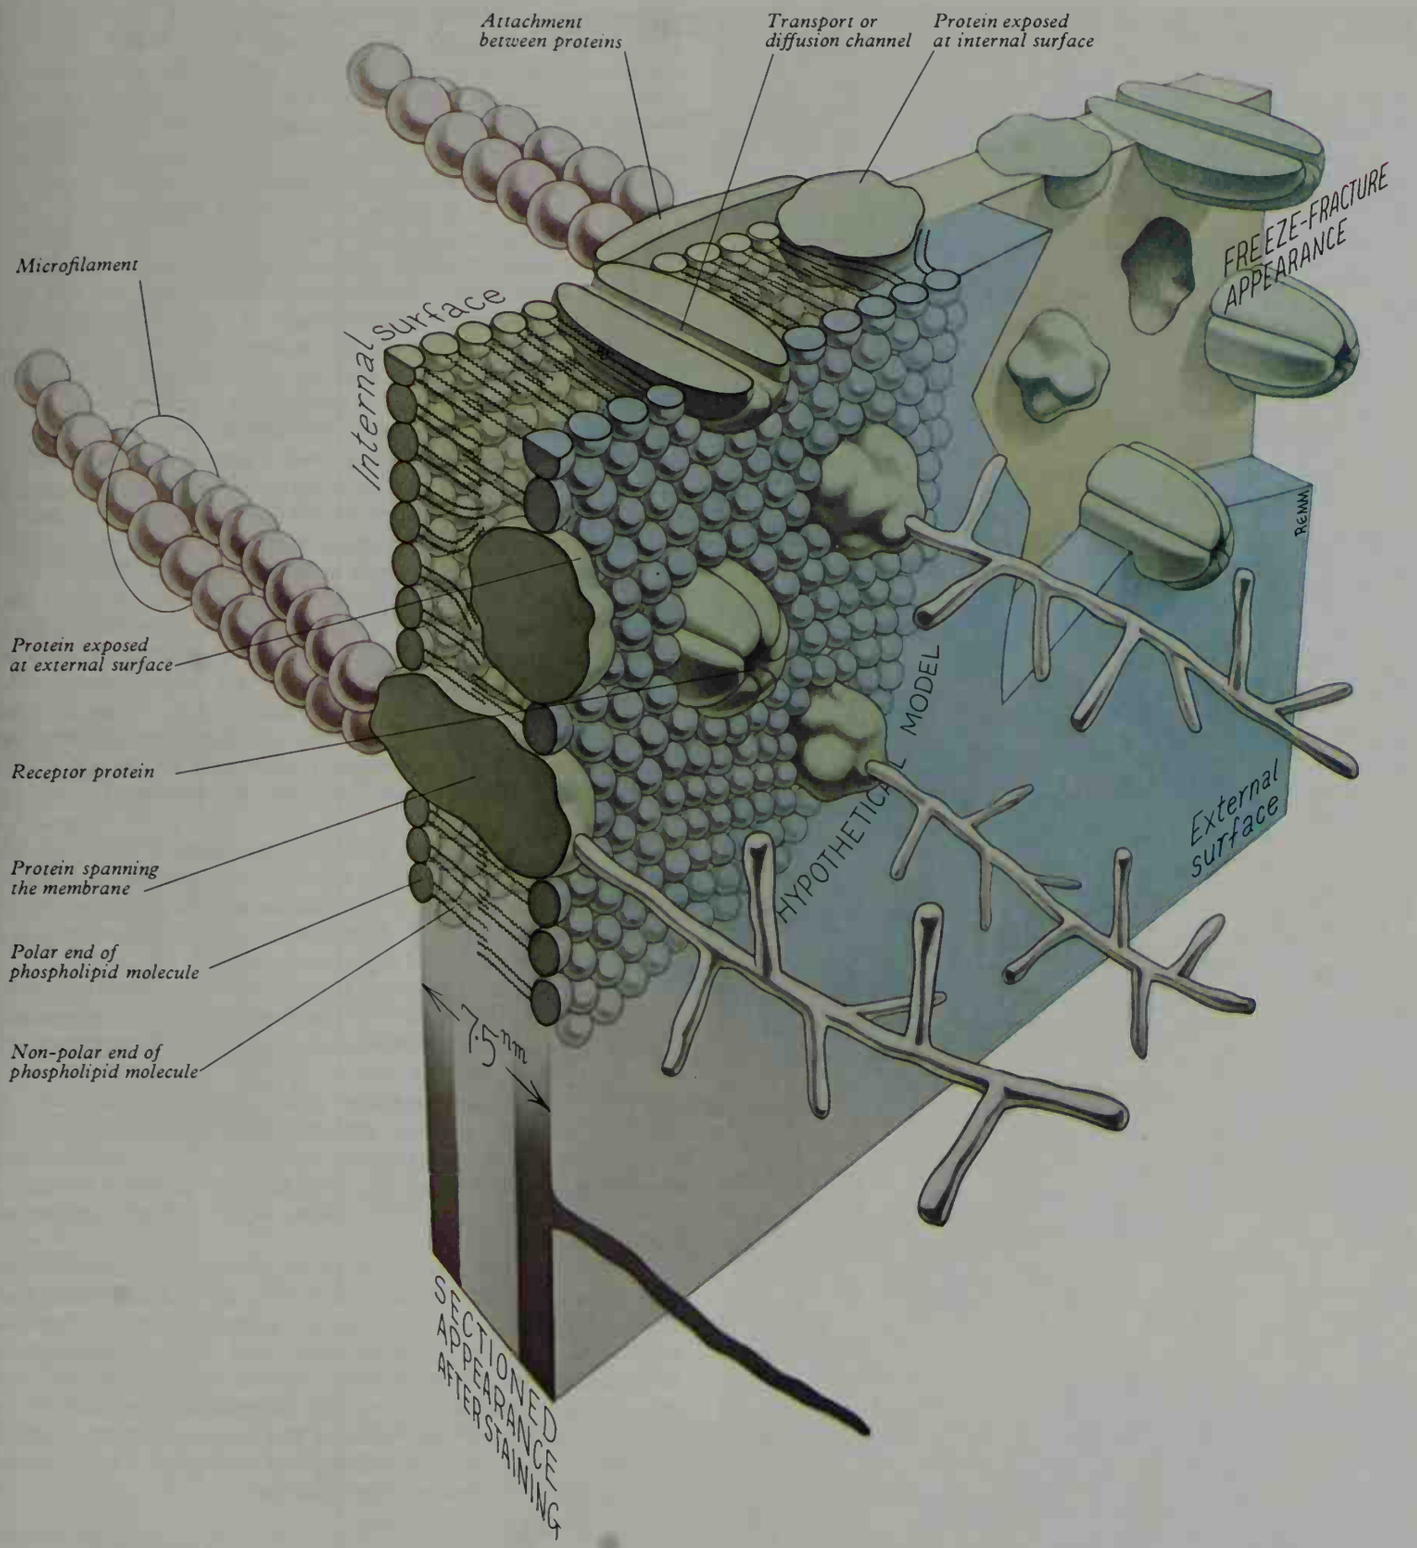
INTERCELLULAR CONTACTS

The plasma membrane is, of course, the surface which establishes contact with other cells and promotes various kinds of cellular interaction. Structurally we can distinguish two main classes of contact: (1) those which are not marked by the formation of obvious cytological surface specializations in the areas of contact, and (2) those in which relatively long-lasting junctional features are cytologically well defined, and which establish and maintain the intercellular contacts. In the first category (Moores and Partridge 1974), which is by far the most common, cells adhere to one another, usually at any part of their surfaces, enabling them, for example, to form loose aggregations whilst permitting some degree of relative movement. A distance of about 20 nm separates the membrane surfaces, a distance probably determined by the interplay of *electrostatic repulsion* and *adhesive forces*, and perhaps by the thicknesses of the cell coats on the adjacent membrane surfaces. It is not clear what type of adhesive forces operate in this type of contact: it has been suggested that attraction between oppositely polarized surface groups may be important, that divalent cations (e.g. Ca^{++}) may form bridges between adjacent surfaces, or that other *non-specific attractive forces* may operate (Curtis 1973). Recently, there has been increasing evidence that at least in some cases, more *specific interactions* may occur between cell surfaces, with complex sites for mutual recognition and adhesion analogous to those between antibodies and antigens. Such specific adhesion is evidenced by the tendency of cells from the same tissues or embryonic germ layers to reaggregate after they have been experimentally separated, and in the migration of cells and growth of cell extensions (e.g. in the developing nervous system) to make contact with specific types of 'target' cell (Cox 1974). It must be added that the degree of adhesion varies considerably in different cell varieties; epithelial cells normally adhere to one another strongly, but macrophages—often highly motile cells—may move freely over other cells. Reduction of the normal adhesive properties of cells occurs in malignant neoplasms which therefore rapidly spread locally, or form secondary colonies (metastases) elsewhere.

Specialized junctional structures are regions of mutually adherent cells where there are distinctive structures visible with the electron microscope (1.7, 8). A number of different types have been demonstrated (Cox 1974; McNutt and Weinstein 1973), including those at which the cell membranes are separated by a 20 nm gap or more, and those where the membranes either approach closely or are actually in contact. The former include the *macula adherens* and *zonula adherens*, the latter the *zonula occludens* and the 'communicating junction' or *junctio communicans*.

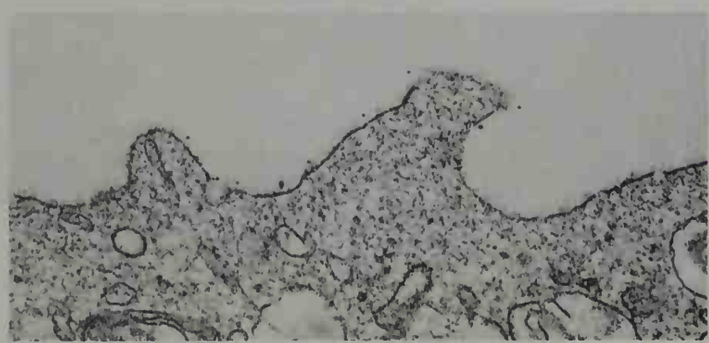
The *macula adherens* (*desmosome*) is a plaque-like structure (1.1, 7, 8) found at any region of the cell surface, where the plasma membrane is coated on its inner aspect with a layer of dense protein into which intracytoplasmic tonofibrils are inserted. The gap between the two cells is bridged by thin looping filaments which interlock, traversed by broad bands of densely staining material. This structure apparently forms anchorage points between cells, particularly where there is a requirement for strong cohesion as in the stratum spinosum of the epidermis, where they are responsible for the post-fixation prickly appearances of the cells. Single-sided or hemi-desmosomes are also found between epidermal (and other) cells and the underlying basement membrane.

The *zonula adherens* (1.1, 7, 8) is a continuous belt formed



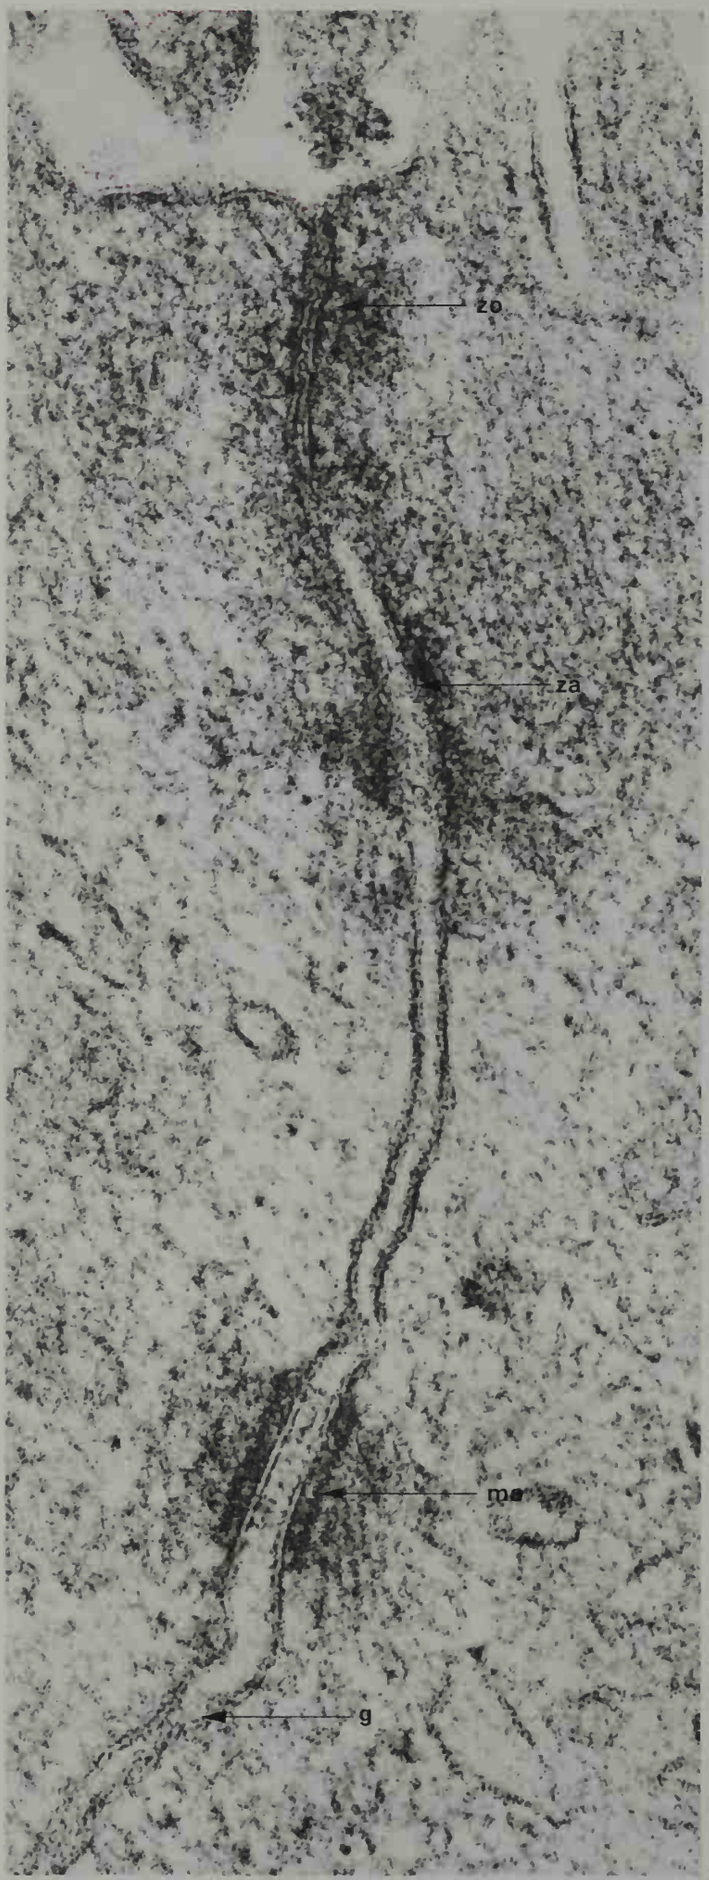
1.5 An electron micrograph of a protein-synthesizing cell in section showing abundant rough endoplasmic reticulum, Golgi apparatus, mitochondria, lysosomes, and a cell membrane with surface protrusions (filopodia). Magnification × 12,000.

around the apices of epithelial cells, or a zone between smooth muscle cells, and as a 'single-sided' junction between muscle cells and their collagenous sheaths. As in the desmosomes, there are cytoplasmic densities beneath the membrane surfaces in these structures, and filaments (usually microfilaments) are often inserted on the cytoplasmic side. No intercellular filaments span the gap between the cell surfaces, however, but it is possible that an adhesive, non-stainable material intervenes at this point. They probably serve anchoring functions like the desmosome.



The *zonula occludens* (tight or occluding junction) is an annular junction (1.1, 7, 8) present around the apices of epithelial cells, between endothelial cells, and is found in other sites where there is a barrier to diffusion through the intercellular space. This is exemplified by the failure of colloidal tracers such as ferritin and horseradish peroxidase to move from the lumen of the intestine into the spaces between the epithelial cells or even deeper into the mucosa. At a zonula occludens the membranes of the adjacent cells are in actual contact, obliterating the gap between them and so creating a barrier to the movement of molecules. The efficacy of this barrier does, however, vary in different tissues, so that relatively 'leaky' tight junctions that allow the slow diffusion of large molecules have been demonstrated in the kidney, blood vessels and in other structures (Friend and Gilula 1972). Freeze-etching has shown the contacts between the membranes to lie along branching and anastomosing lines which, in the case of 'leaky' tight junctions, are said to be discontinuous. The lines take the form of ridges which are probably formed by the incorporation of fibrils or chains of particles within the membranes, distorting and stiffening them at the points of contact. The tight junction is of great importance, for example, in preventing the leakage of toxic substances from the lumina of viscera into the surrounding tissues, and in retaining the colloids within the bloodstream.

Communicating junctions or *maculae communicantes -'gap' junctions, electrical junctions, nexuses*) are similar to tight junctions in sectioned specimens except that the apposed membranes are separated by an apparent gap about 3 nm wide, which is traversed by numerous dense beads arranged in hexagonal arrays on the two membrane surfaces (1.8). Such junctions form limited attachment plaques (Goodenough and Revel 1970) rather than the continuous belts which the tight junctions form, thereby allowing the free passage of substances along the cleft between the cells which they join. They are present in numerous tissues including the liver, epidermis, connective tissues, between embryonic cells, between cardiac muscle cells, and between smooth muscle cells. In the central nervous system (Staehelin 1974) they join adjacent cells belonging to ependyma, to neuroglia, and they form electrical synapses between neurons in some regions of mammalian brains, and more commonly in those of lower vertebrates and invertebrates (*see* p. 829).



The importance of the communicating junction is that it forms channels for the diffusion of ions and larger particles—up to a

1.6A A diagram depicting the various 'appearances' of the plasma membrane as studied with different electron microscope techniques including sectioning and freeze-fracturing, together with current interpretations of the results of these, and other biophysical methods. In this diagram, membrane proteins (green) are either confined to a single leaflet of the lipid bilayer, or they span both layers. Branched carbohydrate chains (grey) are shown attached to some transmembrane proteins on the external surface of the membrane, and a double helical actin filament (pink) is attached to the inside (left). The hydrophobic tails of the lipid molecules are shown as thin black lines, and their hydrophilic heads as spheres—blue for the outer surface of the membrane and yellow for the inner surface. These various shapes are, of course, only schematic, as the various protein, lipid, and carbohydrate molecules of which cell membranes are constituted, have differing detailed shapes.

1.6B An electron micrograph of the surface of a fibroblast in which the presence of a surface carbohydrate has been made visible using concanavalin A conjugated to ferritin, which appears as dark particles. Magnification × 60,000.

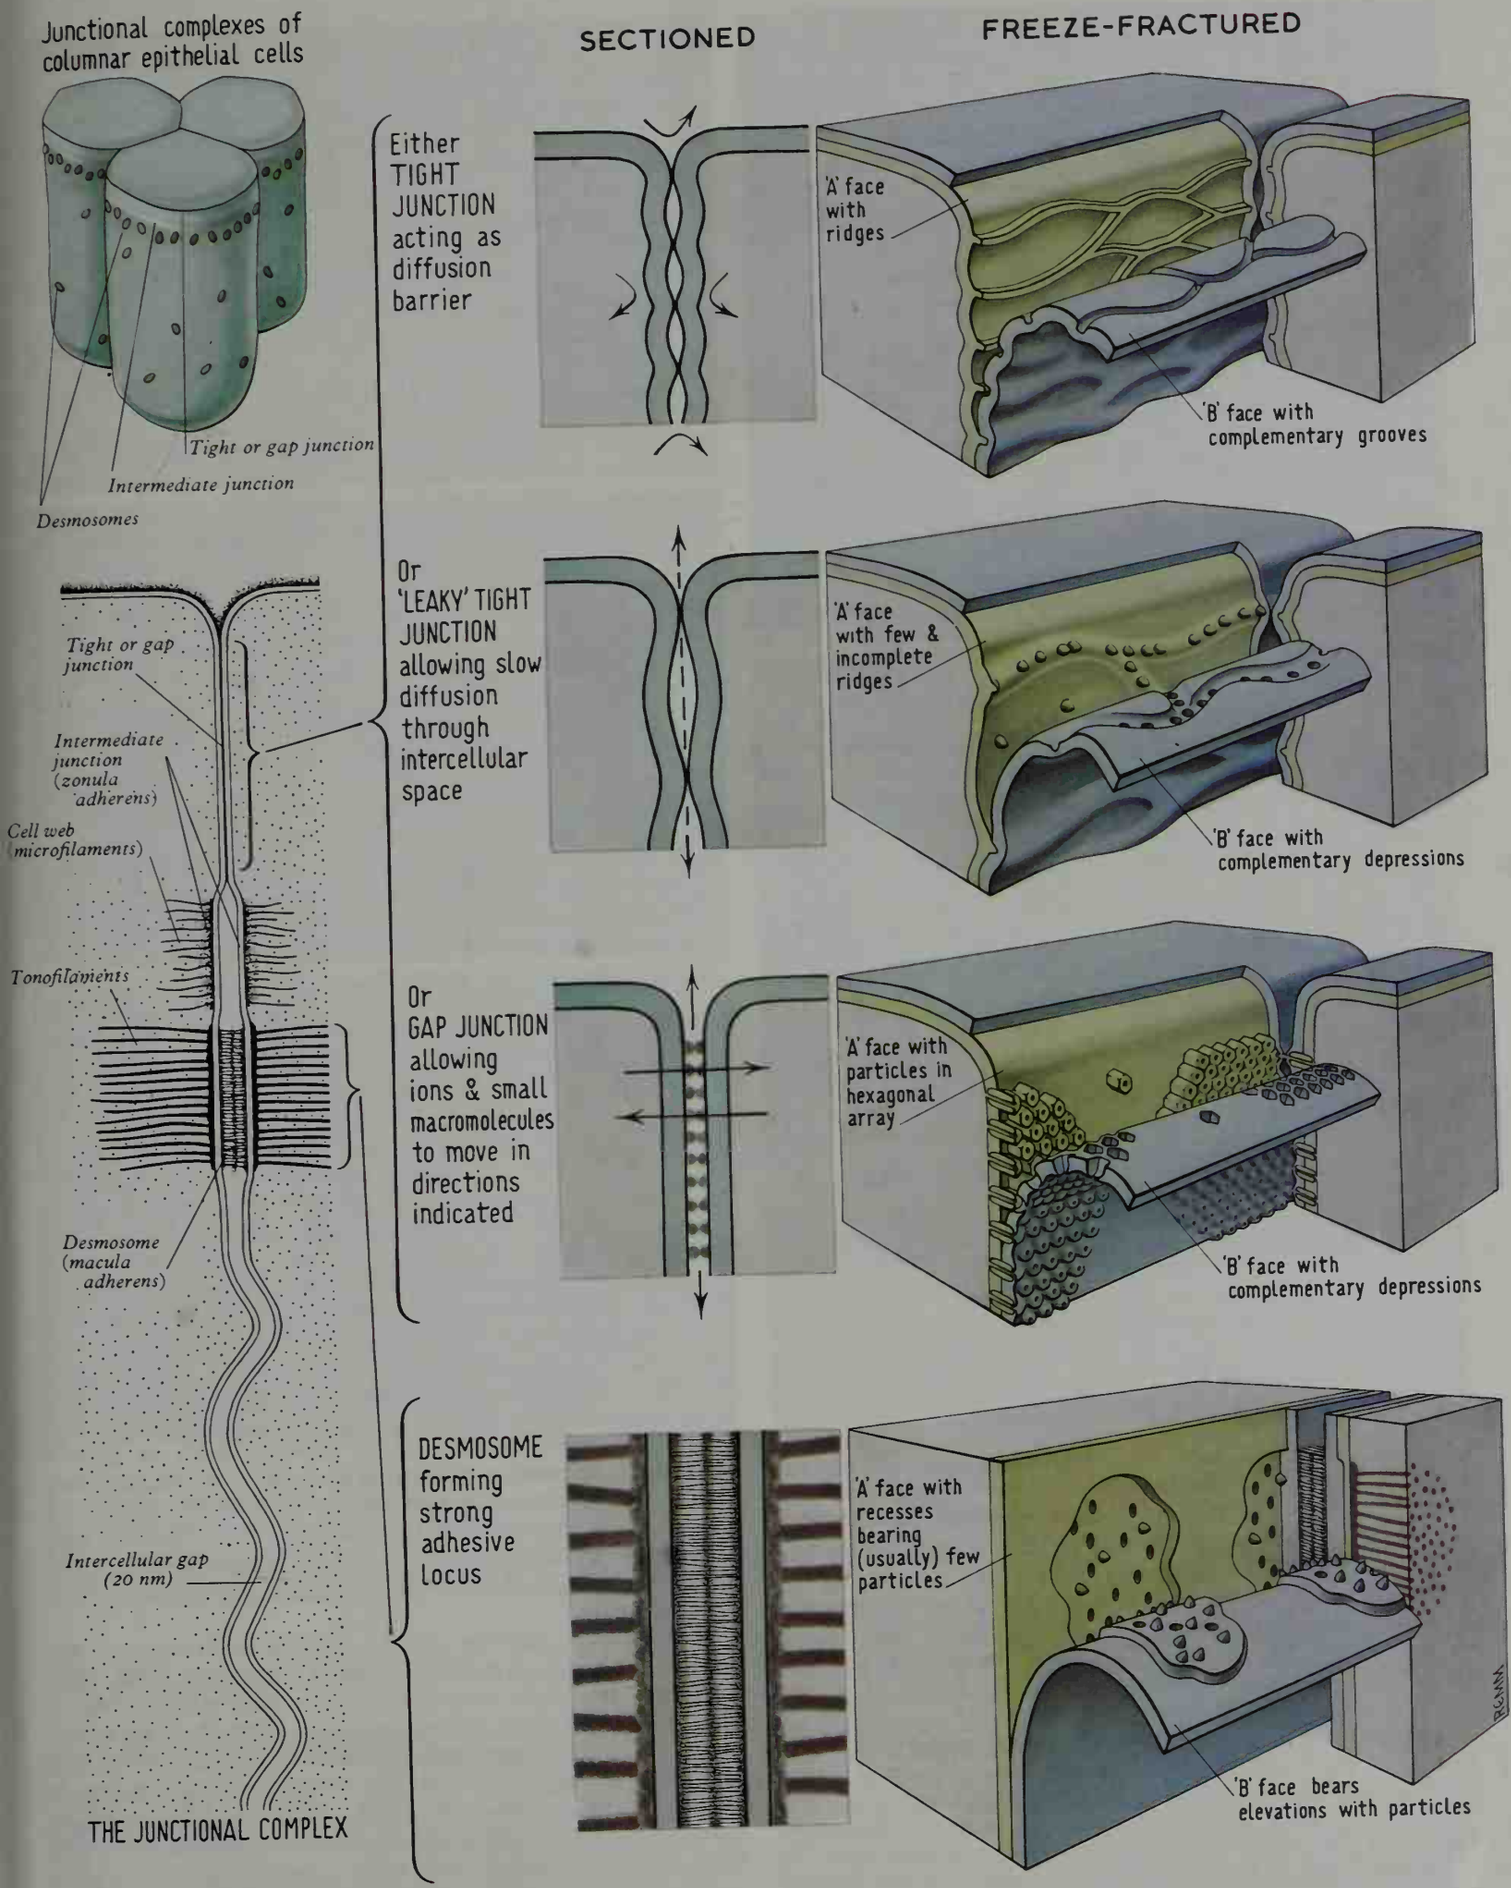
1.7 A high-power electron micrograph of a junctional complex between two epithelial cells showing a zonula occludens (tight junction) (*zo*), a zonula adherens (*za*), a macula adherens (desmosome) (*ma*), and a normal intercellular gap (*g*). Magnification × 130,000.

molecular size of about 4,000 daltons—*from one cell to the next*. Thus, where excitable cells (muscle cells, nerve cells) are concerned, one cell can directly invade its neighbour by electrotonic current flow without the intervention of a chemical transmitter, in contrast to the usual mode of synaptic transmission. In other cells their significance is not entirely clear, although experimentally they have been shown to be permeable to various dyes and to form low resistance pathways to the flow of ionic current. It appears probable that the communicating junction permits metabolic cooperation between adjacent cells or groups of cells. Thus, during embryonic life such junctions are perhaps involved in the establishment of pattern, and in the co-ordinated differentiation of, for example, the whole blastula, within and between germ layers, or of more localized tissues by allowing regulatory substances involved in gene blocking, or gene repression and de-repression, to diffuse freely or establish morphogenetic gradients (*see* p. 85). Communicating junctions may also be involved in the control of cell division since in damaged tissues they disappear, and the cells undergo reparative mitotic divisions until junctions reappear, when regeneration ceases (Bennett 1973; Fusijawa *et al.* 1976).

Freeze-fracturing and -etching studies (Staehelin 1974) have shown hexagonal arrays of membrane particles on both sides of communicating junctions, each particle composed of subunits probably surrounding a central channel (**1**.8) which, when located opposite a similar unit in an adjacent cell, forms a small communicating passage between the two. Such particles may also exist in smaller numbers, or singly, elsewhere on the cell, so that intercellular communication may not be restricted to special junctional *areas*.

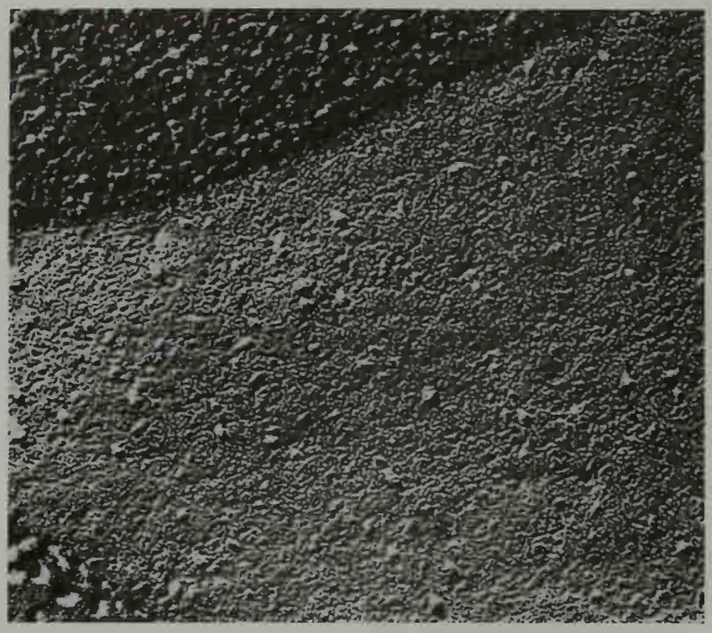
Junctional complexes are present at the apex of epithelial cells (Farquhar and Palade 1963), where a combination of a zonula occludens, zonula adherens and macula adherens (desmosome) is a regular feature (**1**.1, 7, 8). This array of junctions corresponds in part to the *terminal bar* of light microscopy.

Synapses and *neuromuscular junctions* are specialized junctional areas involved respectively in interneuronal and nerve-muscle transmission, and will be described under these headings in a later chapter.



With the exception of the latter two specializations, all intercellular junctions are rather labile, and can be readily resorbed or reformed in suitable circumstances, permitting slow migration and division of cells, and in some cases the passage of other cells along intercellular clefts, as for example, leucocytes between endothelial cells.

Topographical specializations of the plasma membrane include fine finger-like extensions—microvilli, filopodia, microspikes, cilia and flagella; and less regular, often rounded or leaf-like extensions—'blebs', pseudopodia, and ruffled membranes. Indentations of the membrane include small endocytic and pinocytotic vesicles associated with the uptake of materials by the cell, and small exocytic vesicles and larger secretory vesicles involved in the outward transport of materials. These various structures will be discussed in detail later.



ENDOPLASMIC RETICULUM (ERGASTOPLASM)

This term is used to describe the system of interconnecting membrane-lined channels (Palade 1975) within the cytoplasm of most cells (**1**.1, 2, 10A, B, C). These channels are either cisternae (flattened sacs), or tubules, or else they may be vesicular. The membranes divide the cytoplasm into two major compartments, that inside the channel system, and that outside. The former constitutes the space in which secretory products are stored, or transported to the Golgi complex and cell exterior; the latter is made up of the colloidal proteins such as enzymes, carbohydrates and small molecules, together with the ribosomes and ribonucleic acid. As a whole, the extra-channel material is termed *hyaloplasm* or *cytosol*, and that within the channels, the *vacuoloplasm*.

Structurally, the channel system can be divided into *granular* or *rough endoplasmic reticulum*, to the external surface of which ribosomes are attached, and *agranular* or *smooth endoplasmic reticulum* which lacks ribosomes. When cells are fractionated by

1.8 Schemata of various junctions commonly occurring between cells, showing current interpretations of the electron microscopic appearances seen after sectioning, and with freeze-fracturing techniques. For clarity, the freeze-fracturing data are presented as though it were possible to separate and fold back the two leaflets of the plasma membrane, to expose the intramembranous protein particles inserted on their two faces. The *A* face = the *P* fracture face, and the *B* = the *E* fracture face in current terminology.

A

Magnification × 80,000.

disruption and centrifugation, the rough and smooth endoplasmic reticula break up into vesicles collectively termed *microsomes*.

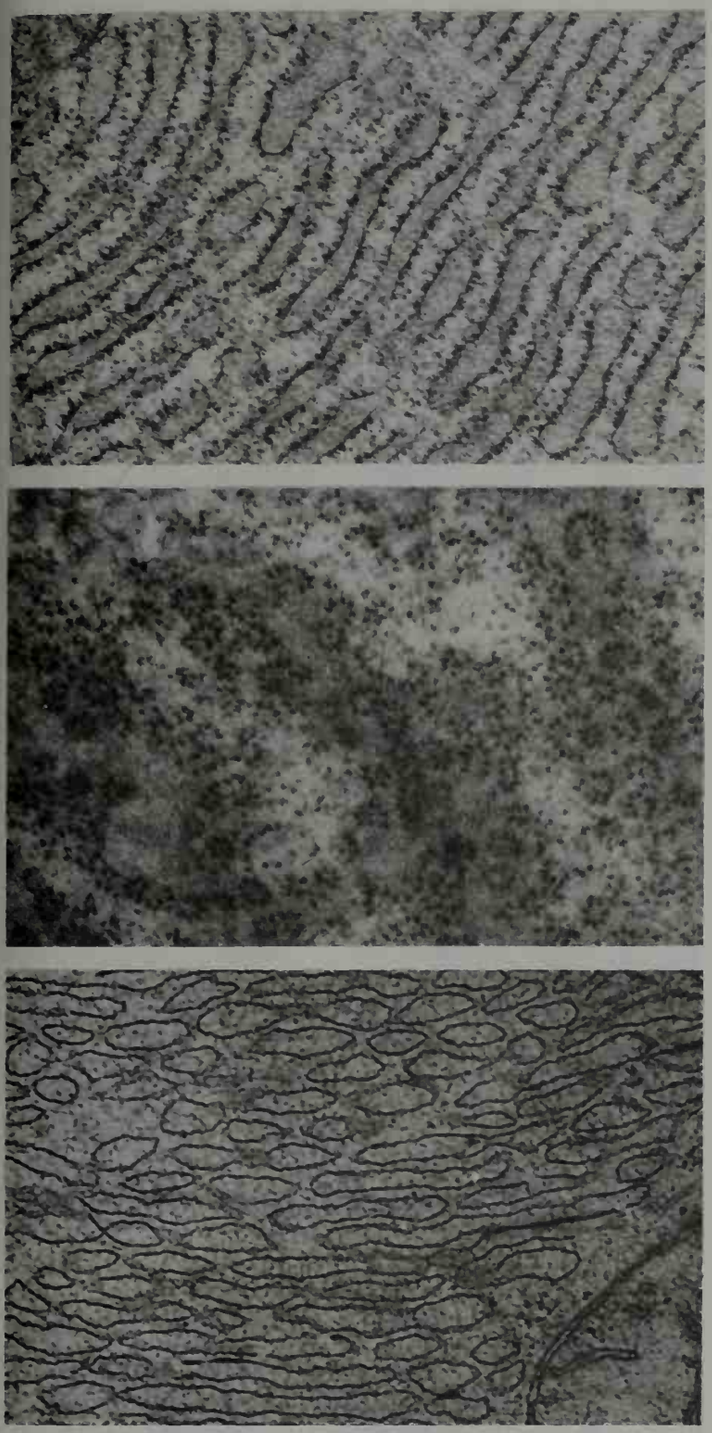
Granular endoplasmic reticulum carries out protein synthesis by means of its attached ribosomes, and is also able to synthesize some carbohydrates (p. 246). Generally ribosomes attached to membranes synthesize proteins which thereafter remain in membrane-bound bodies such as lysosomes or else are secreted to the exterior of the cell. Agranular endoplasmic reticulum is associated with carbohydrate metabolism, and many other metabolic processes, including respiration, detoxification, and synthesis of lipids, cholesterol and other steroids. The membranes of the endoplasmic reticulum as a whole serve as convenient surfaces for the attachment of many enzyme systems which are thus accessible to the substrates in solution within the cell. They also act co-operatively with the Golgi apparatus to elaborate new cell membranes, the protein, carbohydrate and lipid components being added in different regions.

Specialized types of endoplasmic reticulum are present in various cell types. In striated muscle cells the smooth endoplasmic reticulum (*sarcoplasmic reticulum*) is essential to the binding of calcium ions, which are liberated to initiate contraction on appropriate stimulation (p. 512).

In embryonic cells, endoplasmic reticulum although present is scant, and ribosome groups are mostly unattached within the hyaloplasm. With differentiation, the membranes of the cytoplasm usually increase greatly and ribosomes may become attached to form the rough endoplasmic reticulum. In mature cells, synthesis of some proteins starts only when attachment to membranes occurs, a step which is under hormonal regulation in some systems.

RIBOSOMES

Ribosomes (ribonucleoprotein particles) are relatively small bodies about 15 nm across (1.10A, B), composed of protein and (ribosomal) RNA, which are responsible for the synthesis of proteins from amino acids (Palade 1955; Siekevitz and Palade 1960). Each ribosome is made of two subunits (Nanninga 1973; Wittmann 1976), one slightly larger than the other, and sedimenting in the centrifuge at different rates (in nucleated cells mainly at 60S and 40S, where S=the Svedberg unit of sedimentation rate, a function of density, shape, etc.; the whole ribosome sediments at 80S). The subunits can be further dissociated into a number of protein subunits, about 30 in all, composed of *structural proteins* determining the shape and integrity of the ribosome, and *functional proteins* governing its synthetic activity. Two small RNA strands (28S and 7S), highly convoluted, lie in the 60S subunit, and one in the 40S subunit (18S), such RNA molecules all being derived from the nucleolus (see below). The 60S and 40S subunits are usually separate from each other when not engaged in protein synthesis, and can easily be dissociated in the laboratory by ionic manipulation.



Ribosomes may exist as solitary, relatively inactive *monosomes*, or as multiples (*polyribosomes* or *polysomes*) attached to, and in the process of, translating messenger RNA during protein synthesis. Polysomes can be *attached* to membranes, so constituting the granular endoplasmic reticulum (see above) or may lie *free* in the hyaloplasm. Attached polysomes synthesize proteins which remain within vesicles (e.g. lysosomal enzymes), or are secreted by way of exocytic vacuoles (e.g. procollagen); unattached polysomes synthesize proteins for use outside the channel system, including enzymes of the hyaloplasm, structural proteins of the cell (e.g. actin, tubulin) and haemoglobin in erythroblasts.

Since in a mature polysome all the attachment sites of the messenger RNA are occupied as the ribosomes move along it, synthesizing protein according to its instructions, the number of ribosomes in a polysome is a measure of the length of the messenger RNA molecule and therefore of the size of the protein being made.

The two major subunits have separate roles in protein synthesis. The smaller subunit is the site of attachment and translation of the messenger RNA; the larger subunit is responsible for the release of the newly constructed protein and, where appropriate, attachment to the endoplasmic reticulum and thereafter channelling the protein through its membranes into the cisternal cavity.

The subunit proteins of the ribosomes themselves are synthesized in the cytoplasm by other ribosomes. They then apparently pass into the nucleus where they are attached to ribosomal RNA from the nucleolus to form the two major subunits; these then pass separately back into the cytoplasm and only associate to form a complete ribosome when they attach themselves to a messenger RNA molecule. When protein synthesis is over, the two subunits dissociate, but may be used in more than one episode of translation.

The majority of ribosomes in the cell are of the 80S type, as already stated, having a molecular weight of about 4×10^6 daltons; however, those inside mitochondria are smaller (about 55S). The ribosomes of fungi and prokaryote organisms such as bacteria are also smaller than those of the nucleated cells of animals (and plants), which may perhaps reflect the less complex regulatory mechanisms of these relatively primitive species.

MITOCHONDRIA

Mitochondria are membrane-bound organelles of great metabolic significance (Slater 1972). Mitochondria were first observed with the light microscope as thread-like, spherical, or ellipsoidal bodies present in the cytoplasm of most cells and particularly those with a high metabolic rate such as the secretory cells of the exocrine glands. In living cells, when viewed by bright field, phase contrast or interference microscopy, they have been seen to move within the cell, change size and shape, and to divide. In size most mitochondria range from 0·5–2·0 μm wide by 3–4 μm long.

With the electron microscope (1.1, 11) each mitochondrion is seen to be made up of an outer and an inner membrane, the two being separated by a variable gap. The outer membrane is smooth and sometimes in continuity with the endoplasmic reticulum; the inner membrane is highly pleated to form incomplete transverse partitions or tubular invaginations termed *cristae mitochondriales*, or simply 'cristae'. This folding creates a relatively large surface area. The cristae are more numerous and complex in cells with a high metabolic rate than in relatively inactive ones; in heart muscle, for instance, the cristae are numerous and show complex pleats.

In the inner lumen of the mitochondrion lies the finely granular mitochondrial *matrix* which has a variable density. Thus it has been demonstrated that the shape and size of mitochondria can vary with activity, being smaller and with a denser matrix when inactive (Hackenbrock 1972). Within the matrix are many soluble enzymes and also a variety of inclusions have been described, including calcium salts, organic crystals and glycogen. There are also some ribosomes and the nucleic acids RNA and DNA (Nass 1969). The ribosomes and nucleic acids are quite distinct in their physical and chemical properties from those of the rest of the cell; the ribosomes are slightly smaller than those outside mitochondria and they sediment in the ultracentrifuge at a different rate. The DNA thread is joined at each end to form a ring (55S), and has a proportion of nitrogen bases different from that of chromosomal DNA. These components are vital to the continuity of mitochondria, which are able to multiply by division during interphase (Racher 1975); experiments with fungi indicate that some of the proteins of mitochondrial inner membranes are specified by their own nucleic acids, an example, therefore, of *cytoplasmic inheritance*. The ribosomes and nucleic acids are, interestingly, similar to those of bacteria, and speculations have been made on the possible origin of mitochondria in the far distant past as symbiotic bacteria which lost their ability to lead an independent existence.

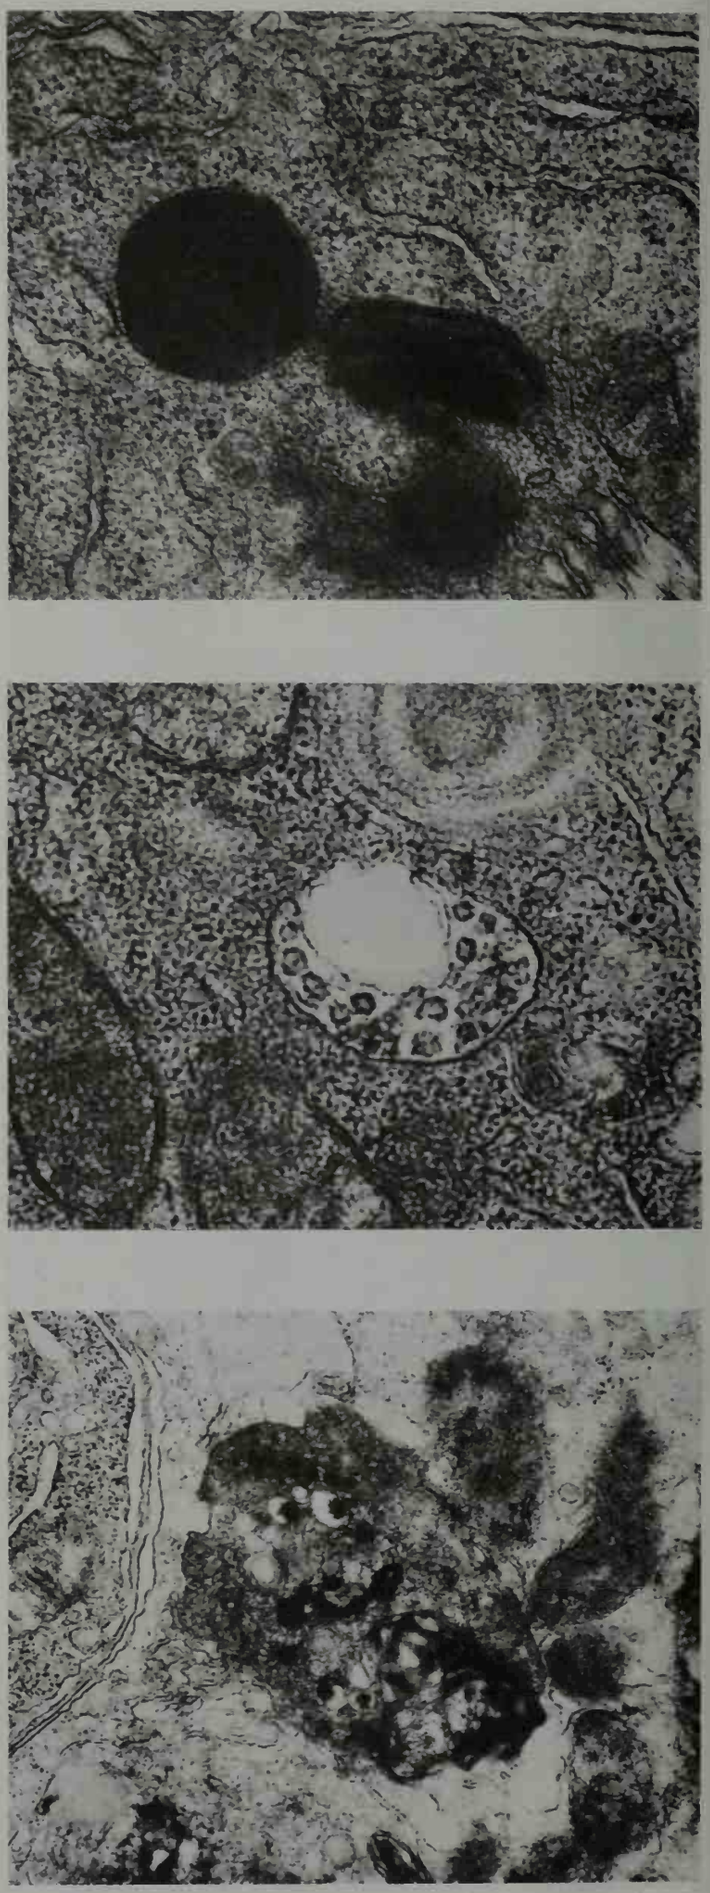
1.11 Electron micrograph showing details of mitochondrial structure: the outer membrane, the inner membrane folded to form cristae, and their related intra-mitochondrial spaces are visible. Magnification × 30,000.

The functions of mitochondria have been extensively examined by cell fractionation techniques, and they have been shown to be the principal site of a number of enzyme systems, particularly those concerned with the oxidative phosphorylation which is associated with the tricarboxylic acid (Kreb's) cycle and the cytochrome electron transport sequences of respiration. They are the chief sites where chemical energy is derived from the breakdown of organic compounds during respiration, to form high-energy organic phosphate compounds (particularly adenosine triphosphate, ATP, and guanosine triphosphate, GTP). These compounds pass to other parts of the cell where they take part in energy-consuming reactions. The various enzyme systems of the Kreb's cycle are situated in the mitochondrial matrix, while those of the cytochrome system and oxidative phosphorylation are localized chiefly in the inner mitochondrial membrane. Some of these ATPases form *enzyme assemblies* which, when mitochondria are hypotonically disrupted and negatively stained, become

visible as minute spheres supported by stalks projecting from the inner membrane. These are termed *elementary* or *stalked particles*. Mitochondria are also concerned with other transformations, particularly fatty acid metabolism (Racher 1975) and with calcium concentration.

It is interesting that mitochondria are distributed within the cell according to regional energy requirements, e.g. near the bases of cilia in certain epithelia, and between the folds of the membrane at the base of the cells of proximal convoluted renal tubules, where considerable active transport occurs.

Estimates of mitochondrial numbers in cells also show variability; in mammalian hepatic cells they average about 800 per cell; in lymphocytes only a few may be present.



LYSOSOMES

Lysosomes are membrane-bound, spheroidal, or ellipsoidal bodies ranging in size from 0·08–0·8 μm, which contain hydrolases capable of degrading a wide variety of substances (DeDuve 1965; Dingle *et al.* 1969a & b, 1973, 1975, 1976; Holtzman 1976). They are present in all cells except erythrocytes, and play a fundamental role in the degradative activities of cells, often being particularly numerous in those with a rapid metabolism, and also in phagocytes. So far, more than 40 lysosomal enzymes have been shown by biochemical analysis of organelles separated from cells by centrifugation methods, including many varieties of proteases, lipases, carbohydrases, esterases and nucleases. Cytochemically, the enzyme acid phosphatase (β-glycerylphosphatase) has been widely used as a marker of lysosomes for light and electron microscopy, although it is not invariably present.

Lysosomes have a rather complex life history, each stage being structurally distinct, and so they may take several forms even in one cell. Their contents are first formed in the granular endoplasmic reticulum where some carbohydrate is added to the enzymes, then passed to the Golgi complex for packaging in vesicular form and final processing; some lysosomes, however, may apparently be formed without the involvement of the Golgi complex. When first released as *primary lysosomes* they are relatively small but may sometimes fuse to form larger primary lysosomes up to 0·8 μm across, typically with dense granular interiors (1.12A). Primary lysosomes can be used either to degrade materials taken into the cell by phagocytosis, pinocytosis and endocytosis (*heterophagy*) or to degrade worn out, damaged or 'unwanted' organelles within the cell (*autophagy*). In the case of heterophagy, phagocytic vacuoles (*phagosomes*) containing objects such as bacteria, fuse with one or many primary lysosomes to form *secondary lysosomes* (*phagolysosomes*) which typically contain signs of digestion—for instance, membranous whorls, fibrillar débris, etc. (1.12A). Smaller pinocytotic and endocytic vesicles, containing fluids or small particles fuse with primary lysosomes to form *multivesicular bodies* (1.12B)—another form of secondary lysosome. In both heterophagy and autophagy, lysosomes become smaller and denser as digestion proceeds, and eventually the residual, undigested, insoluble contents may be ejected from the cell by exocytosis, or they may remain within the cell—an example of '*storage excretion*'. In non-dividing cells such as neurons, *residual bodies* of this type (1.12C), which may fuse to form much larger aggregates, are retained throughout the life span of the cell, so that in old age they are conspicuous in the form of the lipid-rich pigment lipofuscin ('*senility pigment*') within the nervous system.

In some cells, lysosomes are a predominant feature, for instance, in neutrophil leucocytes, where the granules are primary lysosomes employed in the killing of phagocytosed bacteria. Lysosomal enzymes may also possibly be released externally to damage neighbouring foreign organisms, or pathologically, as in certain types of arthritis, damaging the surrounding tissues. Osteoclasts may also erode bone by releasing similar enzymes on to the neighbouring bone surface (*see* p. 261).

Lysosomal membranes, normally impermeable to their enclosed enzymes, may under certain circumstances allow the enzymes to leak. Ionizing radiations, some carcinogens, silica

1.12A–C Electron micrographs of lysosomes in various stages: (A) a group of lysosomes in an olfactory receptor cell showing small primary lysosomes (left), and larger secondary lysosomes containing lamellar débris; (B) a multivesicular body with which endocytic vesicles are in the process of fusing; (C) a residual body, the end stage of lysosomal hydrolysis of engulfed cellular organelles. All magnifications × 30,000.

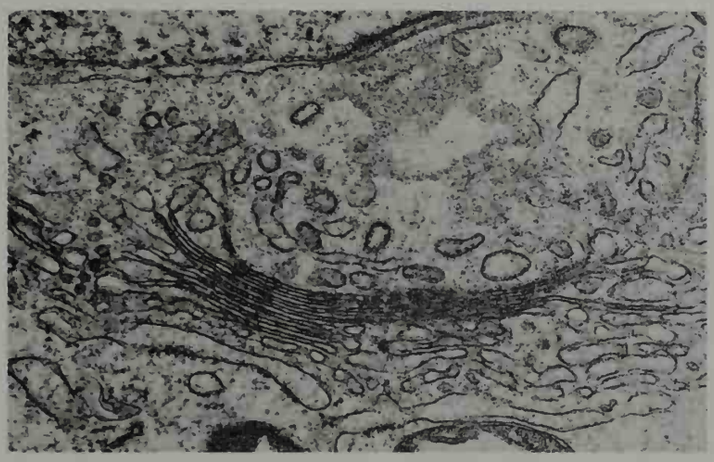
particles, asbestos dust, anoxia, heat, and a wide variety of drugs have been suggested as causing such effects, with consequent cellular damage, cell death or, if the genes are affected, the transformation of the cell into a neoplastic one. Conversely, some drugs, for example cortisone, can stabilize lysosomal membranes, and may therefore inhibit their fusion with phagocytic vesicles. Lysosomal leakage may also be of great natural significance in causing the *programmed death* of redundant cells during the embryonic period, or at least in facilitating their removal once dead (see also p. 79).

Because of their involvement in breakdown processes in metabolism, defects in lysosomal enzymes can lead to profound morphogenetic changes, and a range of genetic disorders (*lysosomal storage diseases*) has also been described. Examples of the latter are Tay-Sachs' disease in which a faulty carbohydrase leads to the accumulation of glycolipid in the central nervous system, with consequent death at an early age, and Hurler's syndrome, where failure to metabolize certain glycosaminoglycans (mucosubstances) causes abnormalities in the formation of connective tissues.

PEROXISOMES

Peroxisomes (*microbodies*) are membrane-bound vacuoles (1.4) about 0·6 μm across, often with dense cores or crystalline interiors (DeDuve 1973). They are concerned with catabolic reactions which release hydrogen peroxide, formed by the action of their contained enzymes—peroxidase, D-amino acid oxidase, and urate oxidase. Catalase, another major enzyme of peroxisomes, destroys hydrogen peroxide released by the others, preventing this toxic material from accumulating. Peroxisomes are probably present in all nucleated cells, and are particularly numerous in hepatocytes where they have been most extensively studied.

Other *membrane-bound bodies* are found in many cells, such as vacuoles containing lipids, mucopolysaccharides, and various secretory or storage products. The complex 'granules' of pancreatic islet β-cells, and the neurosecretory bodies of the neurohypophysis are two such examples.



GOLGI COMPLEX (GOLGI APPARATUS OR DICTYOSOME)

Beginning with Camillo Golgi, the Italian cytologist, optical microscopists of the nineteenth and early twentieth centuries recognized a distinct region of cytoplasm near the nucleus, particularly prominent in secretory cells, which stained heavily with metallic salts. This was considered an artefact by many, but with the advent of electron microscopy it was authenticated as a genuine cellular organelle.

The Golgi complex consists of one or more zones of smooth endoplasmic reticulum (1.1, 4, 13) arranged as stacks of flattened cisternae; membranous channels interconnect the cisternae, and small vesicles are found clustered at their borders. In glandular cells with an apical secretory zone, the Golgi complex is positioned between the secretory surface and the nucleus; in fibroblasts, where the secretory activity is more general, two or more groups of flattened vesicles, and in liver cells up to 50, may form a more widely distributed complex.

The Golgi complex is often cup-shaped, with the convex side nearest the nucleus. Around the perimeter of the concave side, larger *condensing vacuoles* are usually present. Biochemical and autoradiographic studies have shown that the organelle is a metabolically active region where secretory products and lysosomal enzymes are accumulated by fusion of *transport vesicles*. After moving through the cisternae of the Golgi complex, enzymes and secretory products are budded off either to be retained in the cytoplasm or extruded as *secretory vacuoles* (Jamieson and Palade 1967). In passing through the complex the secretory materials are altered; in mucus-secreting cells, for instance, the proteins synthesized in the rough endoplasmic reticulum are condensed in the condensing vacuoles into a smaller space, probably by subtraction of water, and carbohydrates rich in sulphur are added. In other cells, too, much of the carbohydrate moiety of their secretions is added at the Golgi complex, whose membranes serve as a site for attachment of the enzymes associated with carbohydrate synthesis, such as glycosyltransferase. The enzyme thiamine pyrophosphatase is also a valuable histochemical marker of Golgi complex activity.

The Golgi complex is also active in primary lysosome production (*vide supra*) which may in some cases take place in a special region, the Golgi-endoplasmic reticulum-lysosome complex (*G.E.R.L.*)—*see* Novikoff (1973)—and in the synthesis of cell membranes and external cell coats.

1.13 Electron micrograph of a Golgi apparatus in a spermatocyte showing the central multilamellar cisternae, and clusters of peripheral vesicles. Magnification × 15,000.

ANNULATED LAMELLAE AND MYELIN FIGURES

Annulated lamellae are arrays of parallel cisternae which are sometimes found in the cytoplasm and occasionally the nuclei of cells undergoing rapid protein synthesis (Kessel 1968), for example oöcytes, some embryonic and some neoplastic cells. Characteristically the membranes fuse intermittently, where they are punctuated by structures closely resembling nuclear pores (p. 21), reflecting their origin from the outer nuclear membrane. It has been suggested that they may serve as attachment sites for stored RNA, but their functions are otherwise obscure.

Myelin figures constitute regions of tightly packed membranous whorls, frequent within neuronal cytoplasm, and also commonly found in degenerating cells. They may be signs of breakdown of parts of the endoplasmic reticulum, and are often associated with lysosomal activity.

Other inclusions not bounded by membranes, and lying within the hyaloplasm, include clusters of *glycogen granules*, *ferritin*, and a variety of inorganic crystals; the hyaloplasm of erythrocytes is predominantly made up of haemoglobin.

TRANSPORT VESICLES

These include membrane-bound vacuoles, usually less than 0·1 μm in diameter, which are involved in the movement of fluids and particles into, out of, and within the cell (Kanaseki and Kadota 1969; Allison 1973). The process of uptake is broadly termed *endocytosis*, and the passage of materials in vesicles to the cell surface and their release, *exocytosis*. In the case of endocytosis the terminology is somewhat confused, but some authors distinguish between the ingestion of large particles in *phagocytic vesicles*, the bulk uptake of fluids in relatively large, often complex, *pinocytotic vesicles* which is an energy-dependent process, and the formation of small, rounded, *endocytic vesicles* which can still occur in cells deprived of energy sources, and may depend on physical rearrangements of plasma membrane components. Such *micropinocytotic vesicles* often possess a bristly coat on their exteriors, composed of a series of cross-linking pegs of a protein ('clathrin') which may enable them to round up initially, and may also be involved in their transport around the cell as '*coated vesicles*'. Not

all small internal vesicles are coated, however, so the functions of such coats are far from obvious.

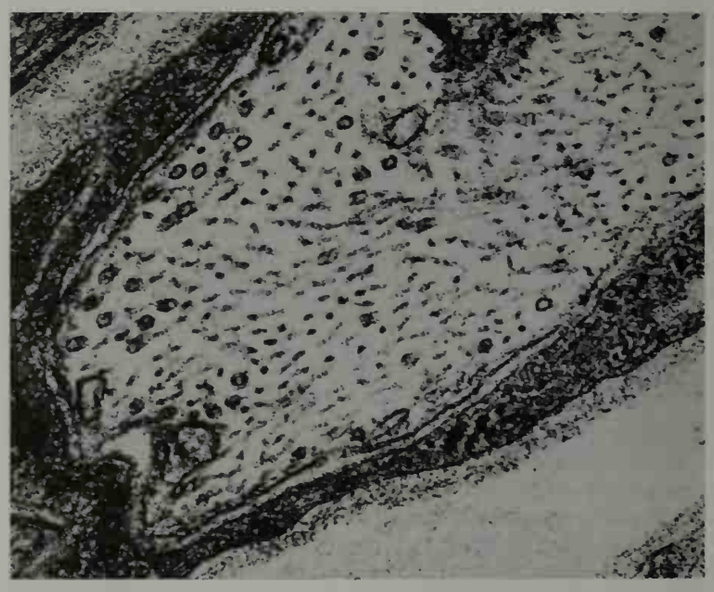
Exocytic vesicles, carrying materials out of cells, vary greatly in size, and may only be distinguished from endocytic vesicles experimentally by using extracellular tracers, which will enter the latter but not the former (*see* pp. 35, 36). Vesicles of these various types are present in all cells, but are particularly numerous where rapid exchange of materials between the cell and its environment is occurring, for example, endothelial cells, synaptic terminals of neurons, and in secretory cells.

MICROTUBULES AND MICROFILAMENTS

Microtubules (1.14A, B, and *see* Stephens and Edds 1976) are elongated cylinders about 24 nm in diameter, of varying length (up to some 70 μm in spermatozoan flagella), and made of protein (*see* Soifer 1975). They are frequently observed components of most cell types, but are particularly abundant in neurons, leucocytes, blood platelets, and in the mitotic spindles of dividing cells. They also form part of the structure of cilia, flagella and centrioles (*vide infra*). Helical microtubules occur in Schwann cells and oligodendrocytes (pp. 835, 843). Massed parallel bundles of interconnected microtubules are found in the pillar cells supporting the sensory hair cells of the cochlea. Microtubules normally show few acute bends, indicating some degree of stiffness.

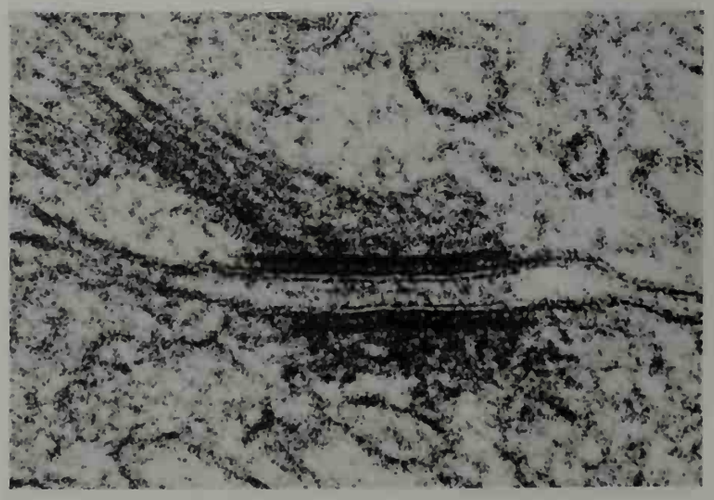
The microtubules are composed of two proteins, *tubulins a* and *b*, arranged as dimers (Fujiwara and Tilney 1975). Each protein molecule is about 5 nm across, and microtubules in transverse section are made up of a ring of 12 or 13 such globular subunits which are arranged in long columns of alternating tubulins a and b, forming the walls of a cylinder. Each column is slightly shifted on its neighbour, so that a spiral pattern of subunits is also generated (Amos and Klug 1974). Microtubules are formed by the simple polymerization of the tubulin dimers, and there is in some cells an equilibrium between polymerized and unpolymerized tubulin, so that some types of microtubule may break down and reform rapidly, although there is much variation in their stability. Consequently, chemicals which bind to tubulin cause the equilibrium to shift, so bringing about the depolymerization of microtubules; the drugs colchicine, colchemide, vinblastin and griseofulvin are well known as anti-microtubule agents acting in this manner.

Formation of microtubules can take place by addition to pre-existing microtubules, or formation *de novo* in, as yet, poorly understood special cytoplasmic centres with a microtubule-organizing capacity such as centrioles, around which spindle microtubules polymerize during cell division (Pickett-Heaps 1975). In other instances microtubule-organizing centres have no obvious structural basis, thus centrioles are not always essential to microtubule formation.



Microtubules are often linked to adjacent structures by filamentous extensions, such connexions having been observed in relation to cell membranes, other microtubules, microfilaments, and transport vesicles. In some of these situations their role is obviously to give mechanical support; in others they appear to be able to cause movement of adjacent structures. Their role in cell motility will be discussed later (p. 35).

MICROFILAMENTS



Microfilaments (1.4, 14A) are thinner (6–8 nm) than microtubules and appear solid in cross-section; they are prominent components of all cells (except perhaps mature erythrocytes) and are intimately involved in cell motility in general (Wessels *et al.* 1971). Microfilaments are composed of *actin*, of which the 6 nm subunits are arranged in two entwined helices. A number of different varieties of actin are known (Goldman *et al.* 1976), some of them forming long relatively stable microfilaments, whilst others form shorter and more transient ones. Some types are primarily associated with cell plasma membranes; others lie deeper within the hyaloplasm (Pollack *et al.* 1975). Muscle cells

contain particularly robust forms of microfilament (p. 507). In all cases, actin is able to bind to the protein *myosin* when an energy source (ATP) is available, and when organized in an appropriate manner. This phenomenon leads to various types of shearing movement which can produce cell motility of different kinds, including muscular contraction (p. 510). The presence of actin microfilaments can be detected electron microscopically by incubating cells, made permeable to proteins, with heavy meromyosin which binds to actin and decorates the filaments with arrowhead formations. The drug cytochalasin B causes depolymerization of some actin microfilaments (*see* Spudich 1972), and is therefore a valuable experimental tool in research into their functions. Often associated with actin microfilaments are a number of other proteins (e.g. troponin, tropomyosin B, actinin) which assist in various motile activities of these organelles (Lazarides 1976).

OTHER CELLULAR FILAMENTS

These include protein filaments of various sizes found in different cell types (Goldman and Knipe 1972). The most widespread are *tonofibrils* (*tonofilaments*) or *intermediate filaments*, often present in large numbers where structural strength is needed (1.14C), as in epidermal prickle cells. They tend to form extensive bundles running for long distances in the cytoplasm, and to be inserted into desmosomes at the cell surface. Tonofibrils are about 10 nm in diameter and often appear tubular in cross-section (Blose and Chako 1976); their precise chemistry has not, as yet, been satisfactorily analysed.

Keratin filaments are similar to tonofibrils in appearance; they are proteinaceous structures confined to the mature (and dead) keratinocytes of the epidermis (pp. 41, 1218).

Neurofilaments (1.14B) are characteristic elements of neurons, both in their cell somata and neurite extensions (axons and dendrites); similar filaments are present in some neuroglial cell processes. They are about 12 nm across, are sometimes hollow in section, and may extend for large distances, perhaps throughout an entire axon. Neurofilaments are proteinaceous; they do not, however, appear to contain tubulin or actin (Shelanski *et al.* 1971). They may be important in providing mechanical support and, incidentally, are of value to the histologist since they can be impregnated with silver salts using specialized staining techniques, thus demonstrating aspects of the histological structure of nervous tissue. For further comment *see* p. 820.

Intranuclear filaments have also been reported in a variety of cell types; the significance of these structures is not clear, although they may have a developmental (or sometimes pathological) connotation in particular instances.

MICROVILLI

These are finger-like extensions of cell surfaces (1.15A-C, 16) from less than 0·1 μm in diameter and up to about 5 μm long. When arranged in a highly regular series, they constitute a *striated border*, as at the absorptive surfaces of the epithelial cells of the small intestine (Limbrick and Finean 1970); when they are less regular, as in the gall-bladder epithelium, the term *brush border* is applied.

Internally they are supported by bundles of actin microfilaments, which are implanted within the apical cytoplasm of the cell amongst other transversely running filaments to create a meshwork, the *terminal web*. The microfilaments are attached to the membrane surface of each microvillus by finer lateral filaments along the margins, and are inserted apically into a dense mass of the protein α-actinin (Mooseker and Tilney 1975).

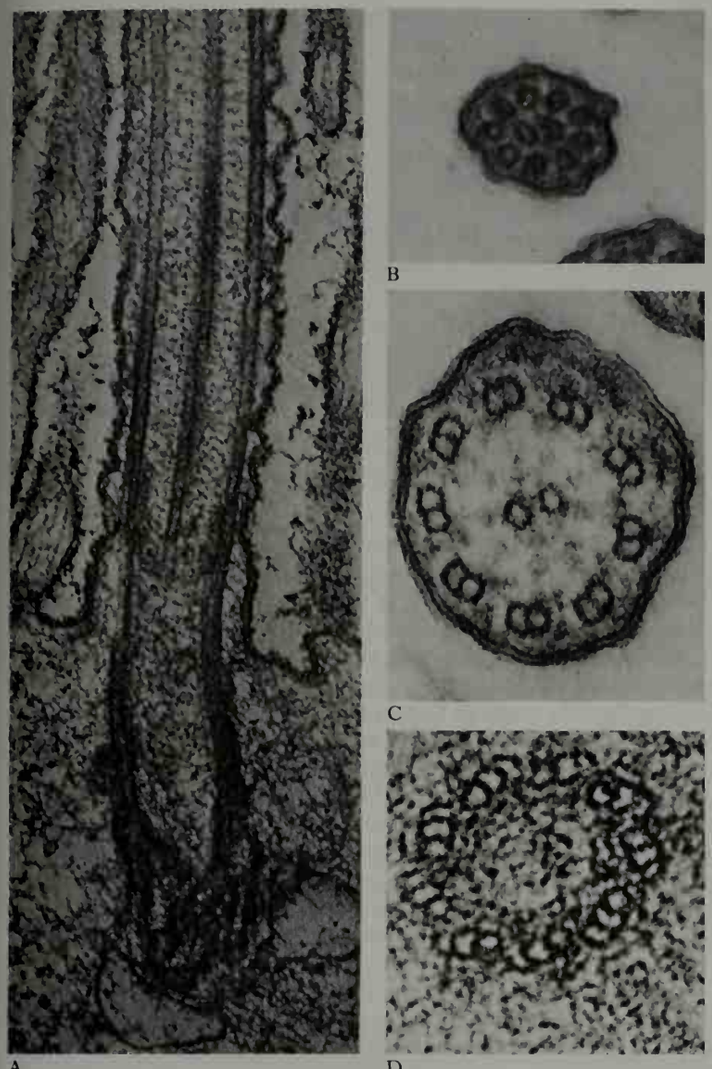
Microvilli create a highly folded cell surface, and are found at sites of active absorption where extensive surface areas are necessary, such as in the proximal and distal convoluted tubules of the kidney. In the small intestine absorptive cells bear microvilli which have a thick cell coat, probably of great importance in providing a site for adsorption of digestive enzymes. The supporting filaments within the microvilli are possibly associated with the transport of absorbed materials from the cell surface to the cell interior. Several enzyme systems associated with active transport across membranes have been localized within striated borders.

Irregular microvilli, or *filopodia*, are also found on the surfaces of many types of cell, particularly free macrophages and fibroblasts. Again, these may be associated with transport processes, particularly phagocytosis, and with cell motility.

Large, regular microvilli (*stereocilia*) also occur at some sensory surfaces, for example, on taste-buds, cochlear and vestibular receptor cells, and in the epididymis.

Similar, though more transient structures, found on developing or motile cells include stiff elongate '*microspikes*' and *ruffled membranes* (*see* p. 36; also 1.37).

CILIA AND FLAGELLA



Seen with the light microscope these are hair-like (cilium = eyelash) and whip-like (flagellum = whip) projections of the cell surface capable of movement, creating currents in the overlying fluid, or movements of a cell to which they are attached. Cilia are found on many lining layers, particularly the epithelia of most of the respiratory tract, and parts of the male and female reproductive tracts, the ependyma lining the central canal of the spinal cord and ventricles of the brain, and the mesothelia of the peritoneal and pleural cavities. They also occur at olfactory receptor endings and, modified, as portions of the rods and cones of the retina; cilia are, in addition, present on many dividing tissue cells. Many cilia may be present on a single cell, as in the bronchial epithelium, or only one or two as with some mesothelial cells. Each male gamete possesses a single flagellum about 70 μm long.

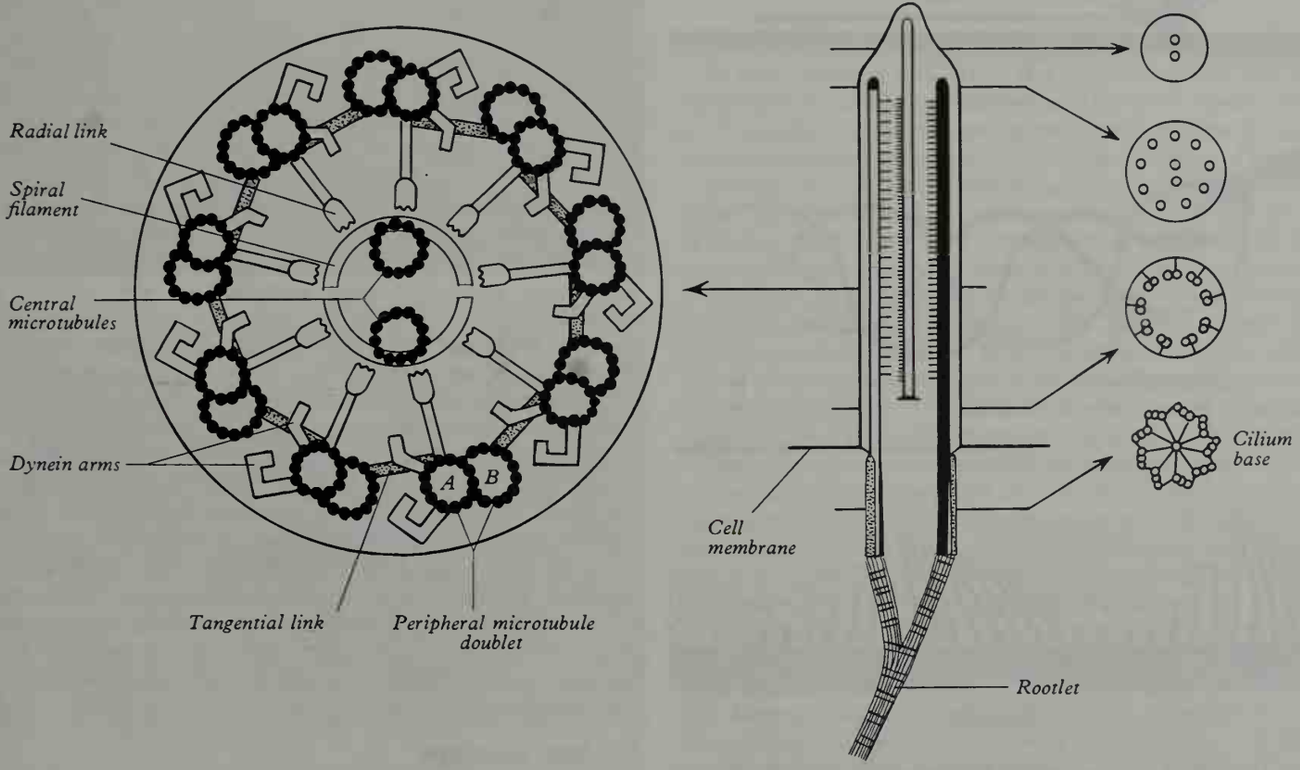
With the electron microscope (1.17A–D, 18) each cilium or flagellum is seen to consist of a *shaft*, constituting most of its length, with a diameter of about 0·25 μm, a tapering *tip*, and, within the surface cytoplasm of the cell, a *kinetosome* (*basal body, basal granule*, or *blepharoplast*) about 1 μm long (Gibbons and Grimstone 1960). The whole structure is bounded, except at its base, by a tubular extension of the plasma membrane. In freeze-fracture preparations chain-like groups of characteristic membrane particles, collectively termed the *ciliary necklace*, are seen to surround the proximal end of the cilium (Gilula and Satir 1972). These particles may be involved in the control of ciliary beating. Within this lies a cylinder of nine double microtubules, surrounding a central pair of single microtubules.

At the *base* of the cilium each microtubule doublet, the two parts of which are designated the A and B subfibres, are twisted through 40 degrees, and another microtubule, the C subfibre, is added. The central pair sometimes end immediately above the cell surface in a dense sphere or *axosome*; beneath this lies a transverse partition or *basal plate*. Associated with the kinetosome are often one or more cross-banded filamentous *rootlets* and a plate-like *basal foot*, which are probably concerned with anchoring the cilium into the cytoplasm.

At the *apical end* of the structure, the various microtubular elements do not continue to the tip; as successive sections are followed, first the A subfibres terminate, then the B subfibres, and finally the central pair.

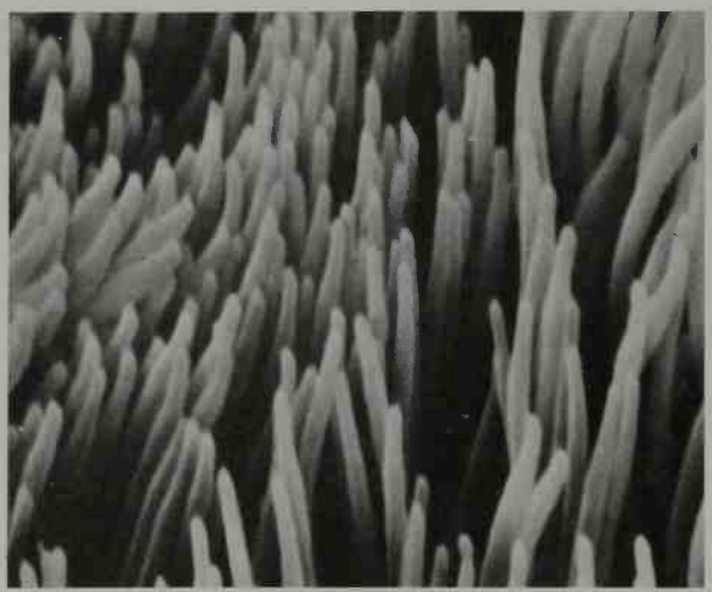
Within the shaft (1.17E) lie several structures associated with the microtubules, such as radial spokes which extend inwards from the outer microtubules towards the central pair. The outer

1.17A–D Electron micrographs of cilia cut (A) longitudinally, and (B, C, D) through the tip, shaft and base respectively. Magnification A × 50,000; B–D × 110,000.



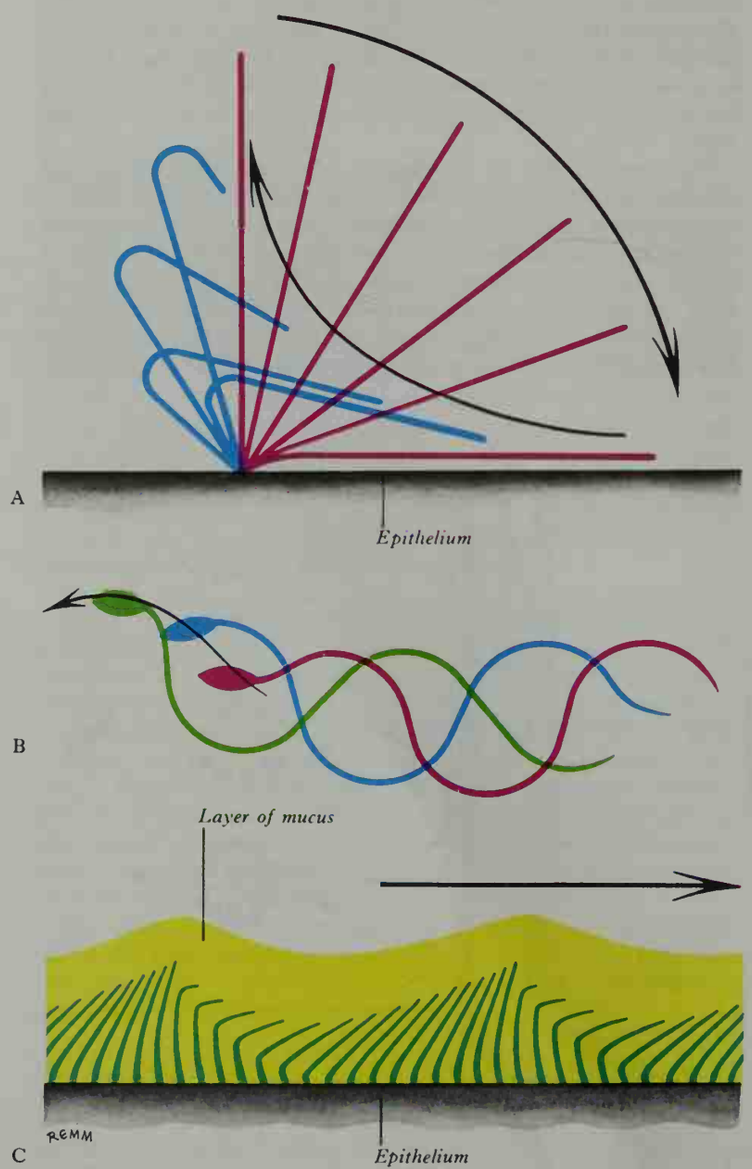
doublet microtubules bear tangentially positioned *arms*; these are attached to the A subfibre of one doublet and point towards the B subfibre of the neighbouring doublet. A helical filament encircles the central pair of microtubules, which are also joined together by ladder-like spokes. Because of the 9+2 pattern of tubules, the cilium (or flagellum) possesses a plane of symmetry which passes perpendicular to a line joining the central pair. The direction of this plane also corresponds closely to the plane of bending of the cilium.

The movements of cilia and flagella (*see* Sleigh 1974, 1977), although somewhat different in detail, are similar in broad outline (1.19A–C).



Flagella cause movement by the passage of rapid successive waves of bending, from the attached to the free end, to generate a resultant motile force in rather the same manner as an eel whilst swimming. In human spermatozoa there is a helical component in this motion, although the precise form is complex from a hydrodynamic point of view (*see* e.g. Brokaw 1975).

In cilia, the beating is planar, but is asymmetrical. In the first phase, the *effective stroke*, the cilium remains stiff except at the base where it bends to produce an oar-like stroke. This is followed by the *recovery stroke* during which the cilium behaves as though flaccid, the wave of bending passing from the base to the tip so that the cilium returns to its initial position ready for the next cycle. The activity of adjacent cilia is usually coupled so that the bending of one cilium is rapidly followed by the bending of the next and so on, to produce long travelling or *metachronal* waves which pass over the tissue surface in the same direction as the effective stroke, in the cilia of vertebrates. This coupling is known to be caused by the viscous interaction of adjacent cilia, although the rate of beating may be affected by extraneous factors (Sleigh 1974).



The mechanism of beating is still not clear; structural observations indicate that when a cilium bends, the microtubules do not change in length but slide upon one another (Satir 1974); biochemical studies have demonstrated in the 'arms' of peripheral doublets a protein 'dynein', with an enzyme site for splitting ATP. An interaction of adjacent doublets involving these arms, to cause mutual sliding, may underly the active beating of cilia and flagella (Gibbons and Rowe 1965). Re-arrangement of the spoke-

1.17E Diagram of the internal structure of a cilium in longitudinal section (centre), and showing the disposition of microtubules at various levels (right), and the detailed cross-sectional appearance of the shaft of the cilium (left). In the latter, hook-like dynein arms extend from the peripheral doublets and radial links with expanded heads project towards the central pair of microtubules. A filamentous spiral encircles the central pair. Adjacent peripheral doublet microtubules are also connected by tangential links. Redrawn from Sleigh (1977).

like elements may also modify the form of the ciliary bending (Warner and Satir 1974).

The cilia of olfactory receptors possess the typical '9+2' arrangement of subfibres; the cilium segment of retinal rods and cones, however, lacks the central pair. Many tissues containing rapidly dividing cells such as the adrenal cortex also show a small number of cilia which protrude from the cell surfaces into the intercellular spaces. The function of these is unknown, and they may represent an unavoidable but mechanically functionless correlate of cell division processes.

Cilia and flagella are formed by the polymerization of tubulin on centrioles which are synthesized deep in the cell, and then move to lie immediately beneath the cell membrane before the cilia begin to sprout (Sorokin 1968; Staprans and Dirksen 1974). Once initial sprouting has occurred, they grow by the addition of tubulin and other materials to the distal end.

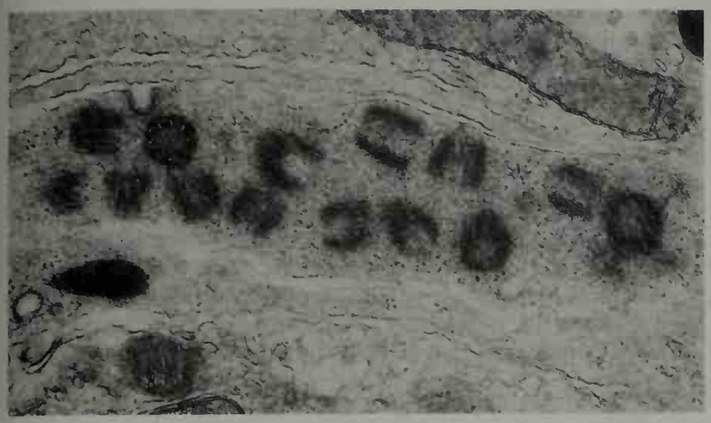
CENTRIOLES

Centrioles are cylindrical bodies about 1 μm long by 0·25 μm in diameter (Fulton 1971), identical in structure with the bases of cilia (*vide supra*) but lying free within the cytoplasm (1.1, 20). At least two centrioles are found in all cells capable of division. Usually they form a pair lying at right angles to each other, within a somewhat dense region of cytoplasm, the *centrosome*. Various filamentous or granular structures (*pericentriolar bodies*) are often associated with the centrioles in their vicinity.

Centrioles, or their peri-centriolar cytoplasm, are concerned in some way with the synthesis of microtubules, as in the generation of the spindle and aster microtubules during cell division, the sprouting of cilia, and the provision of axonal and dendritic microtubules in developing neurons. Prior to cell division a new centriole is formed near each old one, and the resulting pairs pass during cell division to the two new cells (Rattner and Phillips 1973)

The nature of this organizing capacity is not known; in flowering plants spindle microtubules are apparently formed in the absence of centrioles, so they may not be essential to this process.

The Nucleus

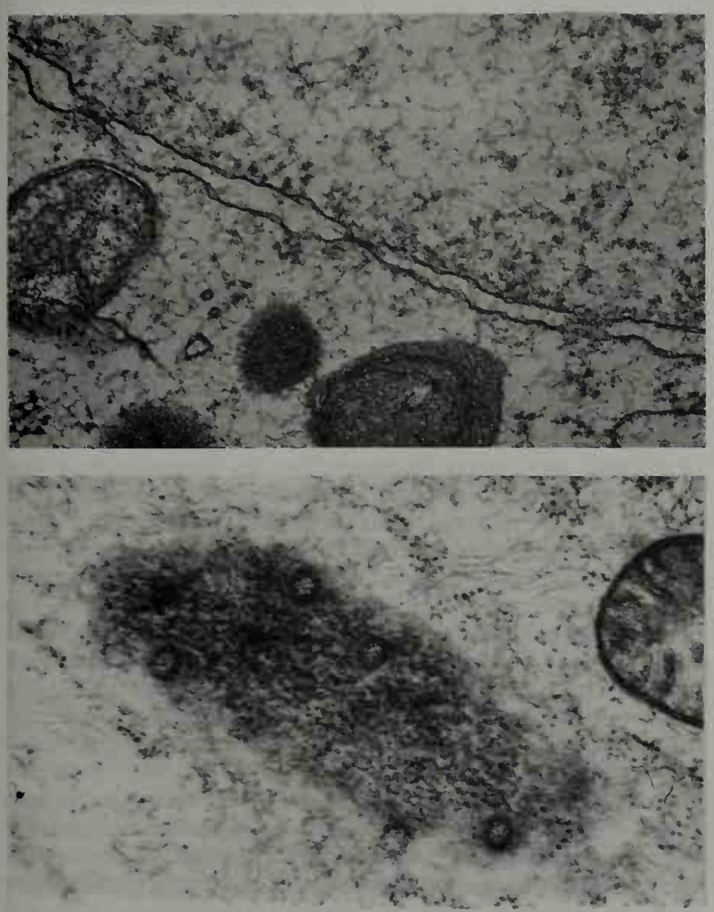


The nucleus of each cell is usually a spherical or ellipsoidal body, often indented, some 4–10 μm in diameter and separated from the surrounding cytoplasm by a membranous nuclear envelope. The nucleus stains deeply with basic dyes such as haematoxylin by virtue of the nucleic acids present in its chromosomes—deoxyribonucleic acid (DNA), and nucleoli—ribonucleic acids (RNA). The DNA is also responsible for the strongly positive reaction found with the Feulgen method. Basic proteins (histones), and some acidic proteins, are also present in the nucleus.

Many investigations of the part played by the nucleus in the life of cells have been carried out, involving experiments such as transplantation of nuclei between different species of protozoa, removal of the nucleus and, recently, the fusion of dissimilar cells from different species of metazoa, after prior treatment with viruses (Harris 1970). Such experiments indicate that although the cytoplasm can survive for a limited time without a nucleus, protein synthesis ceases and the cell soon dies.

Many of the characteristics of intact cells, such as division rate and motility, seem primarily determined by the nucleus rather than the cytoplasm. Isotopic labelling experiments also show that there is a constant exchange of materials between nucleus and cytoplasm; this will be elaborated later when considering the chromosomes.

Nuclear Envelope



This is a flattened sac lined on both sides by the membranes which constitute the innermost two layers of the cytomembrane system, and they are separated by a distance of about 20 nm (1.1, 4, 5). The outer membrane is part of the endoplasmic reticulum proper and

1.20 Transmission electron micrograph of a group of centrioles in a developing nerve cell dendrite. Magnification × 25,000.

often shows attached ribosomes; products of protein synthesis may accumulate between the two membranes.

At points of fusion between the membranes, the envelope is punctured by circular holes, the *nuclear pores*, each about 50 nm in diameter (1.1, 21A, B). Surrounding each pore is a 120 nm ring of dense proteinaceous material composed of eight sets of granules or fibrils, and a diaphragm which, in some circumstances, may restrict the permeability of the pore. This marginal ring is the *annulus* and together with the pore forms the *pore complex* (Wischnitzer 1973). Electrical measurements in some cells, though not in all, suggest that the pores are not always patent. The pores appear to serve chiefly as a passage for diffusion of materials into and out of the nucleus, particularly the large molecules of ribonucleic acid and various proteins.

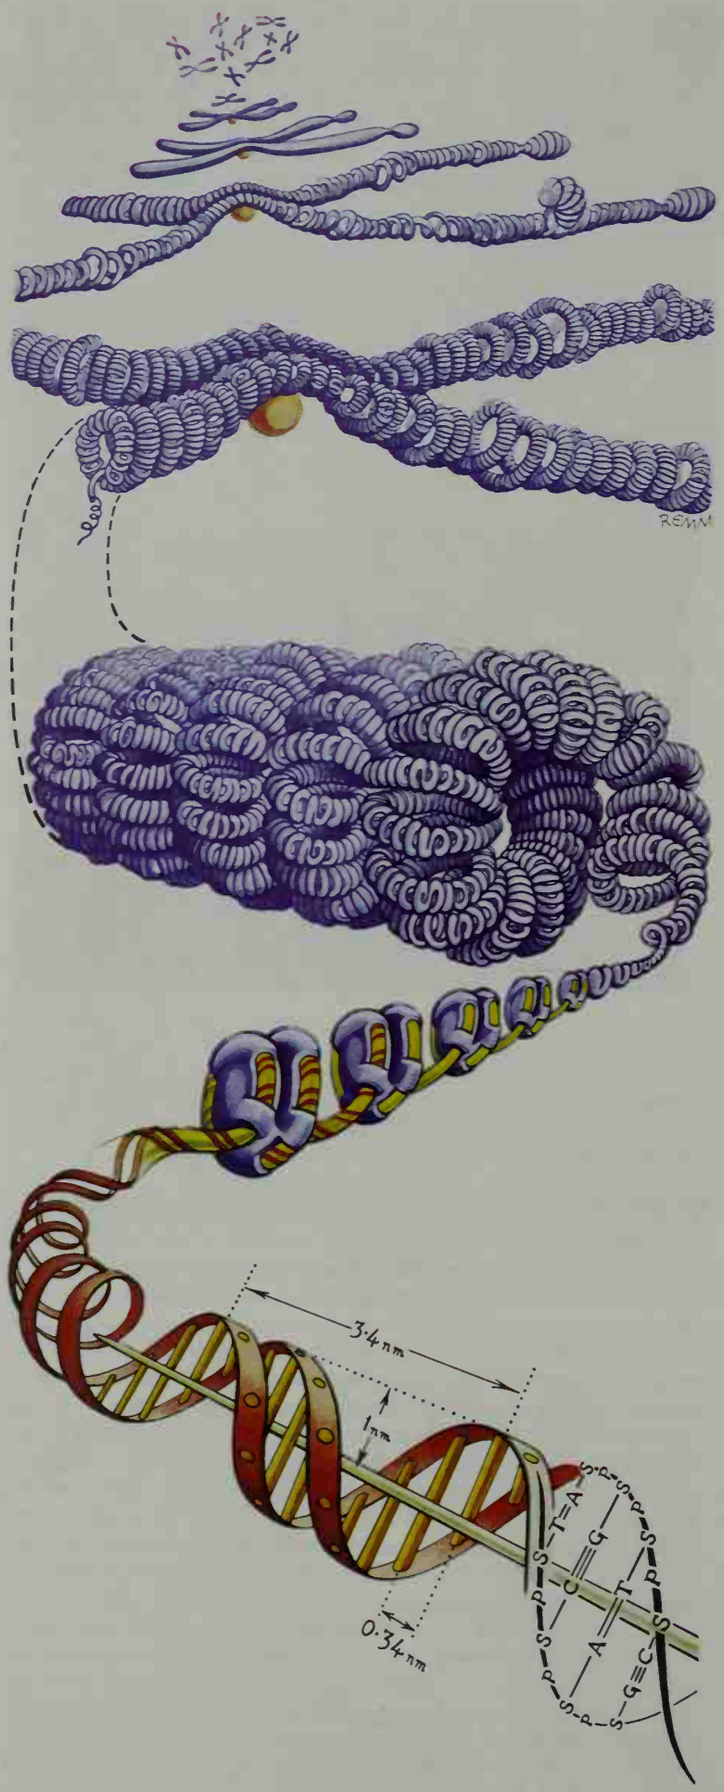
Micrograph (B) kindly provided by Dr. M. Dyson of Guy's Hospital Medical School. Magnification × 25,000.

Chromosomes

Within the nucleus most of the nucleic acid is deoxyribonucleic acid (DNA) which is associated with protein to form elongated threads or chromosomes. Between cell divisions (interphase) the chromosomes are usually highly extended filaments which form a diffuse network collectively termed *chromatin*. This may be rather dispersed and poorly staining *euchromatin*, or clumped and densely staining *heterochromatin* (1.22). These two states are associated, respectively, with high and low degrees of synthetic activity. Nuclei with a largely euchromatic appearance are known as *open-face* nuclei, and are larger in volume than heterochromatic, *closed-face* nuclei. In moribund cells, the nuclei are often small and stain densely (*pyknotic nuclei*). Pathological nuclei (for example in neoplastic cells) may be highly irregular in outline, and take on a variety of appearances (*pleomorphic nuclei*).



1.22 Photomicrograph showing the configuration of chromatin in 'closed-face', heterochromatic nuclei of lymphocytes (small cells), and 'open-face', euchromatic nuclei of larger reticular cells. The section is stained with methyl green-pyronin stain which also gives the characteristic red colour to the nucleolus and cytoplasm of the larger cells, denoting the presence of much RNA.

In most somatic cells there is a mixture of the two states of chromatin; heterochromatin typically lies close against the inside of the nuclear envelope, leaving gaps at the nuclear pores, whilst the euchromatin occupies the more central region of the nucleus.

During cell division (*vide infra*) chromosomes shorten to a small fraction of their interphase length; each cell is seen to contain a fixed number of chromosomes characteristic for that species of organism. In the somatic cells of man this number is 46, which is the *diploid* number; in the gametes and the germinal cells giving rise immediately to them, the number is half this (the *haploid* number—p. 30). When fertilization takes place, the fusion of two haploid sets, one from each gamete nucleus, restores the diploid number. The number of sets is termed the *ploidy*. If more than two sets are present the cell is said to be *polyploid*.

Each chromosome in a haploid set is unique in size and shape; in the diploid set there are two of each type of chromosome (*homologous* pairs), one from the ovum and the other from the spermatozoön. However, two paired chromosomes are not always identical; these are the *sex chromosomes* (*see* Mittwoch 1967), which are distinct (in man) from the remaining 22 pairs of chromosomes (*autosomes*). In the female (the *homogametic sex*) the sex chromosomes are identical, each being termed an X *chromosome* so giving 44 autosomes + 2 X sex chromosomes. In the male (the *heterogametic sex*) there is one X and an unequal Y *chromosome* giving a diploid complement of 44 autosomes + X and Y sex chromosomes.

During gametogenesis the homologous chromosomes separate, one passing to each gamete. This ensures that in the male, there are equal numbers of gametes possessing either an X or a Y sex chromosome, whereas in the female the ova all contain an X

1.23 A diagram showing a possible model for the organization of DNA and protein in chromsomes during early metaphase in mitosis. Each chromosome consists of two chromatids united at the primary constriction where the centromere is also sited. In the exposed region of the DNA molecule, the chemical groups of the 'backbone' of each helix—S (sugar) and P (phosphate), and the bases—A (adenine), T (thymine), C (cytosine) and G (guanine), are represented. Several nucleosomes are also depicted (see text).

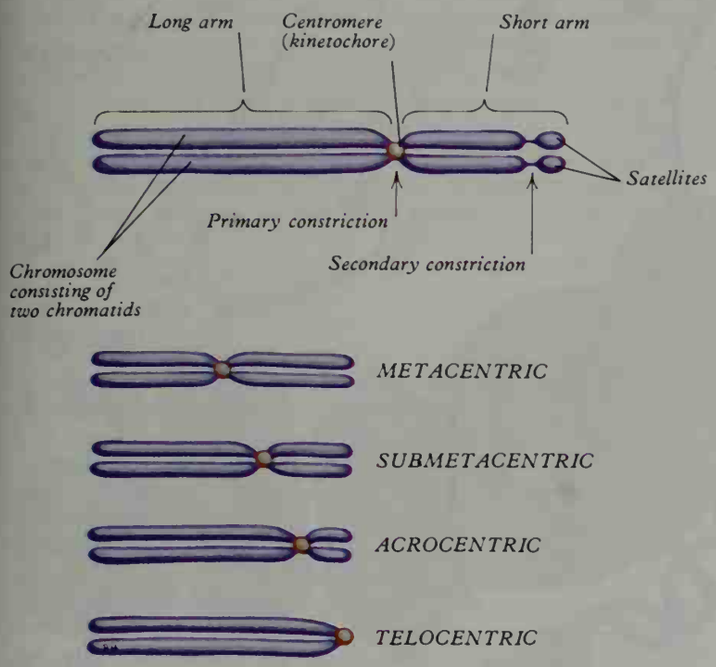
chromosome. At fertilization there is therefore an equal chance of a male (XY) or a female (XX) zygote being formed, although at birth there is a slight predominance of females because of a higher prenatal mortality amongst male embryos.

CHROMOSOMAL STRUCTURE

In early cell division when the chromosomes are quite short and thick, each pair of homologous chromosomes has a characteristic common basic structure (1.23; and *see* Stubblefield 1973). All chromosomes thus consist of two parallel and identical filaments, *chromatids* (1.24, 25), joined together at a narrowed region, the *primary constriction*, within which is a pale-staining region, the

1.24 A spread preparation of metaphase chromosomes of a human fibroblast. Kindly provided by the Paediatric Research Unit, Guy's Hospital Medical School.

centromere or *kinetochore*, which is attached to the spindle fibres (*fusal microtubules*) during cell division. The free ends of the chromatids are known as *telomeres*.



Each chromatid is divided by the centromere into two *arms*. The centromere may be near the middle of the chromosome (*metacentric*) or near one end (*acrocentric*). In some mammals the centromere may be placed at the extreme end (the *telocentric* condition). In certain chromosomes there is another narrowing (the *secondary constriction*) near one end of each chromatid, frequently dividing off terminal *satellite bodies*. These constrictions are believed to be often associated with the organization of nucleoli, which may be attached to the chromosome at this point in interphase. The classification of human chromosomes on the basis of such characteristics will be considered later (p. 33).

Each complete diploid set of chromosomes contains the cell's hereditary instructions, or *genome*, and each cell in the body, apart from the germ cells, has an identical genetic complement. The chromosomal threads bearing these instructions are termed the *chromonemata* (singular: *chromonema*). It is known that each chromosome bears a linear sequence of *genes*, each situated at a characteristic position (*gene locus*), which together determine the inheritable characters of the organism carrying it, the theoretical units of inheritance being termed the *genes*.

During interphase, each chromosome retains its integrity and so the sequence of genes is also preserved. Although the sequence is highly stable, permanent, inheritable changes (*mutations*) brought about by external forces such as ionizing radiation, or exposure to certain chemicals, can occur in the genome. When the affected region is restricted these are called *gene mutations*. When whole arms or relatively large segments are involved, they are termed *chromosomal mutations*. Such mutations are some of the principal factors responsible for the inheritable *variations* which all populations show (but see also meiotic cell division p. 30).

Within members of such a population, homologous chromosomes may determine a number of alternative characters since they may carry some mutant genes; such groups of alternative genes are termed *alleles* (see also p. 101).

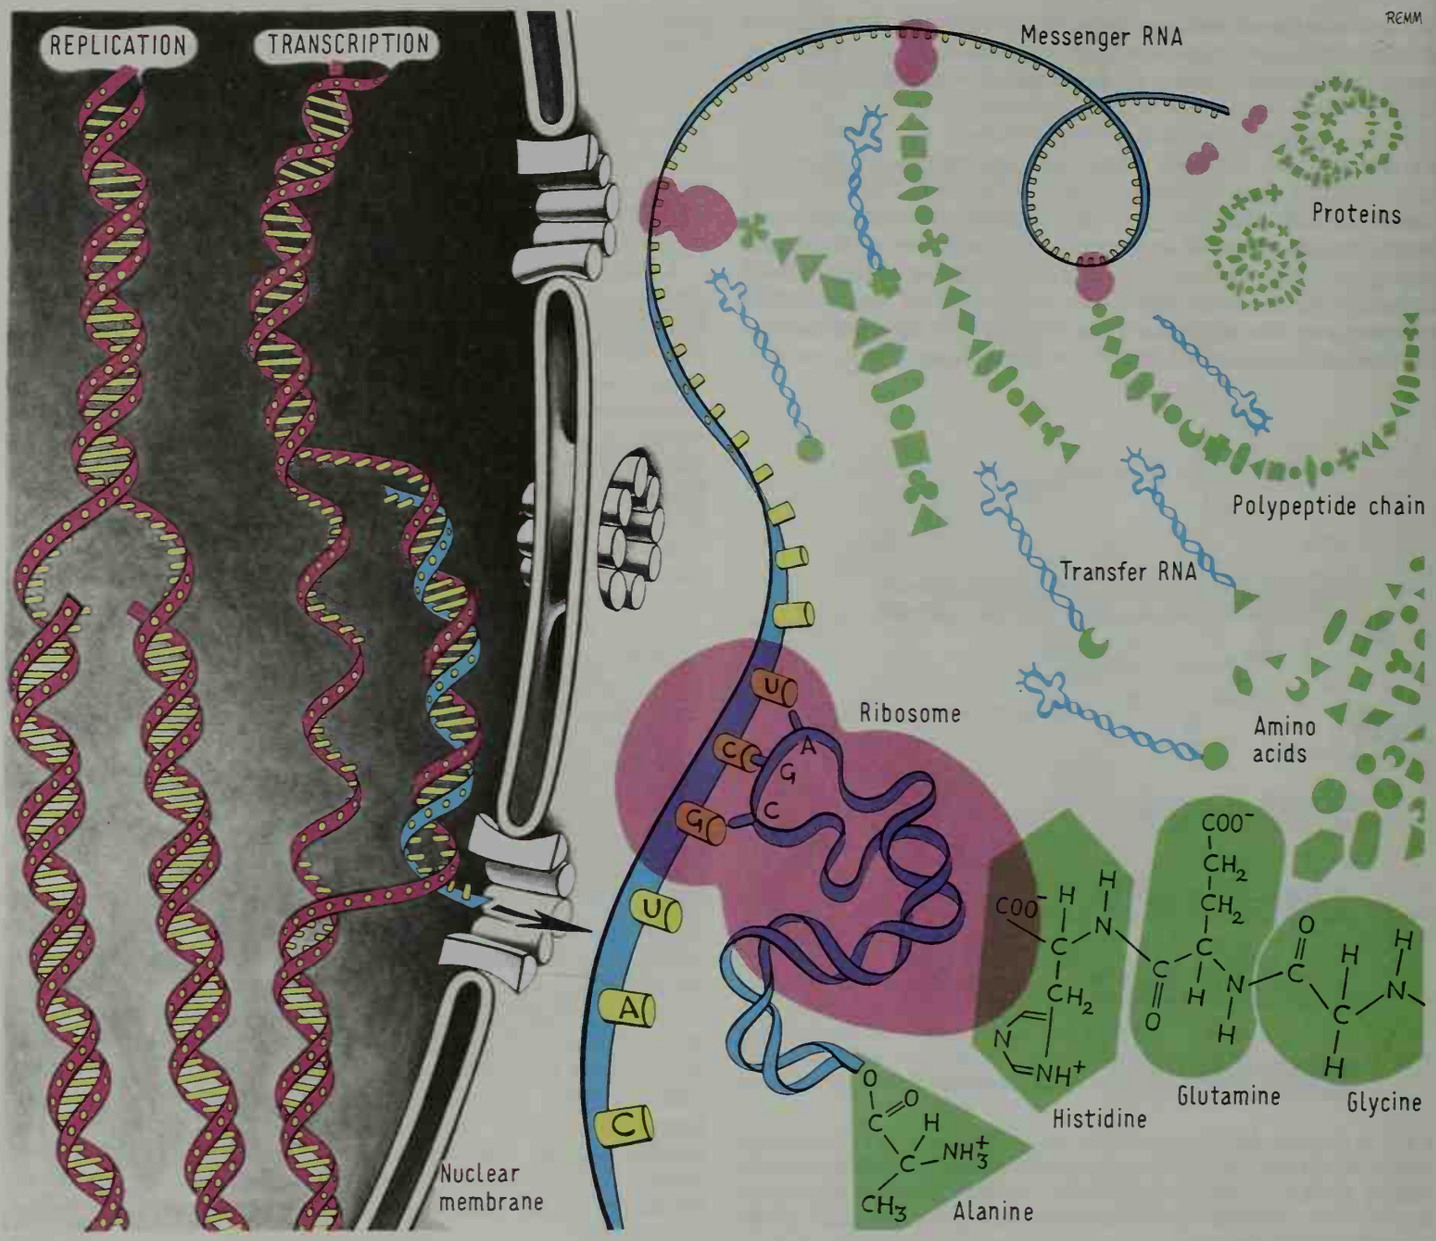
In any genome homologous chromosomes may possess, at a particular locus, identical alleles (the *homozygous* condition) or non-identical ones (the *heterozygous* condition). Since, in the formation of gametes, the homologous chromosomes are segregated into haploid sets, the alleles which they bear are also segregated. The various types of recombination of these which occur at fertilization, and their expression in the resulting organism, are the substance of the basic laws of inheritance, first propounded by Gregor Mendel (see also pp. 101–102).

1.25 A diagram depicting the major structural features of chromosomes seen in mitotic metaphase; the terminology of the different chromosomal regions is given, together with the various major categories of chromosome, classified according to differences in the position of the primary constriction.

COMPOSITION AND ACTIVITIES OF CHROMOSOMES

Chromosomes are made of fine filaments of the nucleic acid DNA (1.23, 26), each associated with varieties of nucleoprotein. In man, each diploid somatic cell nucleus contains about $5{\cdot}6 \times 10^{-12}$ g of DNA (Rudkin 1967). The identification of the latter as the hereditary material has a long history, dating from the characterization of nucleic acids by Miescher in the 1860s, the recognition of the part played by nuclei in fertilization and the cytological events occurring in mitotic and meiotic cell divisions, and their correlation with the laws of inheritance propounded by Mendel in 1865, and then rediscovered in 1900. Further milestones were the analysis of the chemistry and distribution of the nucleic acids within cells, the investigation of viruses, which are largely composed of either RNA or DNA, and the final characterization of DNA by X-ray diffraction crystallography. The latter led to the 'double helix' model of DNA structure (Watson and Crick 1953), which opened a new window on the molecular organization of living systems. Since that time the nature of the genetic store and its mode of action have been intensively studied.

The nucleic acids DNA and RNA act as bearers of coded information which can be translated to direct the activities of each cell, and therefore the structure and metabolism of the whole organism (1.26). DNA is the central molecule, since its information is handed on unaltered from parent cell to its descendants, throughout life, and, by way of the germ cells, to subsequent generations. RNA is the transient intermediary, taking coded information from the DNA of the chromosomes and translating it as the structure of the enzymes and other proteins which determine the morphology and chemistry of the cell. This flow of information has been termed 'the central dogma' of molecular biology, that is, DNA→RNA→protein. At each step in this flow there is an expenditure of chemical energy, and the mediation of previously existing enzymes.



All three of these compounds (DNA, RNA and proteins) have one characteristic in common: they are all composed of molecules arranged as a linear sequence of subunits. Proteins are long chain polymers of 20 types of amino acid arranged in a variety of sequences. They vary in length, each arrangement determining the precise nature of a particular protein; for example, the way in which its chain folds into more complex shapes, such as the macromolecules of globular proteins, and its catalytic activity, in the case of enzymes. Likewise, DNA is a long linear molecule, and there is a direct correspondence between the arrangement of its chemical groups and those of the protein for which it codes. The transfer of information from DNA to RNA by the synthesis of the latter alongside the former is termed *transcription*, and the final decoding of the RNA message into the amino acid sequence constituting a protein is called *translation*. The other activity, the exact duplication of the DNA code to provide each daughter cell with identical gene sequences, is called *replication*.

THE CELL CYCLE

Synthetic activity in the cell is not uniform at all times in its life cycle, since, for example, appreciable protein or DNA synthesis does not occur during mitosis. Likewise in interphase, DNA synthesis is restricted mainly to a middle period of the cell cycle, whereas protein synthesis occurs throughout (Mitchison 1971). Accordingly, we can divide interphase (1.27) into a *G1* (*first gap*), *S* (*synthetic*), and *G2* (*second gap*) stage. DNA replication occurs in the S phase, and the manufacture of proteins to be used in mitosis takes place in G2. The duration of the cell cycle and its different stages varies greatly between cell types. G1 may last from a few hours to many years, or it may be absent, as in the rapidly dividing blastomeres of the early embryo. The S stage usually occupies about 7 hours, and the G2 stage up to 5 hours. Mitosis in human cells is complete in approximately 1 hour.

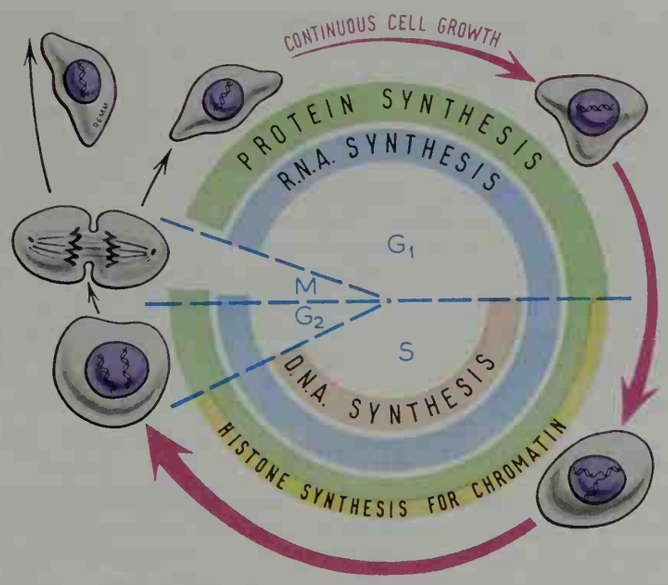
DNA STRUCTURE

The Watson and Crick model of DNA structure, now widely confirmed, proposes that DNA consists of two parallel molecular chains running in opposite directions in the form of a double helix, 2·5 nm in diameter, repeating every 3·4 nm. Each chain is composed of a 'backbone' of pentose sugar (deoxyribose) groups linked by phosphoric acid bridges, in such a way that they confer a particular directionality. Each pentose group bears a nitrogen-carbon ring base, which is directed sideways towards a corresponding group on the opposing chain, and is linked to that base by hydrogen bonds. There are four such bases: the purines, adenine and guanine, and the pyrimidines, cytosine and thymine. These bases are dissimilar in shape; the space between the two chains, and the type of bonding available, dictates that adenine on one chain always pairs with thymine on the other, and guanine with cytosine. The rigid complementary nature of this pairing is the basis of the genetic code. This is written in terms of three-letter 'words', each made up of three bases in a row, corresponding to a single amino acid in the final protein. Multiples of such triplets encode a whole single polypeptide, and such a sequence corresponds to a *structural gene*, or *cistron*, of classical genetics. Some triplets do not code for amino acids, but are, in effect, instructions to start or terminate the formation of amino acid chains, rather like the punctuation in a sentence. Often a number of functionally related proteins, for example, an interdependent system of enzymes, are encoded by a series of genes which may be controlled as a unit, a *supergene* or *polycistron*.

1.26 A diagram of the processes occurring during DNA replication and protein synthesis. The processes of DNA replication (on left), and transcription (middle, right) are indicated; the abbreviations are the same as those used in 1.23, with the addition of U = uridine.

ORGANIZATION OF CHROMOSOMAL DNA

In all eukaryote chromosomes the DNA appears to be present in the form of a single continuous thread (prior, that is, to the S phase, when the DNA is being duplicated). From the known amount of DNA in each human cell it can be calculated that each nucleus contains a total length of about 170 cm, and a single chromosome is as much as 7 cm if fully extended (DuPraw 1968). In life, most of the DNA exists in a highly folded state, seen at its most extreme in the head of the mature spermatozoön (p. 95). In general it seems that the DNA which is active in transcription is most extended (*euchromatic*) and that the inactive DNA regions are most folded (*heterochromatic*), a difference which is seen very clearly in the giant polytene chromosomes of the salivary glands of the fruit fly *Drosophila*, where the active zones form extended loops (*'puffs'*) when suitably stimulated to synthesize RNA (Berendes 1973). As might be expected, the degree of DNA folding varies with the phases of the cell cycle (Golomb and Bahr 1974), in parallel with the rate of protein synthesis; it is most folded during cell division (at metaphase) and, in an active cell, least folded in interphase. However, some DNA remains apparently permanently folded and heterochromatic; this includes the DNA which at some phase of development was active, but later becomes inactive (*facultative heterochromatin*—*see* Brown 1966), such as the inactive X chromosome in human females. Other chromosomal regions which appear permanently heterochromatic (*constitutive heterochromatin*), are the primary and secondary constrictions of some, and perhaps all, chromosomes (Hsu and Arrighi 1971). The significance of constitutive heterochromatin is not clear although many suggestions have been made, for example, that it may have some 'intrinsic' role in maintaining chromosome stability.



Biochemical analyses of DNA have shown that a small proportion of the total consists of highly *repetitive sequences of bases*, rich in guanosine and cytosine, and therefore differing from other types of DNA in buoyant density; this is termed *satellite DNA*. Repetitive DNA of this kind is known to occur at the secondary constrictions of certain chromosomes where ribosomal RNA is synthesized, and at the primary (pericentrosomal) constrictions, where their functions are not known, so that at least in these two situations, constitutive heterochromatin seems to be identical with satellite DNA (Jones 1970). It has been suggested that repetitive DNA may represent parts of the chromosome where many identical genes coding for 'intrinsic' molecules (e.g. regulatory proteins, transfer RNAs, ribosomal RNAs) might be present. Repetitive DNA varies widely in different, even closely related species, so there is no obvious significance in the amounts present.

The exact manner in which the chromosomal DNA is folded has been much debated. It has been suggested that heterochromatin (e.g. in metaphase chromosomes) is thrown into tight loops (DuPraw 1971) or into supercoiled helices (1.23). On a more minute scale, it has recently been shown that the DNA is intermittently wound around groups of protein (*see below*).

Association of DNA and Nucleoproteins

Nucleoproteins form about 80 per cent of the dry weight of chromatin, in which they are closely associated with DNA. These proteins include in particular the basic histones and protamines, and also acidic proteins and enzymes (Elgin and Weintraub 1975). Most of the protein is aggregated in spheroidal particles about 10 nm across, strung like beads along the DNA thread (Olins *et al.* 1976), which is coiled around each particle to form a complex, the *nucleosome* or *ν*-body. Each nucleosome is composed largely of four histones (H2A, H2B, H3, H4) which form two symmetrical groups (Weintraub *et al.* 1976). It has also been suggested that the nucleosomes may be able to move along the DNA, or to become detached when the DNA is perhaps active in transcription.

Enzymes associated with DNA metabolism and protein synthesis are also attached to the DNA; some of these (e.g. RNA polymerase) can be detected structurally as dense granules about 5 nm across adhering to the DNA thread (Miller and Beatty 1969).

1.27 Diagram of the major events occurring during the cell cycle of a growing and mitotically active cell to show the major stages: *G1* or 'first gap' phase; *S* or 'synthetic' phase; *G2* or 'second gap' phase; *M* or 'mitotic' phase.

TRANSCRIPTION

In transcription (*see* Watson 1975) the two helical strands of DNA are able to separate locally to expose a particular cistron on one of them, the *master strand* (the other strand being complementary). Upon this template, another strand of RNA is constructed with the aid of RNA polymerase and ATP. RNA is similar to DNA in composition, except that it is single stranded, contains ribose instead of deoxyribose, and contains the base uracil in place of thymine. The same type of base pairing now takes place so that a chain of RNA is formed alongside the DNA master strand. The DNA triplets are thus transcribed into complementary triplets, or *codons*, of RNA. When the complete cistron has been transcribed in this way, the codon-bearing RNA separates and moves to the cytoplasm, and is therefore known as *messenger* RNA (mRNA). At some point the mRNA attaches to the small subunit of a ribosome which, with other chemical factors, acts as a complex enzyme. By means of another class of nucleic acid called *transfer* RNA (tRNA), specific cytoplasmic amino acids are recognized and matched with the triplet codons of the mRNA. There exist a large number of specific tRNA molecules in the cytoplasm, each capable of 'recognizing', on the one hand, a single mRNA codon and, on the other, a corresponding amino acid. The recognition of the codons again occurs by complementary base-pairing and the relevant part of the tRNA molecule involved is called the tRNA *anticodon*. Recognition of the specific amino acid is less well understood; it may not involve the amino acid directly but, rather, an intermediary specific enzyme involved in its linkage to the growing polypeptide chain.

Each ribosome moves along the mRNA strand, 'reading' its code, so that a corresponding sequence of amino acids is formed, each being linked to the next by a peptide bond. Several ribosomes may be reading the mRNA strand at a given time, so forming the characteristic polysome rosettes or helices. When decoding is complete, the ribosome detaches itself and both mRNA and protein are released.

Since each nucleus contains the whole complement of genetic information for an individual, the expression of this must be subject to complex interlocking control mechanisms for any directed action to occur. These permit only a small fraction of the total to be transcribed at any moment, depending on the demands made on the cell, and its role in the economy of the total organism.

Jacob and Monod (1961) proposed a twofold mechanism of gene control on the basis of bacterial experiments, involving a hierarchial system of three gene types. In the first type of control, *regulation by induction*, each group of structural genes is closely linked to a controlling *operator gene*, so forming a unit or *operon*. The operator gene is normally repressed by a protein, the *repressor*, produced by another gene, the *regulator gene*, which is not necessarily on the same chromosome, and so prevents RNA polymerase from transcribing the structural genes. A metabolite of the cell which induces protein transcription does so by combining with the repressor, which then cannot repress the operator gene, so allowing transcription. Alternatively, a metabolite may inhibit protein synthesis—*regulation by repression*. This second scheme is similar to the first, but proposes that the repressor can only inhibit the operator gene after combining with the inducer substance, which thus prevents transcription by the structural genes.

In higher organisms, the regulatory mechanisms, though basically similar to those of prokaryotes, show important differences. In multicellular animals all the cells of the body, while carrying identical genes, express them in a wide variety of ways, so that in any given cell the great majority of genes are *inactive* and only those few which are relevant to the maintenance of all cells, and to the specialist functions of the particular cell, are expressed. Experimental evidence indicates that the DNA is maintained in the repressed state by its close association with *histones*, the major basic nucleoproteins of chromatin (*see* Elgin and Weintraub 1975, and also p. 85). There are only a few classes of histones and these are very similar in a very wide range of animals, so that they are unlikely to be related *specifically* to any particular pattern of genes, unlike the repressor substances found in bacteria (*see* above, and p. 85). Genes in eukaryotes appear to be activated by another class of *acidic, non-histone proteins* which interact with specific genes (Paul 1972). Many types of such proteins are known, and these vary widely from cell to cell and between different species. They probably operate by first disengaging the histones from their close association with a particular gene sequence, and then by attaching to the DNA to promote the co-attachment of a molecule of RNA polymerase which then proceeds to transcribe the gene or group of genes. Such activities have been studied extensively in the interaction of hormones with specific 'target' cells. In some instances, as in the action of progesterone (a steroid hormone of low molecular weight) on the uterine epithelium, the hormone passes into the cytoplasm of the cell where it combines with specific receptor proteins and then, in this complexed form, moves to the nucleus to combine further with the appropriate region of DNA through its associated histones, resulting in its transcription, and the formation of proteins for cell growth (O'Malley and Schrader 1976; King and Mainwaring 1974). In other examples a hormone of too large a molecular size to pass through the plasma membrane (e.g. the

polypeptide adrenocorticotrophic hormone, ACTH) may instead stimulate an enzyme, adenyl cyclase, present in the plasma membrane, to release an intracellular 'second order messenger' which, by way of a rather complex train of events, eventually activates the relevant genes in a manner similar to that of other hormones (Stein *et al.* 1975). The sensitivity of a target cell to its stimulatory hormone presumably depends on its ability to synthesize the appropriate receptor molecules, and upon the relative susceptibility of its gene sequences to derepression. The establishment of such patterns of gene regulation in a particular cell is poorly understood at present, although this process, *cellular differentiation*, is known to be dependent on many factors both inside and outside the differentiating cell.

CELLULAR DIFFERENTIATION

As development of an organism proceeds, its cells pass through a series of changes in gene expression, reflected in alterations of cell structure and behaviour (see also pp 83–92). Initially, all cells possess rather similar properties, but as embryogenesis gathers momentum, they begin to diversify, first separating into broad categories (e.g. the principal germ layers, etc.) and then into narrower categories (tissue and subtypes of tissues) until finally they mature into the '*end cells*' of their particular lineage (Gurdon 1973). Some cells which are capable of giving rise to others throughout life (*stem cells*) never proceed to the ultimate point of this progression, and retain some embryonic characteristics (p. 60), but in all cases there is a *sequential pattern of gene expression* which changes and limits the cell to a particular specialized range of activities. We can detect such changes as alterations in cell structure and biochemical properties, particularly in the types of proteins which are synthesized. At the level of the gene, differentiation of this kind must be based on a change in the pattern of repression and activation of the DNA sequences transcribing the specific proteins of that stage of development; in the lifetime of a particular cell lineage, many such changes will take place (see, for example, the development of haemal cells—p. 63). It appears that the selection of a pattern of gene activity may occur some while before its expression in protein synthesis. Thus, a cell may be *committed* to a particular line of specialization without manifesting its commitment until later; once 'switched' in this way, cells are not usually able to revert to an earlier stage of development, so that an irreversible repression of some gene sequences must have occurred. *Stem cells* may remain permanently at a level of partial differentiation, although some of their offspring will be committed to full differentiation. In general, as the degree of differentiation progresses, cell division becomes less frequent (e.g. erythroblasts—p. 66), although some structurally specialized cells such as Schwann cells (p. 843) and certain glandular cells, when suitably stimulated, may undergo repeated mitotic divisions.

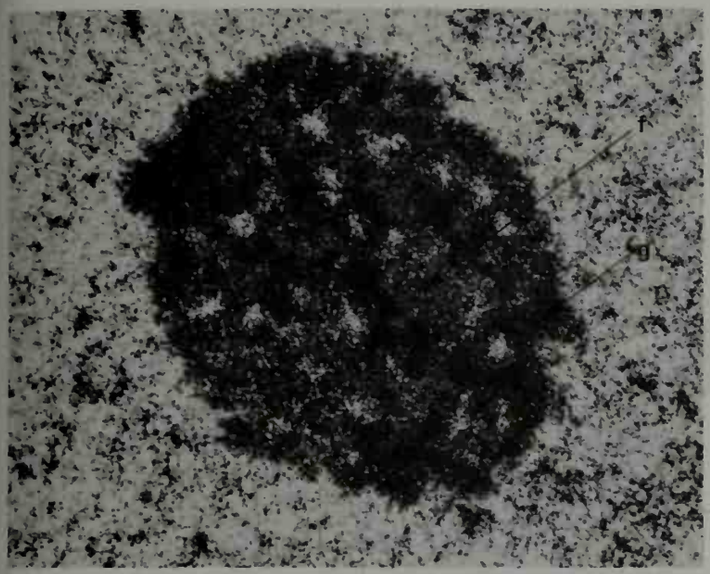
What constitutes the appropriate stimulus for a cell line to differentiate at successive stages in development is one of the most fascinating of biological problems, and one which also lies at the heart of many pathological transformations including carcinogenesis. In the embryo, differentiation depends upon a wide variety of circumstances (*see* pp. 83–92), although in most cases chemical interactions between cells or between different regions of the same cell are thought to be of primary significance. The initiation of a particular pathway of cellular development may, however, also depend upon complex, competitive interactions between cells, or upon the position which a cell occupies within a cell group (*see* discussion on 'positional information' on pp. 85, 87). In addition, differentiation may also depend upon some temporal sequence such as the number of previous cell divisions (pp. 81, 84). Even in mature tissues in which cell turnover occurs, similar mechanisms appear to ensure the final differentiation to a functional end cell. In some cases this is linked to the presence of a physiological stimulus as, for example, in the case of the 'B' lymphocytes which respond to exposure to an appropriate antigen by differentiating into plasma cells which secrete a neutralizing antibody. In other cases, particularly where a cell is part of a highly organized system, more subtle mechanisms must be involved, for example, the regional differentiation of keratinocytes to form undulant epidermal friction ridges in hairless skin.

REPLICATION

Replication involves the separation of the two intertwined DNA chains (**1**.26) and the manufacture of complementary chains alongside each of the originals which, during this process, act as templates so that the sequence of bases is copied exactly. Thus, in each of the two resulting double helices, one chain of the original double helix is conserved, so that replication is said to be *semi-conservative* (Meselson and Stahl 1958; Taylor 1958). During replication DNA is synthesized by a DNA polymerase from nucleotide precursors, so that if radioactive thymidine, a precursor of the specific DNA base thymine, is added to a cell, it is incorporated into the chromosome and can be detected autoradiographically. Using this method it has been shown that DNA synthesis occurs during the S phase simultaneously along many short stretches of DNA, beginning at a series of *initiation points* where DNA polymerase molecules can attach and then move along the chromonema to synthesize new DNA chains. Such regions of synthesis spread in both directions away from the initiation points, forming *replication forks* which can also be visualized by autoradiography (Cairns 1966; Taylor and Hozier 1976), until the whole chromosome is replicated.

Each type of chromosome has a characteristic pattern of DNA synthesis; permanently heterochromatic regions replicate later than the rest, and the inactive heterochromatic X chromosome in females replicates later than other chromosomes in the set (German 1964).

While the majority of the chromosomal DNA synthesis is confined to the S phase, there is also a constant low level synthesis of DNA which is concerned with the *repair* of minor damage to the chromosomes resulting, for example, from ultraviolet light impinging on epidermal cells. A variety of enzymes are needed for such reparative activities, including endonucleases which recognize a damaged DNA strand and begin to cut it, exonucleases which excise the damaged region, a DNA polymerase which synthesizes new DNA alongside the unaffected chain, and a ligase which joins the new portion to the cut ends of the old. In diseases where repair mechanisms are faulty, the body may be very sensitive to mutagens, such as in *xeroderma pigmentosum*, where the skin is easily damaged by ultraviolet light.



A small amount of DNA synthesis also accompanies the first meiotic prophase in gametogenesis (Stern and Hotta 1969), and this may be concerned with the exchange of genetic material between homologous chromosomes (p. 32).

The number of DNA threads within a single chromatid is not certain; the genetic evidence suggests one thread for each. After DNA synthesis the two chromonemata separate into the two distinct chromatids, so that each cell now possesses the tetraploid amount of DNA. At mitotic division (*vide infra*) the content in each cell is reduced to the diploid amount, to be doubled again in the following interphase.

It is interesting that wide variations of DNA content occur within the cells of different species of animal, even though closely related, suggesting that segments of DNA may be repeated many times. It is possible that in some cases many copies of each gene are present so that when activated, large-scale transcription can be initiated rapidly, as for example in the case of the nucleolar genes, of which there are multiple copies. Such a repetition of genes may also be a source of genetic variability.

NUCLEOLI

Each nucleus possesses a number of spheroidal nucleoli, dense bodies which take up basic dyes strongly; in man their number varies (one or several may occur), and collectively they are considered to consist of five pairs of nucleolar fragments related to particular chromosomes (*vide infra*). Nucleoli vary in size up to about 4 μm in diameter (**1**.28). Each nucleolus consists of a heterogeneous mass of fine granules and fibrils set in a less dense matrix, the whole agglomeration often containing cavities or

1.28 An electron micrograph of a nucleolus from a highly active cell, showing the pars filamentosa (f) enclosed in the darker pars granulosa (g). Magnification × 25,000.

channels continuous with the surrounding nucleoplasm, so that with the light microscope it may have the appearance of a folded thread (*nucleolonema*). With the electron microscope four structural elements can be detected: an inner region of dense filaments (*pars filamentosa*), an outer granular zone (*pars granulosa*), both of the former embedded in an apparently structureless matrix, the *pars amorpha*, whilst centrally is a series of somewhat less dense elongate DNA-rich regions, constituting the *pars chromosoma* (*see* Noel *et al.* 1971). These various parts can be correlated with the synthetic pathway of ribosomal RNA which is transcribed on the nucleolar organizing genes of certain chromosomes, situated in the pars chromosoma. The ribosomal RNA when first made is exceptionally long, forming the basis of the fibrils in the pars filamentosa, but is later broken into fragments, probably to form the pars granulosa, from which point the final ribosomal RNA passes to the cytoplasm through the nuclear pores. A considerable amount of phosphoprotein is also present in the nucleolus, together with various enzymes, and these may, at least in part, form the pars amorpha.

In man, *nucleolar organizing centres* are thought to be present on those chromosomes with *secondary constrictions*, and within a single nucleolus several such centres may be active. In some lower vertebrates there are large numbers of such organizing regions, and in oöcytes, hundreds of nucleoli are formed; regions of such chromosomes synthesizing nucleolar RNA form lateral loops giving the whole chromosome a bristly appearance (*lampbrush chromosomes*) and these, under the electron microscope, are seen to be festooned with RNA strands in the process of being transcribed (Mott and Callan 1975). As might be expected, cells with a high rate of protein synthesis and thus a large demand for ribosomes, have large nucleoli, for example, large neurons with extensive complex arborizations of neurites, active embryonic cells, and the cells of malignant neoplasms.

During cell division, when protein synthesis is suspended, the nucleoli disintegrate and their chromosomal portions are drawn back into the main mass of their parent chromosomes; at the end of cell division the nucleoli are rapidly reformed.

OTHER NUCLEAR INCLUSIONS

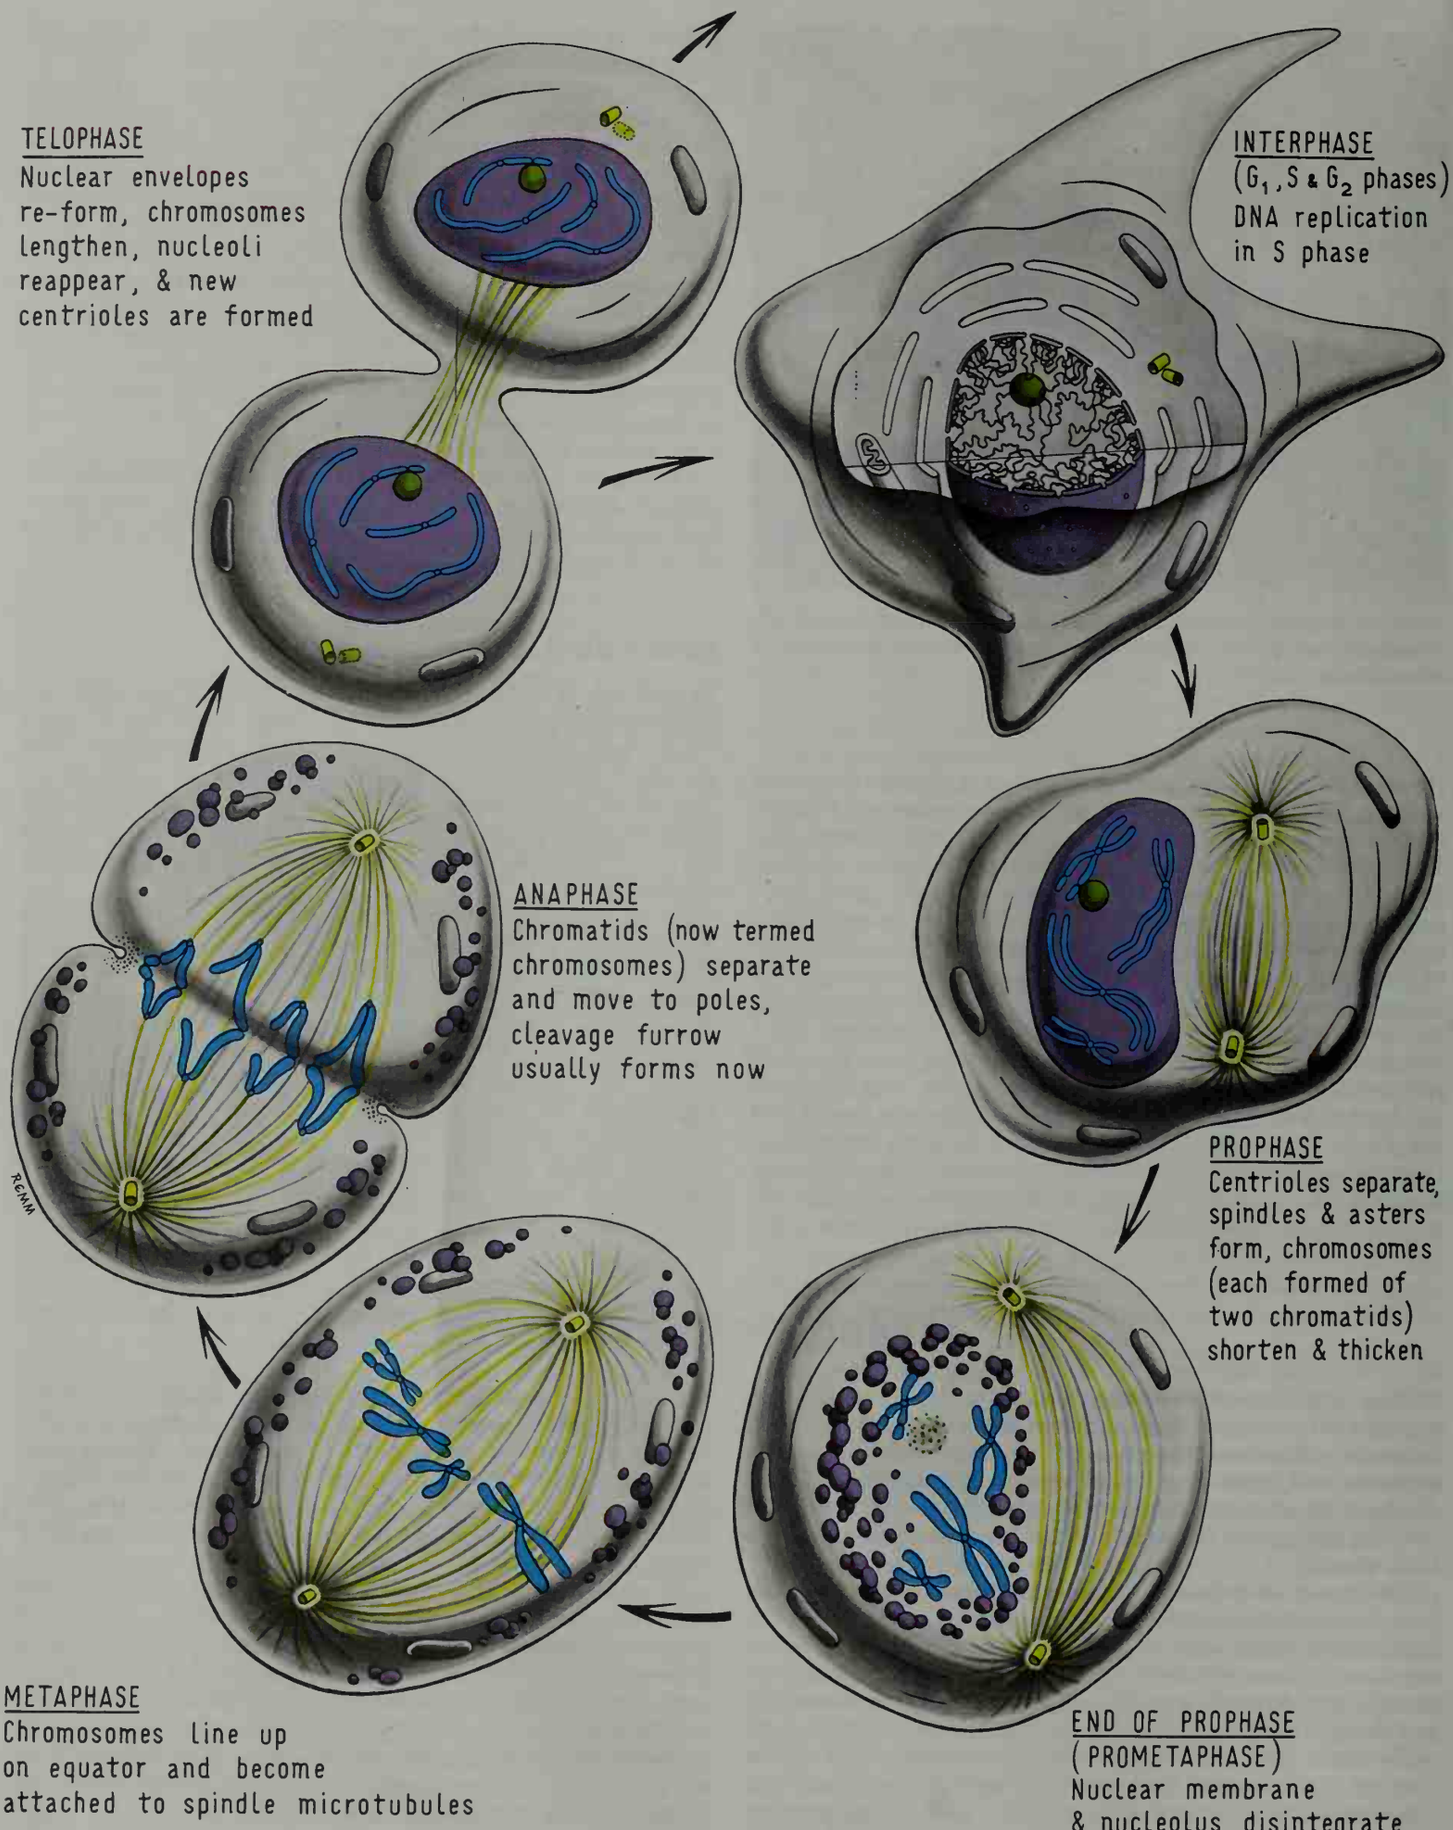
In addition to chromosomes and nucleoli, there are other less prominent structures present in all nuclei (Wischnitzer 1973). These include *granules*, some of which are associated with chromatin margins (*perichromatin granules*), about 40 nm across, and others lying between the chromatin masses (*interchromatin granules*) about 20 nm across, the significance of both types being obscure. *Perichromatin fibres* are also present at the margins of the chromatin.

In the prophase of the first meiotic division, long, fibrillar *synaptinemal complexes* form connexions between adjacent chromosomes (p. 32). Various other structures which have been reported in different types of cell include membranous vesicles and lamellae, bundles of filaments, crystals and further varieties of granule. Some of these may represent symbiotic C viruses which are common inhabitants of mammalian nuclei. The functions of the other inclusions are obscure. The nucleoplasm also contains numerous enzymes, nucleotide precursors and proteins which can only be demonstrated by cytochemical or biochemical means; these are, of course, involved in nuclear metabolism.

REPRODUCTION OF CELLS

During embryonic development most cells are undergoing repeated division as the body grows in size and complexity. As a particular cell matures it becomes differentiated with respect to its structure and function and may eventually lose the ability to divide, as do neurons, or it may persist as a stem cell capable of dividing throughout life, as do the blood-forming elements of the bone marrow.

The rate of cell division varies considerably in different tissues; in many epithelia subject to mechanical wear and tear, the replacement of damaged cells by division of stem cells may be rapid, as in the crypts between intestinal villi; it may also vary according to demand, as in healing of wounded skin, where cell proliferation rises to a peak and then drops again to the normal cell replacement level. The rate of cell division is therefore tightly coupled to the demand for growth and replacement; where this coupling is faulty, the tissues either fail to grow or replace their cells, or else they overgrow, giving rise to neoplasms.

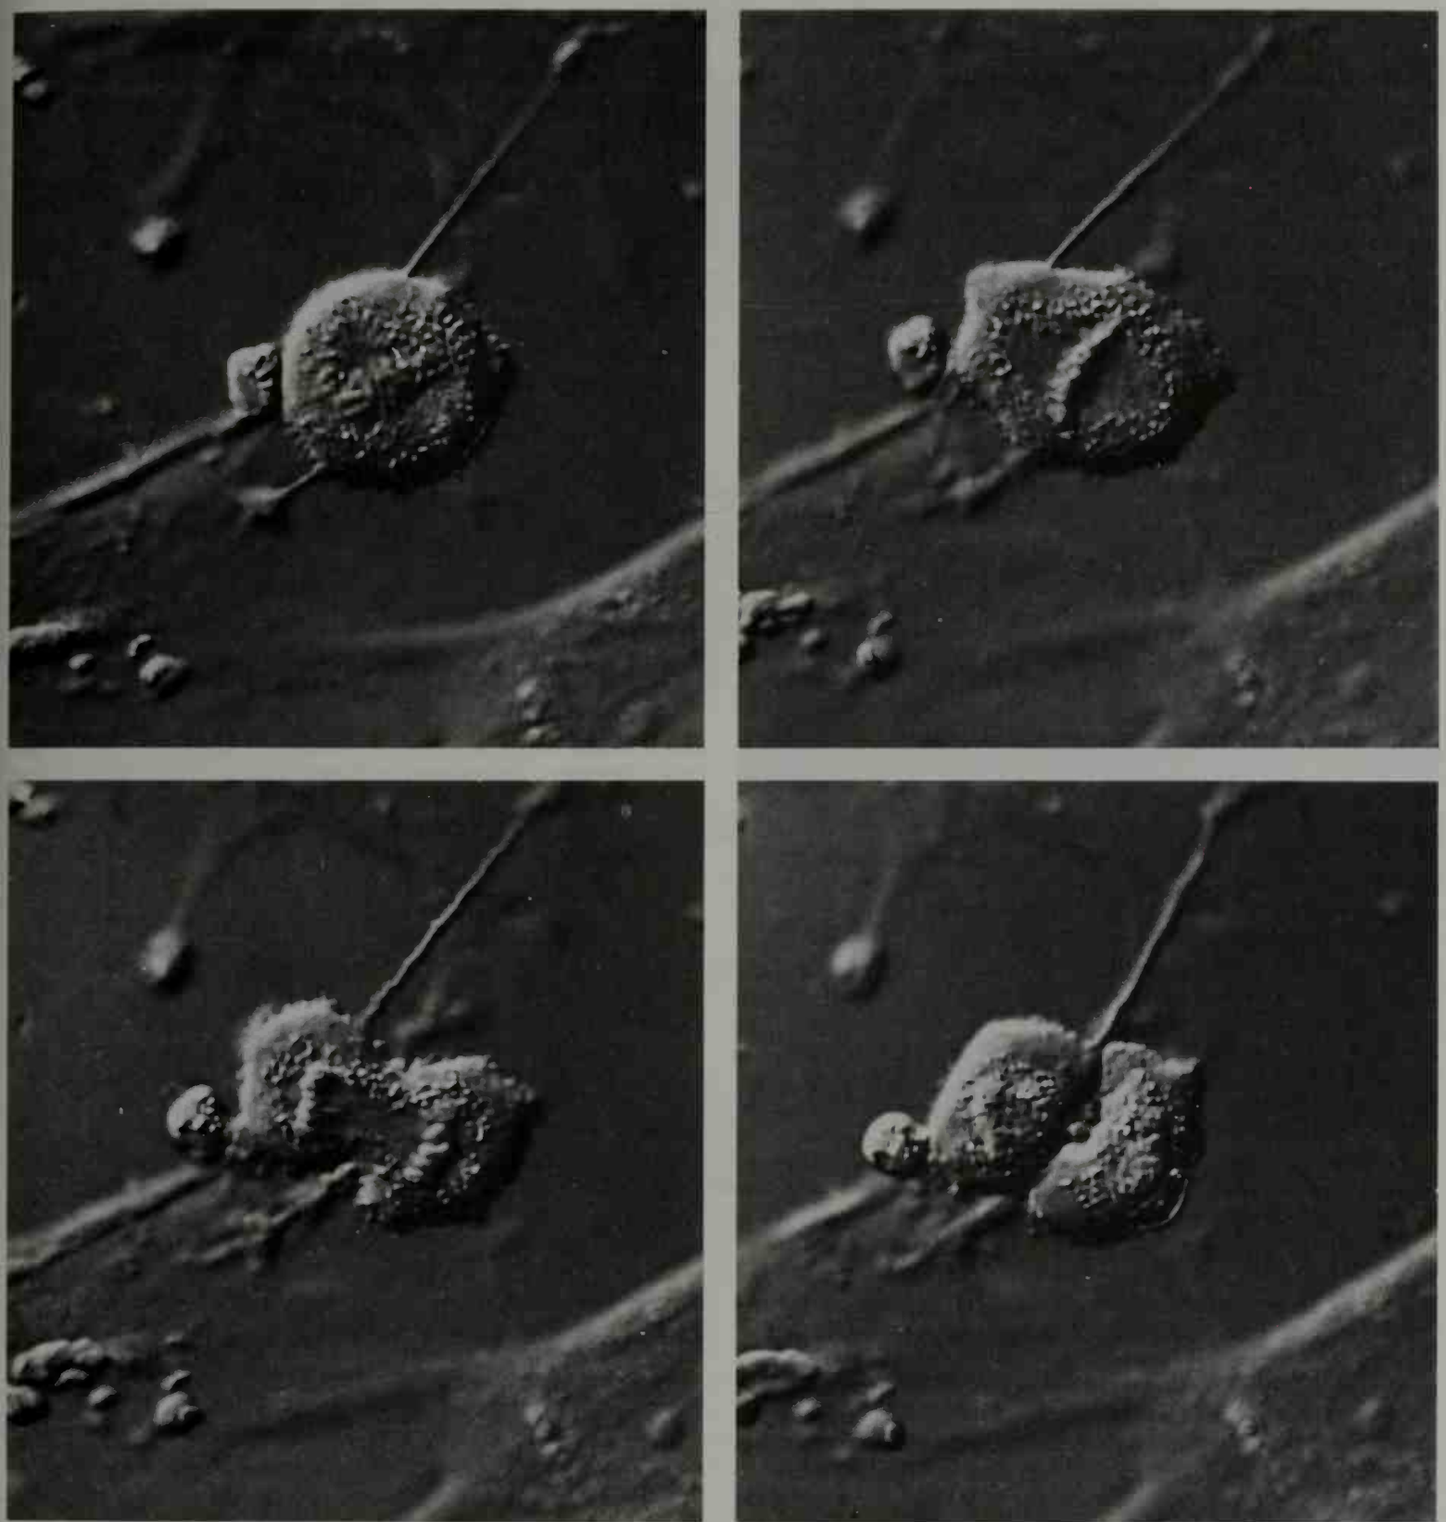


The mechanism of normal control is poorly understood. During the earlier phases of embryonic life, the control appears to be local, involving the diffusion of metabolites from one cell group to another, so stimulating or inhibiting the division of cells. At later stages, general hormonal control is also involved. Several hormones are known to affect cell division rates either throughout the body (e.g. somatotrophic hormone), or of local regions (e.g. progesterone), although the precise mechanism of these effects is not fully understood. Some hormones may act on cell division indirectly by affecting general metabolic rates (thyroid hormones) or protein synthesis (some corticosteroids and somatotrophic hormone). At least some of these effects may be mediated by the release within the cell of cyclic adenosine monophosphate (cyclic AMP) which inhibits the synthesis of new DNA during the S phase.

In adult tissues, local control of cell division is an important factor in such phenomena as wound healing. A class of compounds termed *chalones*, which inhibit cell division, has been isolated from normal tissue cells (see also pp. 78–81). A possible model for their action is that normal cells produce chalones which inhibit division of the cells in their locality; when some cells are damaged or destroyed, the concentration of chalones drops allowing cell division to occur, until the normal levels are restored, when division is again inhibited.

The Mechanism of Cell Division

Two distinct events occur in cell division, the division of the nucleus (*karyokinesis*) and that of the cytoplasm (*cytokinesis*); they are usually, but not always, coupled.



Nuclear division can be achieved in three ways; in the first, termed *amitotic* or *direct division*, nuclear material is randomly distributed to the resultant cells. This process, once thought to be common, is now known to be restricted to pathological

1.29 A diagram of the main stages of the mitotic cycle of a somatic cell.

conditions; in the other two types of nuclear division, complex chromosomal manoeuvres take place (*indirect division*).

Mitotic division (1.29) occurs in most somatic cells and results in the distribution of identical copies of the parent cell's genome to the resulting cells. In *meiosis*, which occurs in the divisions immediately preceding the production of gametes in the gonads, the number of chromosomes is halved to the haploid number, so that when fertilization takes place the diploid number is restored; some exchange of genetic material also occurs between homologous chromosomes so that a *reassortment* of genes takes place (*see*, for example, Lewis and John 1970; Whitehouse 1973; White 1973). This leads to a wide range of genetic variability in a

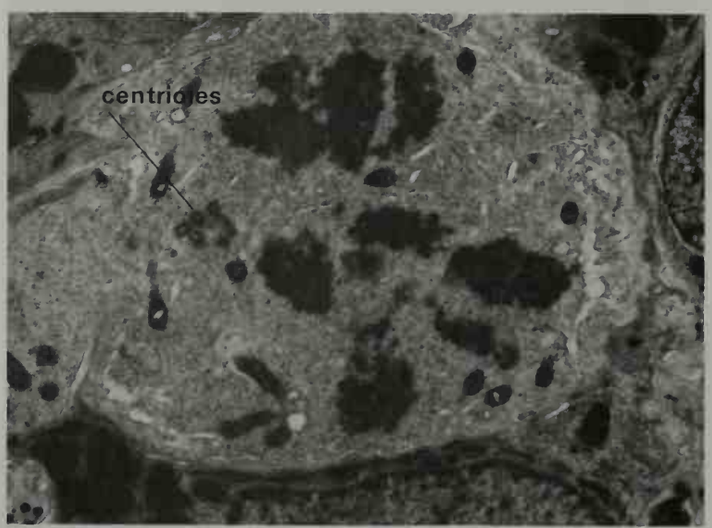
population, which is of great evolutionary advantage (see also p. 30).

Mitosis and meiosis resemble each other in many respects, differing chiefly in the behaviour of the chromosomes during early stages of cell division; meiosis is also considered to comprise two divisions in quick succession, the first of them, unlike mitosis (*meiosis I, heterotypical* division), the second, being more like mitosis (*meiosis II, homotypical* division).

Mitosis

As already stated, new DNA is synthesized during the S phase of interphase, so that in normal diploid cells the *amount* of DNA has doubled by the onset of mitosis to the tetraploid DNA value, although the chromosome *number* is still diploid. During mitosis, this amount is distributed equally between the two resulting cells, so that DNA quantity and chromosome number are now diploid in both. The nuclear changes which achieve this distribution are divided for descriptive purposes into four phases: prophase, metaphase, anaphase and telophase, (1.29, 30, 31).

Prophase



The strands of chromatin, which before mitosis are highly extended, begin to shorten, thicken, and resolve themselves into recognizable chromosomes, each made up of two chromatids joined at the centromere. Outside the nucleus the centrioles begin to separate and move apart, one to each pole of the cell; parallel

microtubules are synthesized between them to create the *central spindle*, and others radiate out from the centrioles to form the *astral rays*, collectively termed asters. The spindle and the two asters together constitute the *achromatic figure*, or *diaster* (amphiaster).

Towards the end of prophase, the nucleoli disintegrate and disappear. The termination of prophase is marked by a sudden breakdown of the nuclear envelope to release the chromosomes. The membranes of the envelope disintegrate into small vesicles indistinguishable from those of the endoplasmic reticulum.

Metaphase

As the nuclear envelope disappears, the spindle microtubules invade the central region of the cell and the chromosomes move towards the equator of the spindle (a period known as *prometaphase*). Once they have arrived at this imaginary plane (the *metaphase* or *equatorial plate*) the chromosomes become attached by their centromeres to spindle microtubules and are so arranged in a star-like ring when viewed from either pole of the cell.

1.31 An electron micrograph of an epithelial cell in mitotic metaphase. The chromosomes are seen as blocks of dense material, and are sectioned approximately along the plane of the equator. Magnification × 10,000.

Anaphase

The centromere in metaphase is a double structure; it now separates into its two components, each carrying an attached chromatid, so that the original chromosome has, in effect, split into two new chromosomes. These move apart, one towards each pole of the cell. The mechanism of this movement is not yet understood, but it is known that the spindle microtubules are necessary for movement to occur. It has been suggested that the two halves of each centromere become attached to separate categories of microtubules, one from each pole of the cell (McIntosh *et al.* 1969). These microtubules would then move towards their respective poles, possibly by sliding interaction with other microtubules, pulling the new chromosomes along with them. Alternatively it has been proposed that the progressive disintegration and reassembly of microtubules might generate similar movements by addition of tubulin at the equator and removal at the poles (Inoué and Sato 1967).

Telophase

As a result of the events in anaphase the chromosomes become grouped at each end of the cell, both groups being diploid in number. The chromosomes now re-extend, and the nuclear envelope reappears, beginning as a series of membranous vesicles on the end surfaces of the chromosomes. The nucleoli also reappear.

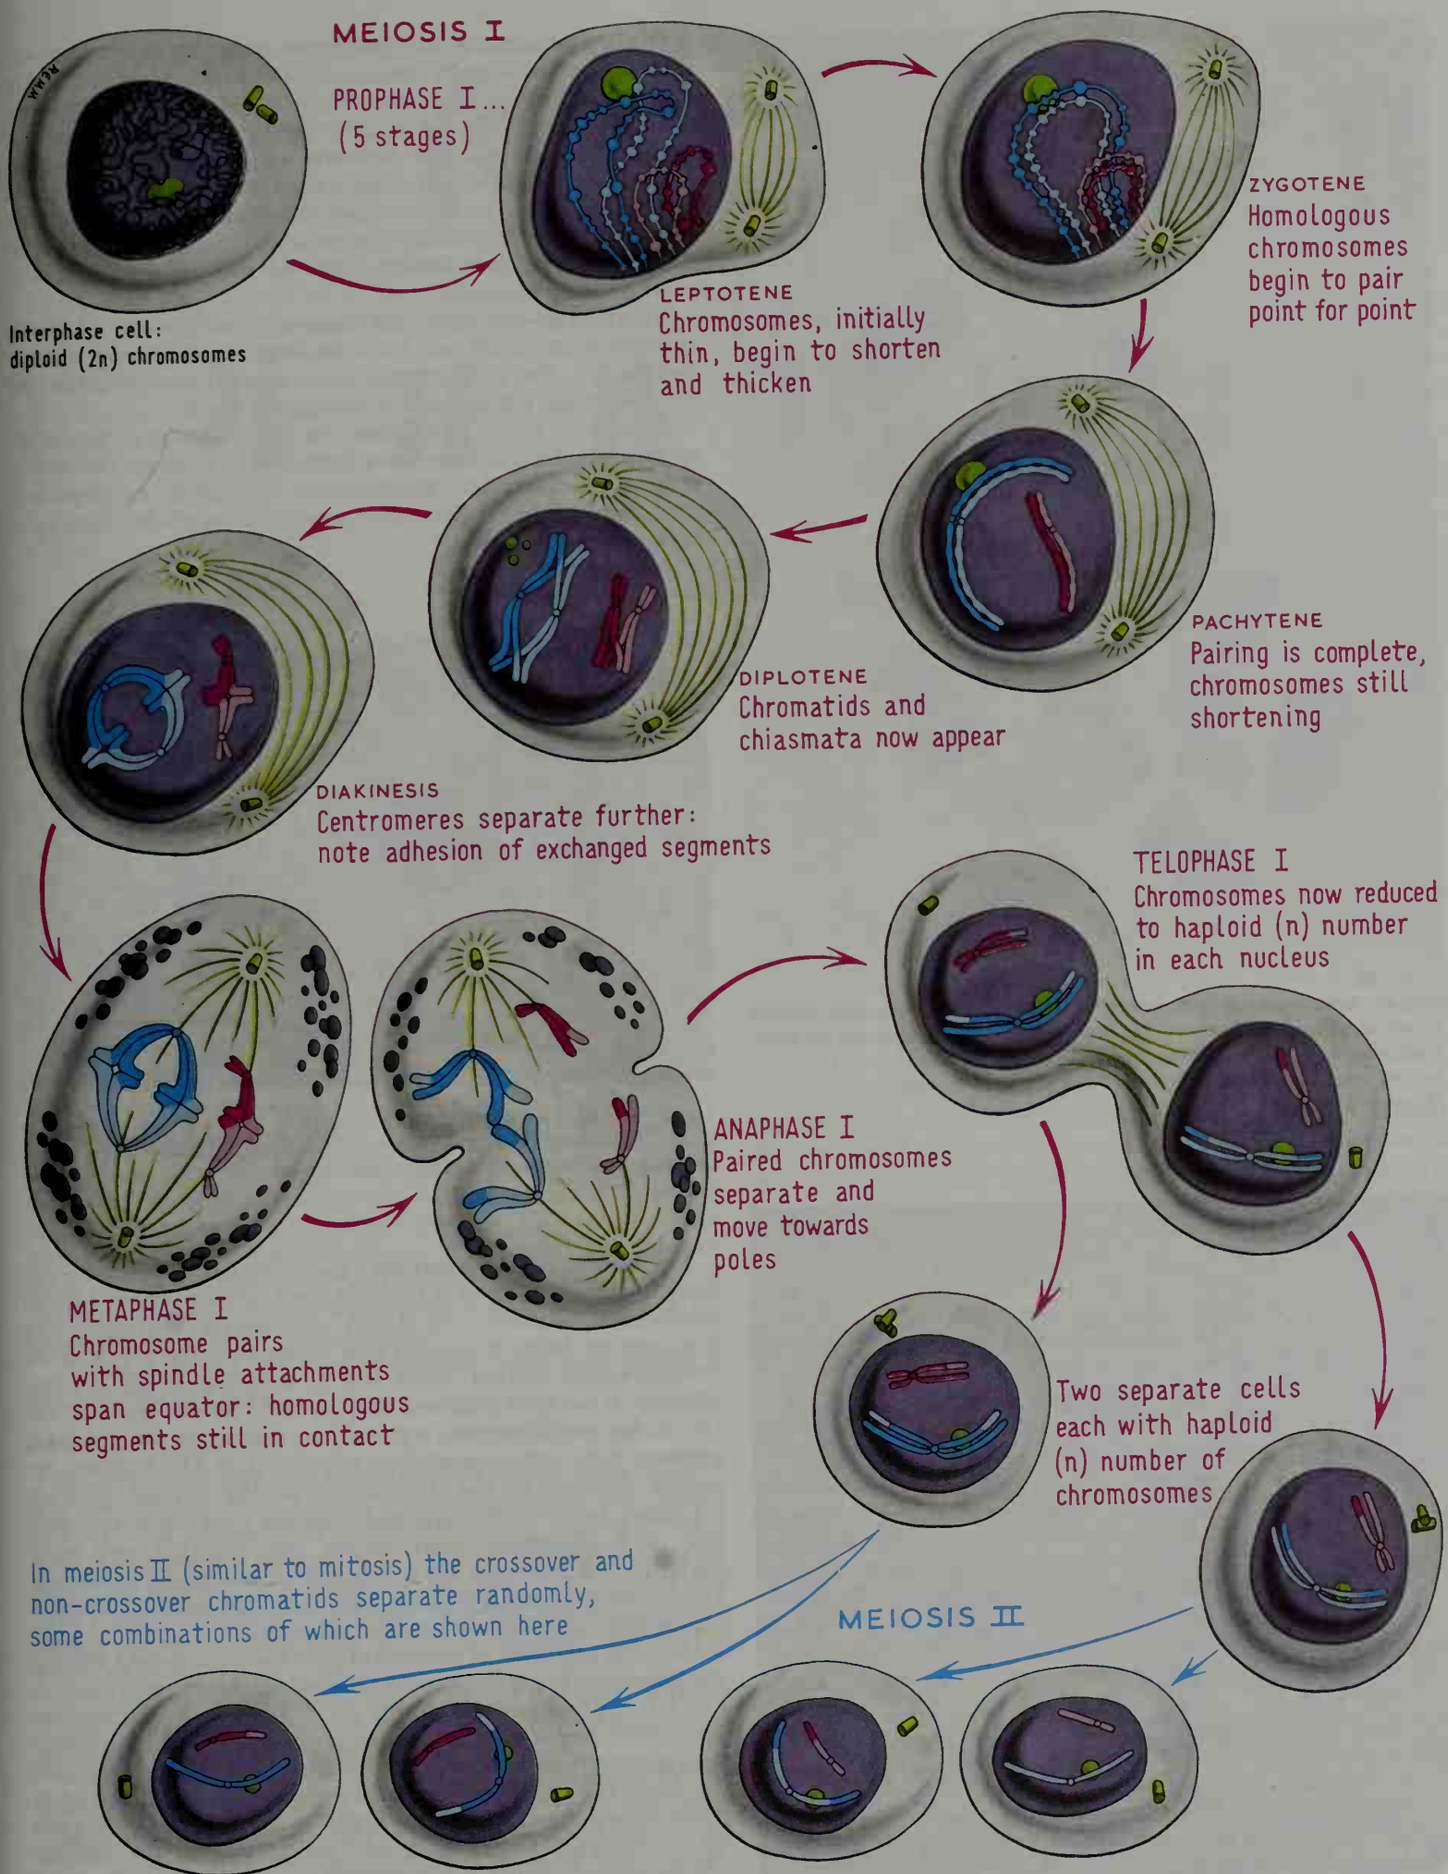
Meanwhile, cytoplasmic division, which usually begins in early anaphase, is well started. This process is signalled at late metaphase by cytoplasmic movements involving the equal distribution of mitochondria and other organelles around the cell periphery. In anaphase an infolding of the cell equator begins and deepens as the *cleavage furrow* (Szollosi 1970). Small vacuoles form in the cytoplasm along the plane of cleavage, and eventually the furrow constricts the cell into two. Where the constriction meets the remains of the spindle a dense region of cytoplasm, the *mid-body*, is visible, but eventually the two new cells separate, each with its derived nucleus. The spindle remnant now disintegrates. When the cleavage furrow is active, a peripheral band of microfilaments has been observed in the constricting zone in some species; the contraction of this band is probably responsible for furrow formation. During telophase the filaments of the cleavage furrow eventually contract down on the remaining spindle microtubules to form the dense mid-body, which finally disappears, presumably by de-polymerization of its actin and tubulin constituents.

Failure of *disjunction* and '*lagging*' of chromatids may sometimes occur, so that two paired chromatids pass to the same pole. Of the two new cells, one will have more, and the other less, chromosomes than the diploid number. Exposure to ionizing radiation enhances the frequency of such events, and may, because of chromosomal damage, inhibit mitosis altogether. A typical symptom of *radiation sickness* is the failure of epithelia to replace lost cells, with consequent ulceration of the skin and mucous membranes.

Mitosis can also be disrupted by several chemical agents, particularly colchicine and its derivatives colcemide, podophyllin and podophyllotoxin, and by viniblastine. These compounds act by inhibiting or reversing spindle microtubule formation, so that mitosis is arrested in metaphase. This phenomenon is of great value in cytogenetic studies, since chromosomes are most easily examined in the metaphase condition.

Meiosis

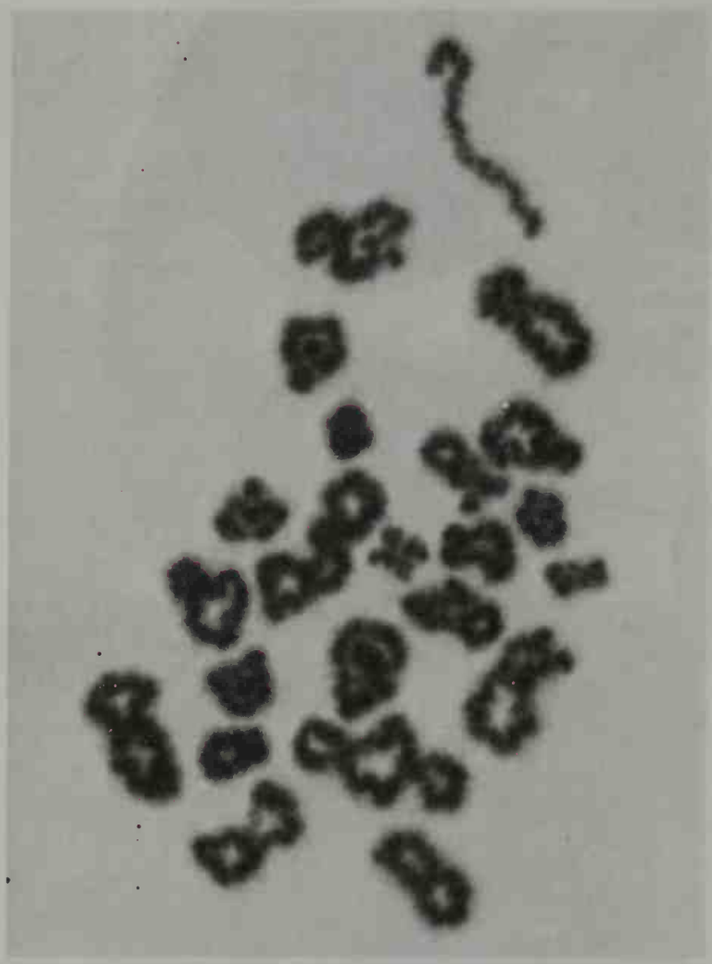
During meiosis (1.32, 33A, B) there are two cell divisions (*see* Whitehouse 1973): in the interphase prior to the first division, DNA is replicated in the usual manner, resulting in the tetraploid amount of DNA, the number of chromosomes being diploid. During *meiosis I* the DNA is reduced to the diploid *amount* in each resultant cell, although the chromosome *number* is halved to the haploid value; in *meiosis II*, the DNA in each new cell formed is reduced to the haploid amount, the chromosome number remaining haploid.



Prophase I

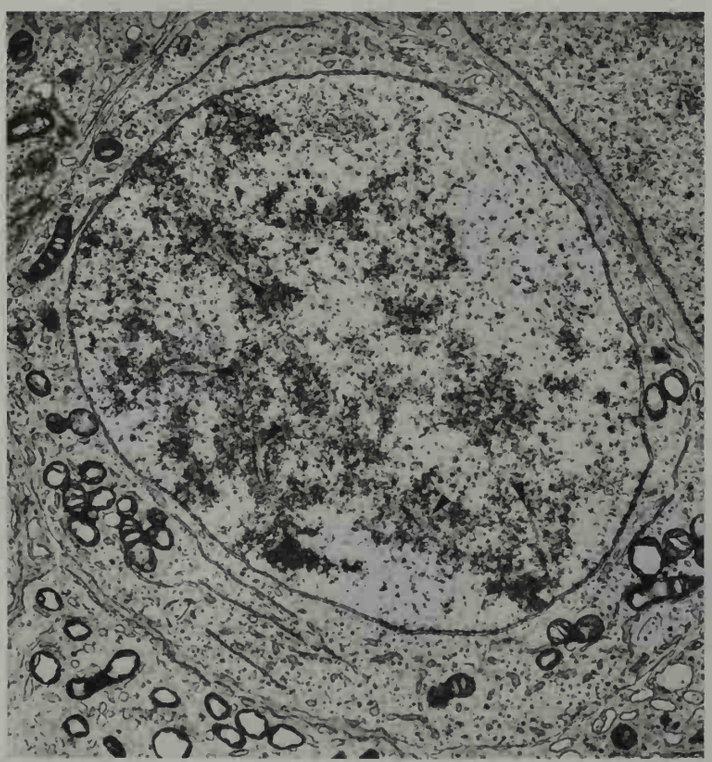
This is a long and complex phase differing considerably from mitotic prophase. It is customarily divided into five, the leptotene, zygotene, pachytene, and diplotene stages and diakinesis (for details of structural changes *see* Comings and Okada 1972; Moens 1974; John 1976).

Leptotene stage—the chromosomes become visible as individual threads attached at one end to the nuclear envelope, and show characteristic beads (*chromomeres*) throughout their length.



Zygotene stage—the chromosomes are seen to have come together side by side in homologous pairs, a process which may already have occurred as early as the telophase of the previous mitotic division. The homologous chromosomes pair point for point progressively, beginning at the attachment point to the nuclear envelope (Moens 1974), so that corresponding regions lie in contact. This process is *synapsis*, *conjugation*, or *pairing*. Each chromosome pair is now termed a *bivalent*. In the case of the unequal X and Y sex chromosomes which during zygotene and pachytene are sequestered in a secluded zone of the nucleus, the *sex vesicle* (Solari and Tres 1967), only limited segments (the *pairing segments*) are homologous and these pair end to end (1.33); the remaining parts are *differential segments*. With the electron microscope, homologous chromosomes are seen to be held together by a highly structured fibrillar band, the *synaptinemal complex* (1.33C), which occupies the space (about 100 nm wide) between them (Gillies 1973).

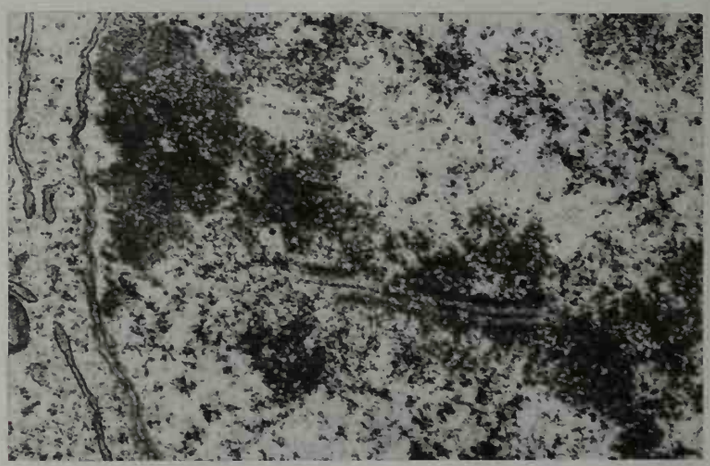
Pachytene stage—spiralized shortening and thickening of



1.32 Chief stages in the meiotic cycle (male). For clarity only four chromosomes out of the total 46 are shown.

each chromosome continues progressively, and each is now seen to be formed of two chromatids joined at the centromere. Each bivalent pair therefore consists of four chromatids and is called a *tetrad*. During this stage, two chromatids, one from each bivalent chromosome, become partially coiled around each other. Also during this stage it is probable that exchange of DNA (*crossing over* or *decussation*) by breaking and rejoining occurs, perhaps facilitated by the synaptinemal complex.

1.33A A photomicrograph of chromosomes from a human spermatocyte in late prophase (diakinesis) of the first meiotic division showing bivalents beginning to separate. Note the paired sex chromosomes which are joined end to end. Kindly provided by the Paediatric Research Unit, Guy's Hospital Medical School.

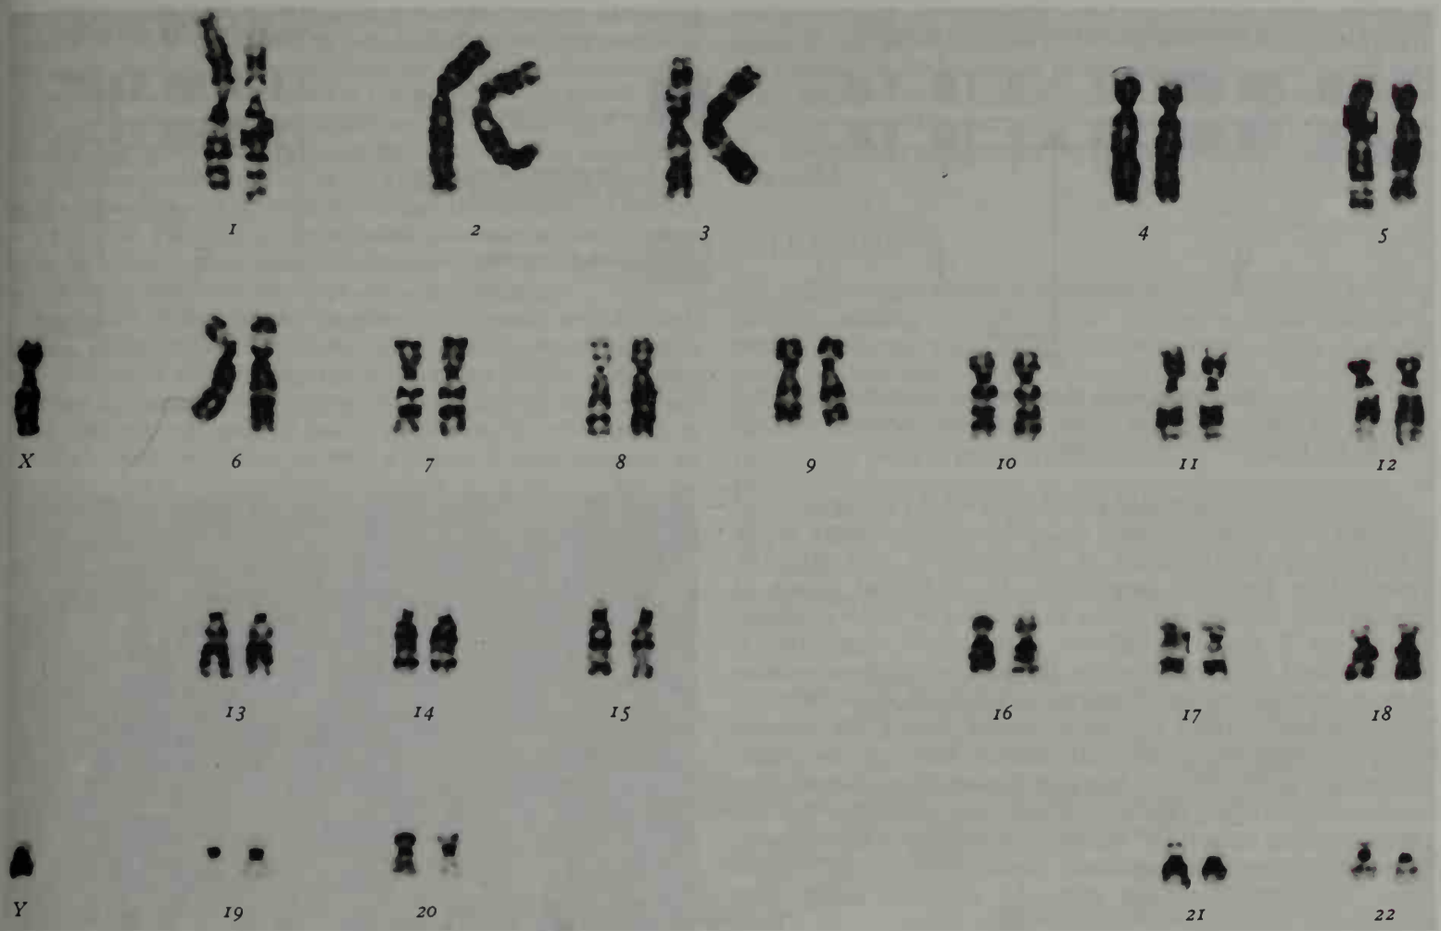


1.33B Electron micrograph of a primary spermatocyte (mouse) showing the nucleus in early prophase of the first meiotic division. Five synaptinemal complexes are visible (arrowheads). Magnification × 10,000.

Diplotene stage—the homologous pairs, by this time much shortened, move slightly apart except at the points where crossing over has occurred (*chiasmata*). Sometimes, the chiasmata move towards the ends of the chromatids (*terminalization*); normally at least one chiasma forms between each pair of homologous chromosomes, and up to five have been observed (even up to ten in some species). In human meiosis, primary oöcytes become diplotene by the fifth month *in utero*, and remain in this state until the period prior to ovulation (some for decades, and even fifty years, in some instances).

Diakinesis—the remaining chiasmata finally resolve, and the chromosomes, which still form bivalents, become even shorter and thicker. The bivalent pairs move away from each other and become spread out against the nuclear envelope.

During the events of prophase the nucleoli have disappeared, and the spindle and asters have formed as in mitosis. The end of prophase is marked by dissolution of the nuclear envelope and movement of the bivalent chromosomes towards the equatorial plate (*prometaphase*).



1.33C Detail of a synaptinemal complex in a cell similar to that shown in B. Note the masses of heterochromatin, and the fibrillar core of the synaptinemal complex. Magnification × 20,000.

Mechanism of decussation—the exchange of genes between homologous chromosomes involves some extraordinarily precise mechanism whereby the DNA, at exactly corresponding positions on both, is severed and rejoined to the DNA of its corresponding partner. How this is achieved is not certain, although it has been proposed that the DNA double chains of the two exchanging chromatid segments are exchanged one at a time, perhaps with some remodelling of redundant DNA chains by partial dissolution and resynthesis in the correct position (Holliday 1964; Whitehouse and Hastings 1965). It is probable that such exchanges occur during late zygotene and early pachytene (Whitehouse 1973), when there is a certain amount of DNA synthesis, and it is likely that the synaptinemal complex is an important mediator of genetic exchange.

Once the segments of chromatid have been exchanged and the chromosomes begin to separate, the regions where crossing over has taken place become visible as *chiasmata*; these therefore represent a *past event* and chiasma formation is *not* synonymous with genetic recombination. It is interesting that after diakinesis the paired chromatids of a given chromosome adhere to each other more strongly than to those of homologous chromosomes, even when exchange has taken place, giving rise to the curious configurations which chromosomes adopt in metaphase of meiosis I (1.32).

Metaphase I

This is similar to that of mitosis except that the bodies attaching to the spindle microtubules are bivalent and not single chromosomes. These become arranged so that the homologous pairs lie parallel to the equatorial plate with one member on either side.

1.34 The human male karyotype prepared from a metaphase chromosome spread, stained by the Giemsa banding technique, to demonstrate the pattern of dye-binding used to characterize different chromosomes. The autosomes are shown on the right, and the sex chromosomes on the left. The numbering is that agreed by the Paris Convention (*see* text). Kindly provided by the Paediatric Research Unit, Guy's Hospital Medical School.

Anaphase and Telophase I

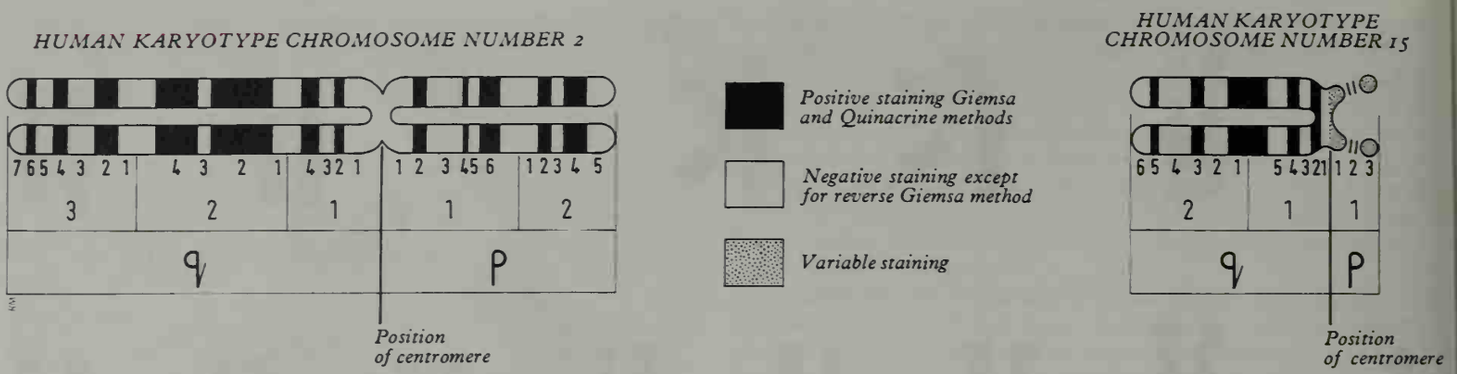
These also occur as in mitosis, with the exception that in anaphase, the centromeres do not split; thus, instead of the paired chromatids separating to move towards the poles, whole homologous chromosomes made up of two joined chromatids depart to opposite poles. Since positioning of bivalent pairs is random, there is a random assortment of maternal and paternal chromosomes in each telophase nucleus.

During meiosis I, cytoplasmic division occurs as in mitosis to produce two new cells.

Meiosis II

This commences after only a short interval during which no DNA synthesis occurs. This second meiotic division is more like a mitosis, with separation of chromatids during anaphase; but it should be noted that unlike mitosis, the separating chromatids are dissimilar genetically. Cytoplasmic division also proceeds and thus a total of *four* cells results from meiosis I and II. (However, during spermatogenesis there was some evidence that further divisions occur, but *see* p. 96.)

If cytoplasmic division fails during meiosis I, gametes with the diploid number of chromosomes result, and thus give, at fertilization, a triploid zygote.



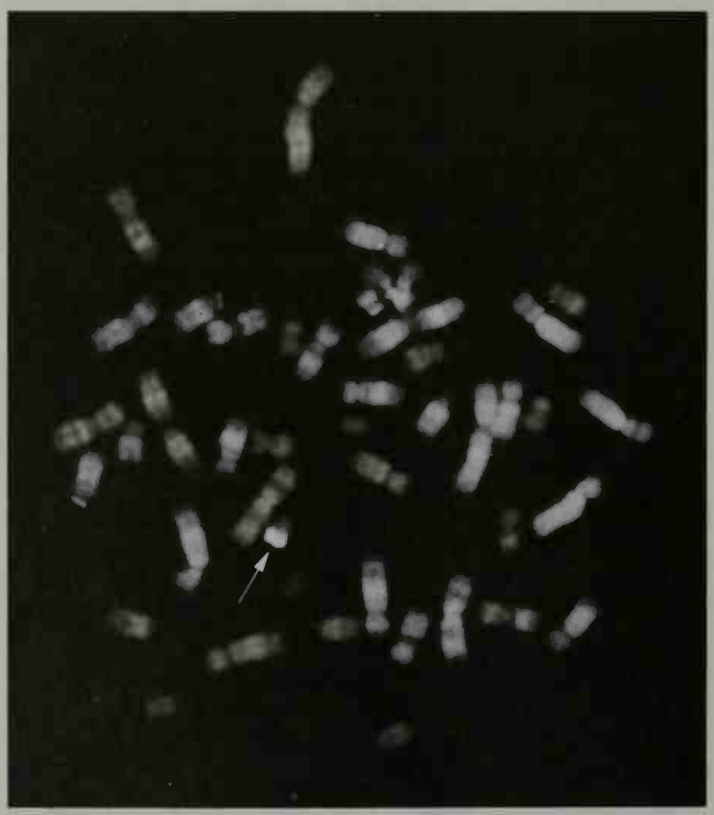
Other abnormalities, some of them viable, are produced by *non-disjunction* of chromosomes, or by the *lagging* of individual chromosomes, during anaphase. These will be discussed later (p. 136). There is much evidence that with increasing maternal age, there is an increased frequency of such abnormalities.

CLASSIFICATION OF HUMAN CHROMOSOMES

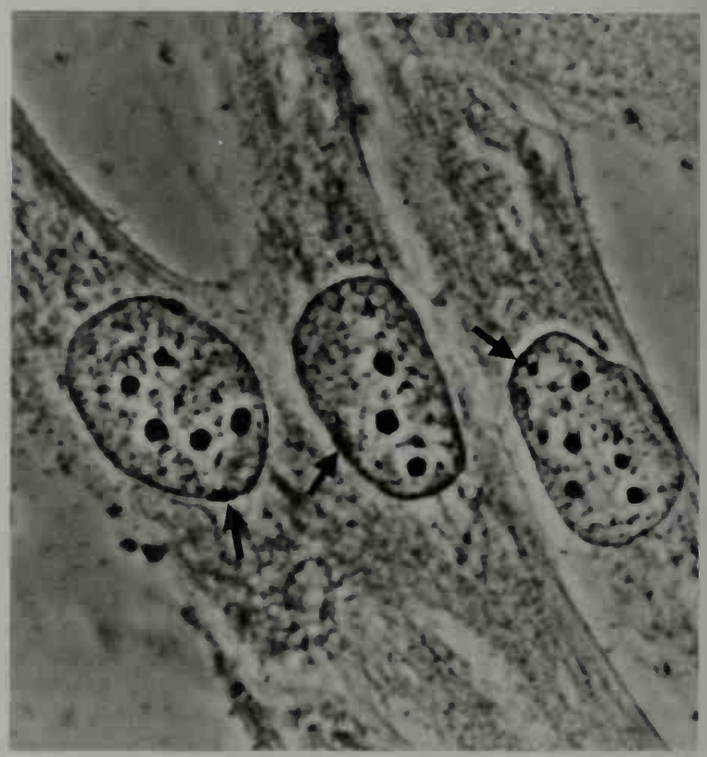
Since a number of genetic abnormalities can be directly related to the chromosomal pattern, the characterization or *karyotyping* of chromosomes is of considerable diagnostic importance. Their identifying features are best seen during metaphase.

Living cells taken from blood samples, nasal swabs or other sources, can be cultured *in vitro* and caused to divide by treatment with mitotic stimulators such as phytohaemagglutinin. Mitosis is later interrupted at metaphase with spindle inhibitors (*see* p. 16), and the chromosomes are then dispersed by swelling the cells in hypotonic solutions followed by air drying, or squashing, to rupture the cells and flatten the chromosomes. These can then be treated by a variety of staining procedures to allow the identification of individual chromosomes by their size, shape, and overall distribution of stain. Methods of staining include *general techniques* to show the obvious landmarks, for example, length of arms, position of primary and secondary constrictions; and various *banding techniques* to demonstrate differential patterns of binding of the dye, which is characteristic for each chromosome type (1.34, 35). Since the invention and introduction of the original banding methods (Caspersson *et al.* 1968), several further procedures have been developed (*see* Caspersson and Zech 1973) such as fluorescence staining with quinacrine mustard and related compounds (1.36A), Giemsa staining after treatment with alkali, 'reverse-Giemsa' staining in which the light and dark areas are reversed, and the staining of constitutive heterochromatin (C-banding; see also p. 34).

Using these different methods, chromosomes can be classified according to their overall length, positions of primary and secondary constrictions, presence of satellites, the number and positions of the transverse bands, and the distribution of constitutive heterochromatin. A standard system of numbering the autosomal pairs of chromosomes in order of decreasing size, from 1 to 22, is adopted according to the conventions agreed in London (1960) and Chicago (1964). Before the introduction of banding, some chromosome types could not be easily distinguished from each other, and thus were grouped together. However, the more recent methods allow unambiguous identification, and a full system of classification agreed in Paris (1972) is now employed.



1.35 Diagram of the nomenclature of the banding patterns in two human chromosome types, designated by the Paris Convention, for different staining techniques (for details *see* text).



These advances have also greatly helped the recognition of *abnormal chromosome patterns*, since the origins of extra whole chromosomes, or fragments of chromosomes, can often be identified in abnormal karyotypes. An additional means of identification exploits variations in the *time* of DNA synthesis during the S phase in different chromosome types; this is demonstrated by pulse-labelling the replicating chromosomes with ^{3}H-thymidine at specific times during the S phase, followed by autoradiography of the chromosomes during the ensuing metaphase (Gianelli 1970). Alternatively they can be pulse-labelled in a similar manner but with the analogue of thymidine, bromo-deoxyuridine (BrDU), which has different staining properties from normal DNA (Pain *et al.* 1976). For example, the inactive X-chromosome replicates particularly late (p. 26), and extra X-chromosomes can easily be detected using these techniques.

Sex Chromatin

Interestingly, it was observed some years ago that the nuclei of female mammals are structurally different from those of males, in that a heterochromatic body is usually seen close against the nuclear envelope in females (1.36B). This body, the *sex chromatin* or *Barr body* (Barr and Bertram 1949), may form a protrusion (drumstick) from the surface of polymorphic nuclei. It is now thought to be one of the X chromosomes which is synthetically inert, and thus heterochromatic, its euchromatic partner carrying out all necessary synthetic functions (Lyon 1962). The inert X chromosome also replicates later during interphase than its homologue.

1.36A A chromosome spread from a normal human male cell, treated with a fluorescent dye (see text) and photographed using fluorescence microscopy. In addition to the terminal fluorescence of the long arm of the Y chromosome (arrow), bands which fluoresce less strongly are also present on the other chromosomes, providing a basis for their identification. 1.36B Fibroblasts from a human female in tissue culture, showing dense heterochromatic Barr bodies (arrows) lying close against the nuclear envelope. Kindly provided by the Paediatric Research Unit, Guy's Hospital Medical School. Magnification × 2,000.

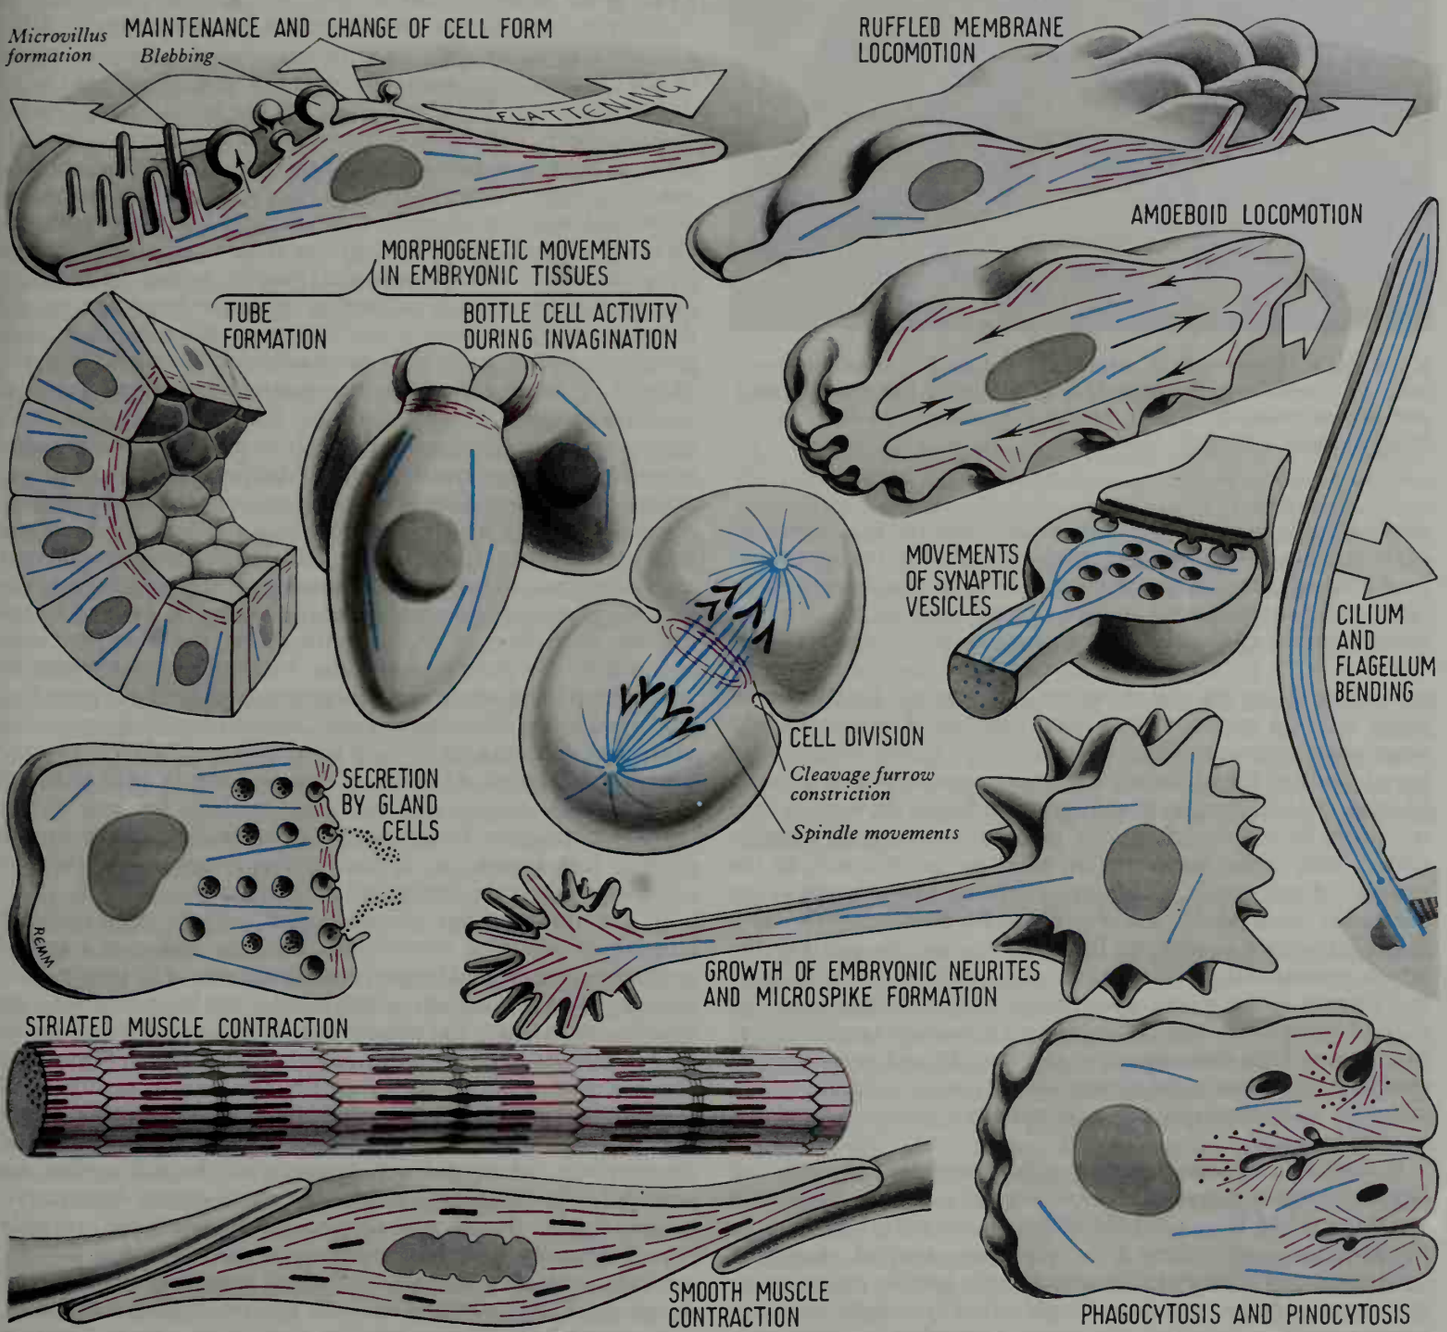
Chromosome Abnormalities

As already stated, aberrations in mitotic and meiotic cell divisions result in chromosomal abnormalities. Extreme examples such as the formation of more than the doublet (diploid) set of chromosomes to form *polyploid genomes* (triploid, tetraploid, octoploid, etc.) are found in some organisms, but are lethal in advanced animal forms.

Failure in the equal segregation of chromosomes in anaphase can result in either more or less than the full number. If this takes place in germ cell development, the resulting offspring will also possess an altered number, either of autosomes or of sex chromosomes.

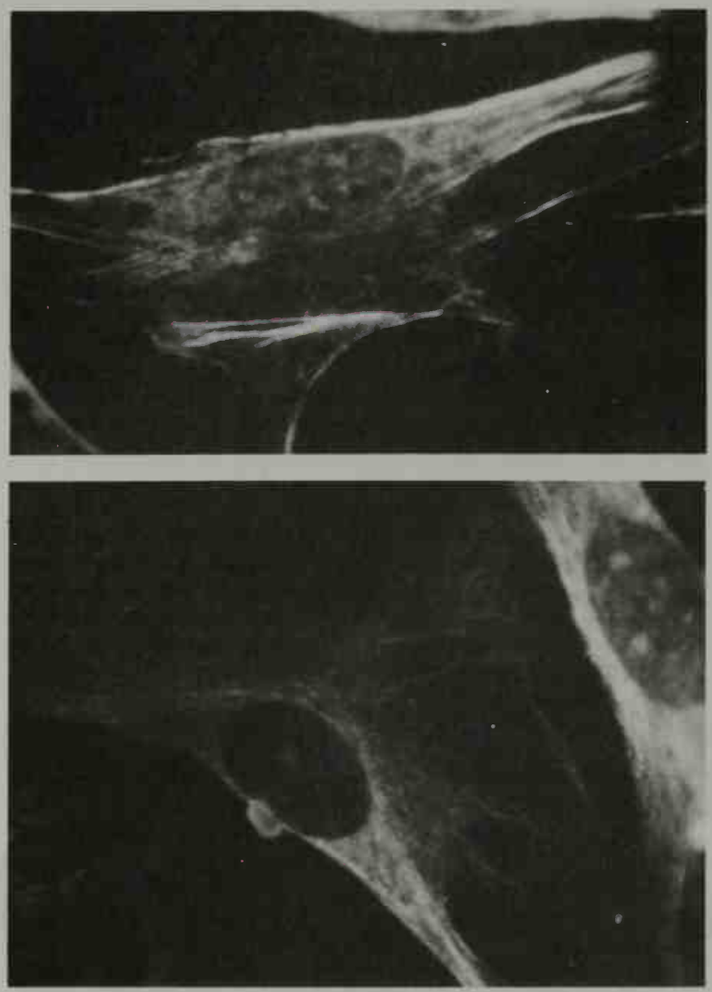
Where, instead of a homologous pair, three chromosomes are

present (*trisomy*), the additional chromosome may be identified by a variety of accessory techniques, including banding methods; the same applies to the presence of unpaired chromosomes (*monosomy*), where the number is reduced.



In mongolism, in which there are 47 chromosomes in the somatic cells, the additional number is one of the smallest of the set, known to be number 21. In a few cases of mongolism, the extra chromosome is attached to another chromosome of the set, as a result of a structural chromosome anomaly termed a *translocation*. Other abnormalities of chromosome structure include *ring forms* in which the two ends are joined together.

Anomalies of the sex chromosome complement are also well known. In the trisomy of Klinefelter's syndrome the cell contains an additional X chromosome (44 autosomes + XXY); these cases are male in character (phenotypically male), but the testes remain small, and spermatogenesis fails to occur. On the other hand, in Turner's syndrome there is only a single X chromosome (44 autosomes + XO); the subject is female in character, but the ovaries are rudimentary, and full oögenesis does not occur, although the embryonic ovary may appear normal with plentiful oögonia. Higher multiples of sex chromosomes (e.g. 44 autosomes + XXXXY), have also been described.



Chromosome abnormalities and triploidy, in man, are quite common (about 0·6 per cent of all conceptions), and occasionally are compatible with survival to birth. However, it is known that many instances of such abnormalities are lethal in embryonic life, thus accounting for their rarity among survivors at birth; 20–30 per cent of spontaneously aborted individuals are chromosomally abnormal.

CELL MOTILITY

All cells, except perhaps erythrocytes, exhibit some form of motility, ranging from the minute streaming of the cytoplasm, which is characteristic of all nucleated cells, to the powerful contractions of muscle cells. The types of motility vary widely; in most tissues there are constant modulations of cell shape and detailed surface topography, including the rounding of cells, particularly prior to mitosis, their flattening or elongation, e.g. in the developing neuroblasts of the neural tube, the formation of microvilli or of larger 'blebs' and pseudopodia at the cell surface (1.37). Such changes in shape are prominent in embryonic development and, later, in the repair of damaged tissues; many morphogenetic movements of cell layers are a result of the

1.37 A diagram summarizing some major examples of cell motility associated with actin filaments (red) and microtubules (blue).

1.38A and B Fibroblasts in tissue culture stained by immunofluorescence techniques to demonstrate the distribution of: (A) actin filaments, and (B) microtubules. Kindly provided by Dr. L. Mallucci (Guy's Hospital Medical School).

combined alteration of their constituent cells (p. 86). Examples of the latter are—the rolling up of the neural tube, brought about by the transformation of approximately parallel-sided columnar cells of the neural plate into wedge-shaped elements (2.5), and the formation of cup-like depressions by the apical contraction of 'bottle cells' (1.37). Changes of cellular shape associated with the movement of the internal cytoplasm occur in the locomotion of many cells. In amoeboid movement, typical of neutrophil and some other migratory cells, the central cytoplasm streams into pseudopodia at the advancing edge, and is withdrawn at the rear. In other cell varieties, for example macrophages, the leading edge is marked by a series of delicate undulations, creating a highly folded, thin *ruffled membrane*, or, as in the growth cone of the neurites of nerve cells, long narrow processes or *microspikes* are constantly being formed and resorbed as the cone moves forward. Some cells carry specialized features such as cilia and flagella, which generate fluid movements at their surfaces by undulatory movements, either to move the mucus on the surface, as in the ciliated lining of the respiratory tract, or to move the entire cell, as in the case of the spermatozoön. Muscle cells and myoepithelial cells lie at the extreme end of this range of motility, although their activities have much in common with the movements of less specialized cells.

Cytoplasmic streaming within cells enables metabolites and organelles to move in a directed manner and at a much more rapid rate than could be accomplished by simple diffusion. Cells in tissue culture, which have been extensively studied, show that such streaming is restricted to certain fairly specific pathways, so that there is often a rapid flow of highly fluid cytoplasm through a landscape of relatively immovable organelles. Cytoplasmic streaming is particularly well developed in very large and extensively branched cells such as neurons, where metabolites are conveyed for distances of, in some cases, a metre or more to the peripheral extremities of axons and dendrites, some materials then retracing the route back towards the cell soma. Speeds of up to 25 mm/day have been recorded for *axoplasmic flow* in peripheral nerves in the centrifugal direction.

Other internal cellular movements include the passage of secretory vacuoles towards the surface of glandular cells, with the subsequent release of the secretory product, the uptake of materials by the cell surface (endocytosis, phagocytosis, and pinocytosis: *see* p. 15) and their movement into the cytoplasm, and the movements of chromosomes during mitosis and meiosis.

The mechanisms of these various types of movement are far from being fully understood, but it is beginning to emerge that many of them have a fundamentally similar basis at the molecular level, particularly concerning the presence of the proteins actin and myosin, and in some cases, also tubulin (*see* Allison 1973). Motility is best understood in the highly organized cytoplasm of striated muscle fibres which lend themselves particularly well to structural, biochemical and biophysical analyses (p. 506). Contraction is now known to involve the energy-dependent sliding interaction of filaments of actin and myosin, both of which are polymers of smaller molecules, g-actin and tropomyosin A, respectively. These proteins are also present in a less organized form in all other nucleated cells, being most prominent in contractile units such as smooth muscle and myoepithelial cells, but are also easily detectable in endothelial cells, fibroblasts (1.38A), macrophages and many other cell types. They can also be demonstrated in blood platelets, which are also capable of contraction (p. 67). Actin is present in its polymerized form (*f-actin*) as microfilaments which are thought to exist in more than one state, some being relatively stable, whilst others are highly labile and may be assembled or dispersed in a few seconds (Wessels *et al.* 1971). The polymer is in equilibrium with an intracellular pool of actin monomer (g-actin), so that agents which disturb this equilibrium can either cause the formation, or the dismantling, of at least some classes of microfilament. Cell membranes often form sites of attachment for microfilaments. Myosin is more difficult to demonstrate structurally, and is probably present in monomeric or dimeric form, or as small aggregates in most cells, and it is only in muscle cells that larger assemblies are permanently present. Many movements of cells are caused by the interaction of actin and myosin, as stated above. In fibroblasts, which have been intensively studied, it is proposed that myosin may form sliding cross-links between adjacent microfilaments, thus generating shearing forces which cause the network of microfilaments to extend or contract as a whole, by the mutual interaction of its constituents. If the filaments were attached to the plasma membrane, such movements would be transmitted to the whole cell, giving rise to flattening or rounding according to the direction of shear. Special, localized extensions of the actin network could form microvilli, or, if directed by the presence of orientated bundles of microtubules (1.38B), to which the actin may also be attached, could perhaps produce certain types of locomotion. Contraction of bundles of actin filaments by sliding interaction, is probably also responsible for the cytoplasmic cleavage during cell division (p. 30).

It has further been proposed that certain very transient structures, including microspikes, and the waves of a ruffled membrane, are created by the rapid conversion of actin monomer into a network of filaments, which is stabilized by interaction with myosin, into a finger-like process or ridge. Such structures can be easily dismantled by depolymerization, and their presence or absence depends upon local fluxes of certain ions or other cell metabolites. Actin-myosin interactions also probably occur during some types of endocytosis, such as pinocytosis and phagocytosis, where major movements of the cell surface are involved. The drug, cytochalasin-B, which causes depolymerization of some, though probably not all, types of actin, severely impairs a wide range of cell movements (Allison 1973), so that, for example, multinucleate cells are formed because of the failure of the cleavage furrow to separate cells into two during mitosis.

A number of regulatory proteins accompany actin and myosin both in muscle and non-muscle cells, and these include tropomyosin B, troponin, and actinin; these can be demonstrated

clearly, often in strikingly beautiful networks, by means of immunofluorescent labelling with antibodies evoked specifically against these proteins (Lazarides 1976).

Another major protein associated with movement is tubulin, which polymerizes to form microtubules (p. 16). These organelles are prominent, for example, during spindle extension in mitotic cells, and they may be involved in the movement of neurotransmitter vesicles in synaptic endings, in axoplasmic flow, and in the movements of cilia, flagella, and of some glandular cells. In some instances microtubules can be dispersed by colchicine and other drugs which bind to the cytoplasmic pool of dimers, and thus shift the equilibrium away from the polymeric form. Under these conditions motility is often affected (Stephens and Edds 1976). In cilia and flagella motility is achieved by the sliding interaction between adjacent microtubule pairs through the mediation of another protein, dynein (p. 18) which causes bending movements. In other sites it is probable that vesicles, and other organelles or colloids, may be able to slide along the outside of microtubules by means of interacting side arms, to produce directed movements and perhaps some types of cytoplasmic streaming (**1**.37). Other types of microtubule-induced movement may involve the assembly and dispersal of these structures, and certainly the growth of cilia and flagella is brought about in this way.

Finally, there are a number of other movements which probably operate by different mechanisms. These include the transport of various membrane-lined vesicles from one part of the endoplasmic reticulum to another, and the formation of minute endocytotic vesicles during micropinocytosis.

The patterns of control of cell movements are also of great significance, particularly in the study of morphogenesis, teratogenesis, and various pathological states in the adult. Ionic fluxes, perhaps associated, in some cases, with the release of such metabolites as cyclic adenosine monophosphate (cyclic AMP), within the cell are associated with many types of motile control.

EPITHELIUM

The term *epithelium* is applied to the layer or layers of cells which immediately cover or line the body surfaces. Embryologically, epithelia are derived from all three major cell layers: those covering topologically external surfaces (the integument, alimentary tract and the distal parts of the urogenital tracts) are of ectodermal and endodermal origin. Those lining internal cavities and the proximal parts of the urogenital tract stem from mesoderm, and are variously known as *mesothelia* (lining the pericardial, pleural and peritoneal cavities), and *endothelia* (lining vascular channels), or again *epithelia* in the case of the urogenital passages.

Most glands are of epithelial origin, since they arise as diverticula of the body surfaces. The largest of these is the liver.

Epithelia in the broad sense function as selective barriers, capable of facilitating or preventing the passage of materials across the surfaces which they cover; they may also protect the underlying tissues against dehydration, chemical and mechanical damage; they may elaborate and secrete materials into the spaces which they bound; they may function as sensory surfaces. Indeed, many features of the central nervous system suggest that nervous tissue as a whole can be regarded as a modified epithelium.

Structure of Epithelia

Epithelia (**1**.39) are predominantly cellular, that is, they possess only a small proportion of extracellular material. The single or multiple layers of cells rest on a mucopolysaccharide *basement membrane* (*see* p. 52), and the 20 nm intercellular gaps between adjacent cells are occupied by glycoproteins. Junctional complexes (p. 10) are usually numerous. The shapes of the cells, which are typically polygonal, are in part determined by their array of internal organelles, and features of their microenvironment including the mechanical forces created by close-packing within a confined volume.

Epithelia also possess a marked ability to regenerate when injured, as seen most dramatically in the liver, which is able to replace excised portions rapidly. Constant cell replacement is also important at surfaces subject to wear and tear, and most epithelia covering external surfaces show a steady rate of cell division, which offsets the loss of cells caused by abrasion. Perhaps, as a correlate of this ability, tumours of epithelial origin (papillomata and carcinomata) are of common occurrence.

Usually, blood vessels are absent from epithelia, nutrition of which depends on diffusion from capillaries of neighbouring tissues. This puts a limit on the possible thickness of living cell layers. The epithelial cells, together with their supporting connective tissue, can often be removed surgically as one 'layer', collectively known as a *membrane*. Where the surface is moistened by mucous glands it is termed a *mucous membrane*, and where it is covered with a film of thin serum-like fluid, a *serous membrane*.

Classification of Epithelia (**1**.39)

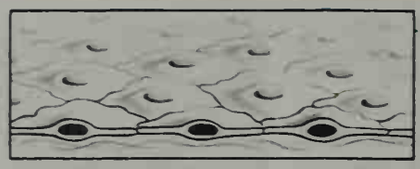
They can be grouped into *unilayered* or *simple* epithelia—single layers of cells resting on a basement membrane; and *multilayered* epithelia—more than one cell layer. The latter can be subdivided into *replacing* or *stratified squamous* epithelia, in which superficial cells are constantly replaced from the basal layers, and *urothelium* (*transitional epithelium*), lining parts of the genito-urinary tract, and in which cells are only replaced when patches of cell death have followed injury.

Unilayered (Simple) Epithelia

This group may be further subdivided according to the shape of the constituent cells into squamous, cuboidal, and columnar types. The shape of the cells is largely related to the distribution of their internal constituents; where little cytoplasm is present, denoting low metabolic activity, the cells are squamous or low cuboidal. Highly active cells, such as those bearing cilia or possessing secretory functions, contain abundant mitochondria and endoplasmic reticulum, and are tall cuboidal, or columnar, in shape.

Various special structures such as cilia, microvilli (brush and striated borders), secretory vacuoles (in mucous and serous glandular cells) and a sensory apparatus may also characterize particular types of epithelial cell. *Myoepitheliocytes*, which are contractile, do not form complete sheets but occur as small isolated groups of cells.

SQUAMOUS (PAVEMENT) EPITHELIUM



This is composed of flattened, interlocking, polygonal cells (*squames*). The cytoplasm may in places be as little as 0·1 μm thick, and the nucleus usually bulges into the overlying space (**1**.39, 40). This type of epithelium lines the alveoli of the lungs, renal corpuscles, the thin segments of the nephric tubules, various parts of the inner ear, and as a *mesothelium* it forms the surfaces of the pericardial, pleural and peritoneal cavities. Here, each cell possesses one or two cilia. As *endothelium* it lines the blood vascular and lymphatic channels (p. 622).

Squamous epithelium is often associated with passive movements of water or electrolytes, but may also be active in transport, as evidenced by the numerous pinocytotic vesicles often seen in such cells. The presence of *zonulae occludentes* between adjacent cells (*see* Staehelin 1975) ensures that materials pass primarily through the cells rather than between them, except where they are specially punctuated by holes, as in the fenestrated endothelia of the renal glomeruli.

NERVOUS TISSUE (often classified as a separate tissue, but retains many characteristics of its epithelial origins.)

1.39 A classification of the major types of epithelia and associated tissues described in the ensuing section.

1.40 Part of a renal corpuscle showing vertically sectioned simple squamous epithelial cells in Bowman's capsule. Masson's trichrome stain.

CUBOIDAL AND COLUMNAR EPITHELIA

These consist of cylindrical cells set together to form a palisade-like layer (1.41–48). Each cell is polygonal in horizontal section; cuboidal cells are square in vertical section, whereas columnar cells are taller than their diameter. Commonly, microvilli are found on the free surface of such cells, providing a large absorptive area (p. 18), as in the epithelium of the small intestine (columnar cells with a striated border), the gall bladder (columnar cells with a brush border) and the proximal and distal convoluted tubules of the kidney (large cuboidal cells with brush borders). Ciliated columnar epithelium lines most of the respiratory tract (1.44, 45, 46, 47) as far as the respiratory bronchioles (excepting

1.41 Simple cuboidal epithelium in renal collecting ducts. Masson's trichrome stain.

the lower pharynx and vocal folds), some of the tympanic cavity and auditory tube, the uterine tube and patches in the cavity of the infantile uterus, and the efferent ductules of the testis.

In the surfaces of the respiratory tract there are also mucous glands, and the cilia sweep a layer of viscous fluid and trapped dust particles, etc. from the lung towards the pharynx (the *rejection current*), so clearing the respiratory passages of inhaled particles. In the uterine tube, ciliary action assists the passage of ova from the peritoneal cavity to the uterus.

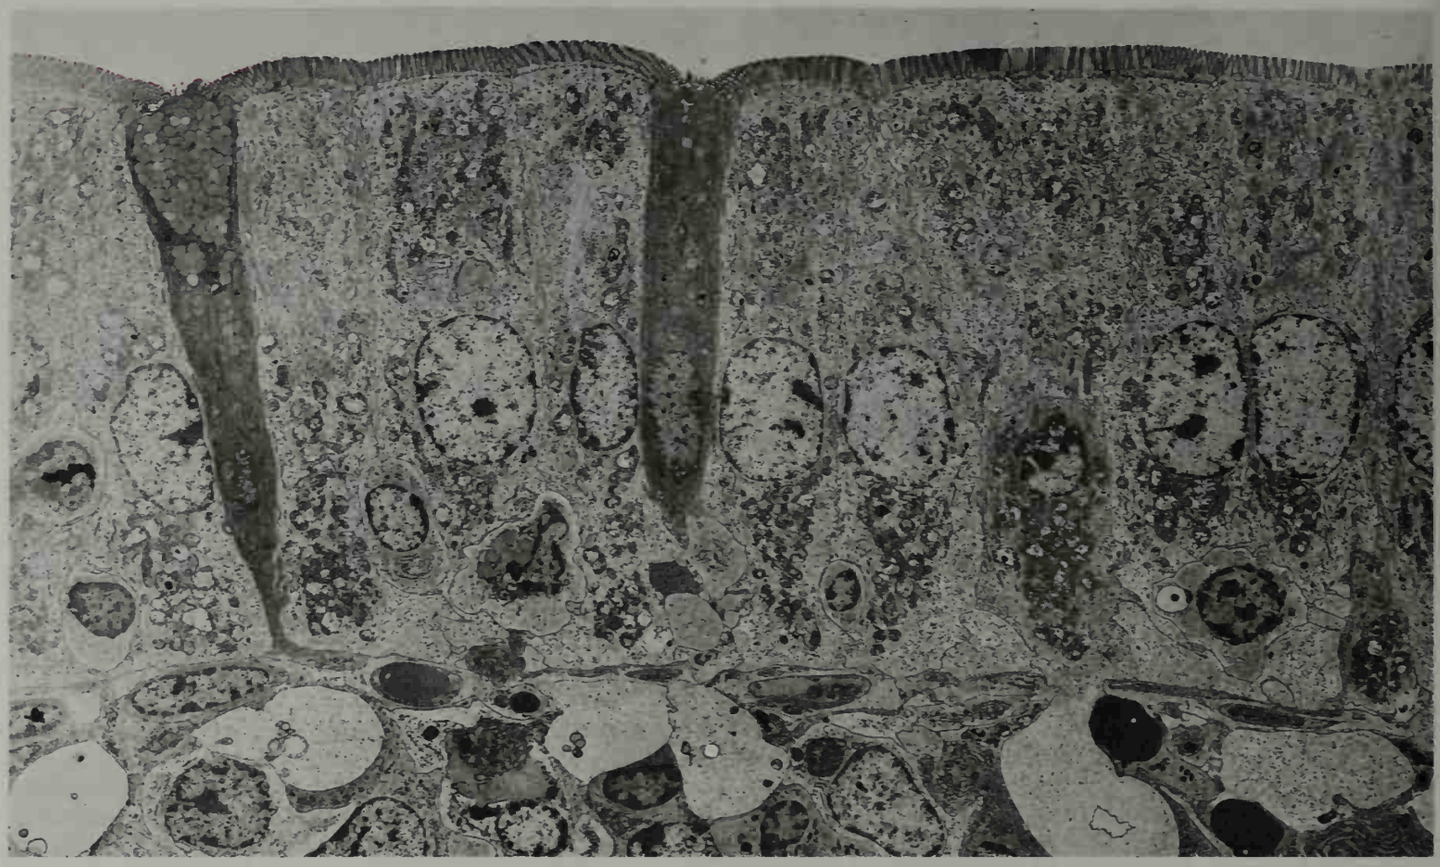
Some columnar cells are glandular, and their apical regions contain mucus or protein-carrying vacuoles. The mucin-secreting cells, and the protease-secreting chief cells of the gastric epithelium are typical examples. Often the mucous secretory cells are interspersed between non-secretory ones, and this allows the expansion of the apices of the secretory cells, giving a characteristic cell shape. The latter are known as *goblet*, *chalice* or *calciform* cells (1.42, 43), and they are particularly abundant in the intestinal epithelium.

1.42 Simple columnar epithelium of the small intestine showing absorptive cells with a striated border and goblet cells. PAS stain.

Mucus is a viscous suspension of complex glycoproteins containing both sulphated and carboxylated glycosaminoglycans. Their long polymeric chains bind water and so protect surfaces against drying. They can also slide over one another with ease, providing good lubricating properties, and their negative charges may also assist in binding cations such as Na^+.

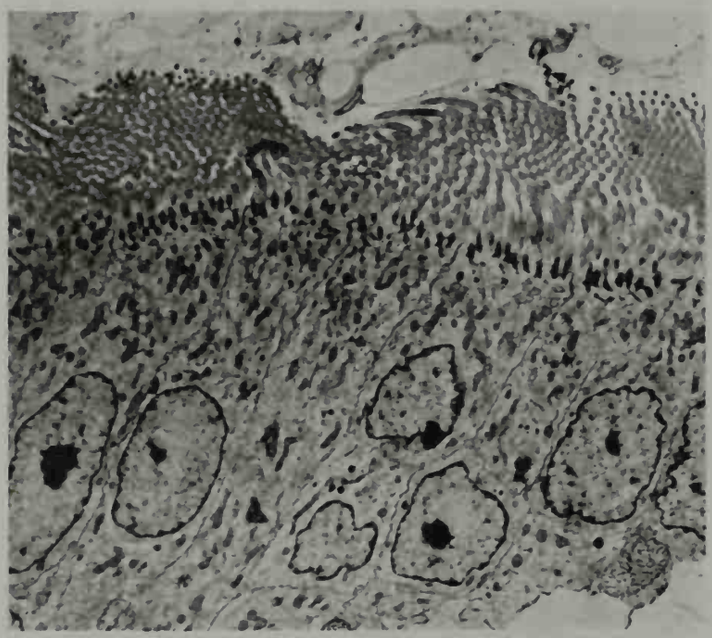
The synthesis of mucus has been followed in goblet cells by light and electron microscope autoradiography (Peterson and Leblond 1964). Protein synthesized in the rough endoplasmic reticulum is transported to the Golgi apparatus, where it is conjugated with sulphated carbohydrates to form the glycoprotein, *mucinogen*. This then passes out in small dense vesicles which swell as they approach the cell surface, and finally fuse with it, to release the mucus.

PSEUDOSTRATIFIED EPITHELIUM



This is a simple columnar epithelium in which the regular arrangement of the cells is such that their nuclei lie at different levels in a vertical section. The cells may be twisted with respect to each other so that only partial profiles of some cells appear in vertical section, giving the false appearance of more than one layer of cells. Columnar cells in many situations assume this appearance if subjected to lateral compression forces (1.48). In other cases some cells do not extend through the whole thickness of the epithelium, and may constitute a basal cell layer, often capable of cell division. It is also possible for migrating lymphocytes within a columnar epithelium to give the appearance of a pseudostratified epithelium because their nuclei are placed at different depths.

SENSORY EPITHELIA



These epithelia are restricted to the special sense organs of the olfactory, gustatory and vestibulo-cochlear receptor systems. All of them contain sensory cells surrounded by supportive, non-receptive cells. The olfactory receptors are modified neurons, their axons passing directly to the brain, but the other types are specialized epithelial cells synapsing with the terminals of afferent (and sometimes efferent) nerve fibres. They will be considered further in *Section 7 (Neurology)*.

MYOEPITHELIOCYTES

Also sometimes termed *basket cells*, these are dendritic in form, containing actin and myosin filaments, and are capable of contraction when suitably stimulated by a nervous or neurohormonal signal. They are present around the secretory portions

and ducts of some glands, for example, mammary and salivary glands, where they assist the initial passage of secretion into the larger channels.

Multilayered Epithelia

These constitute surfaces where there is considerable wear and tear; their chief characteristic is the continued replacement of superficial cells by division of more deeply placed cells.

STRATIFIED SQUAMOUS EPITHELIUM

This type of epithelium consists of several layers of cells which vary greatly in shape. Those of the deepest layer are, for the most part, columnar and are placed vertically on the basement membrane. Superficial to these, the succeeding layers consist of polyhedral cells which become more and more compressed as they approach the surface; the most superficial cells are flattened scales (*squames*) which overlap one another and so present an imbricated appearance. The cells of the deepest layers proliferate and undergo a progressive change in structure as they pass towards the surface, where they are continually lost by abrasive wear and tear.

In stratified squamous epithelia the cells are closely bound to each other by desmosomes (p. 7), and their cytoplasm is pervaded by tonofibrils which act as an internal skeleton to strengthen the cell. Where surfaces are moist, the cells of the superficial stratum, though flattened and degenerating, still retain their nuclei. At dry surfaces they lay down the protein keratin and lose their nuclei. The keratin-filled squames effect waterproofing and afford mechanical protection. The first of these two types, termed *non-keratinizing* epithelium (1.49), is found in the mucous membranes of the mouth, lower pharynx, oesophagus, vagina, part of the cervix uteri, and in the conjunctiva and anterior surface of the cornea. The second type, *keratinizing* epithelium, forms the epidermis of the skin (1.50) and occurs in parts of the mouth. The degree of keratinization is dependent upon the amount of mechanical stress and dehydration experienced by the epithelium, and also on dietary factors. Diets deficient in vitamin A induce keratinization in many otherwise non-keratinizing epithelia, such as that of the cornea.

It has recently been shown that the 'parent' basal cell and its progeny (together forming an epidermal 'proliferative unit') have a very precise geometric relationship. Each mitosing basal cell forms a single vertical column of cells which ascends in a somewhat spiral manner because of the prismatic shape of its cellular elements (Potten *et al.* 1976).

1.45A Detail of a group of cilia cut in various planes at the surface of a ciliated columnar epithelial cell from the upper respiratory tract. Note the presence of small microvilli interspersed between the cilia. Magnification ×7,500.

Epidermis

The epithelium (epidermis) of the skin (1.50, 51) shows several distinct layers of cells, the *keratinocytes*, arranged in two *zones* (Montagna and Parakkal 1974). The deeper of these, *zona germinativa*, consists of a single layer of columnar cells, the *stratum basale* (*stratum germinativum* or *Malpighian layer*), and a more superficial layer of variable thickness composed of polyhedral cells, the *stratum spinosum*. In the stratum basale the cells are placed perpendicularly on a basement membrane to which they are attached by half-desmosomes. Most of the mitoses are confined to this layer, and occasional pigment cells (*melanocytes*) of neural crest origin, which spread dendritic processes amongst the more superficial cells, are located here. The pigment produced protects the mitotic layer from adverse effects of ultraviolet radiation. Pale staining *Langerhans* cells, of possible phagocytic function, are also situated in this layer.

In the *stratum spinosum* the cells have a complex highly folded surface, covered with desmosomes which are associated with cytoplasmic tonofibrils. In sections of paraffin-embedded skin, these cells shrink away from each other except at the desmosomes, so giving the appearance of cells studded with spines ('prickle' cells). Mitosis also occurs in the deeper layers of this stratum.

In the more superficial zone, *zona cornea*, there are three strata of cells. As the cells are pushed upwards from the stratum spinosum, they flatten and synthesize *keratohyalin granules* which stain deeply with basic dyes. These cells constitute the *stratum granulosum*. As they move outwards, these cells lose their nuclei and the keratohyalin granules fuse and mingle with the tonofibrils, changing to fibrous *keratin*, composed of fine filaments, and surrounded with lipid (*vide infra*). The cells first form a clear layer, the *stratum lucidum*, which is prominent only in the thick skin covering the palms and soles. The cells become compressed into opaque squames which are now full of the horny protein *keratin* and tonofibril remnants. These squames constitute the outer layer, the *stratum corneum*.

Keratohyalin is a protein which is rich in proline and sulphur-containing amino acids; it is a precursor of keratin, a highly insoluble and mechanically stable fibrous protein which provides skin with its waterproofing qualities. In skin, keratin adopts the α-configuration in which the molecules have a pleated or helical form. These can be cross-linked by disulphydryl bonds between adjacent cysteine groups, so giving great tensile strength. This type of configuration is particularly prominent in hair, which, as a derivative of the epidermis, is also highly keratinized. As final stabilization occurs in the stratum corneum, each keratin strand is covered with a layer of lipid, in the absence of which keratinization may be defective. The epidermis will be further considered in *Section 7*, p. 1216.

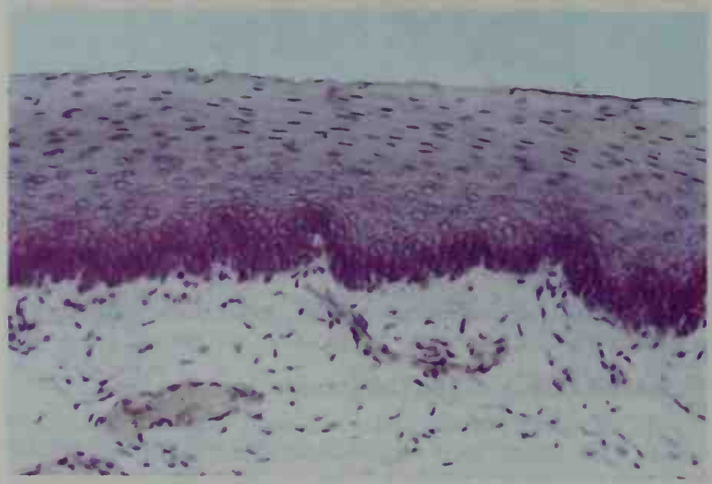
Stratified Cuboidal and Columnar Epithelia



Two or more layers of cuboidal or columnar cells are typical of the walls of the larger ducts of some exocrine glands, such as the pancreas and salivary glands, presumably affording more strength than a single layer. In some regions, for example, some parts of the epiglottis, the covering stratified columnar epithelium is also ciliated.

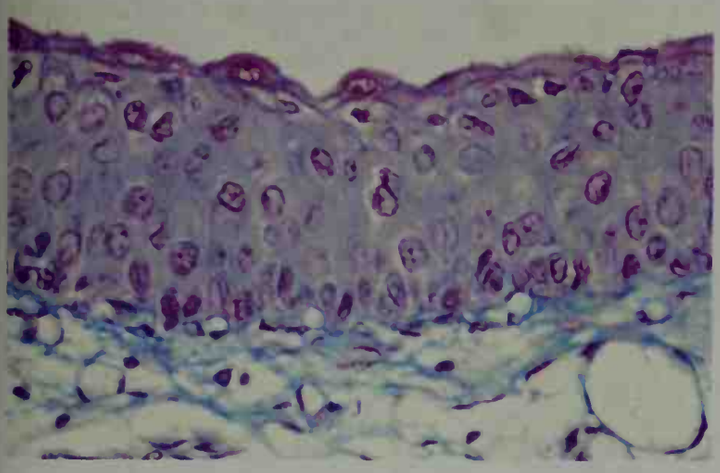
Urothelium (Transitional Epithelium)

This epithelium (1.39, 52, 53A–C) forms the characteristic lining of much of the urinary tract, extending from the ends of the collecting ducts of the kidneys, through the ureters and bladder to the distal end of the urethra. During development part of it is derived from mesoderm and part from ectoderm and endoderm. The epithelium is 4–6 cells thick, and lines organs which undergo considerable distension and contraction; it is therefore capable of being greatly stretched without losing its integrity. During such movements, the cells become flattened, or more rounded, without altering their positions relative to each other, since they are firmly connected by numerous desmosomes (*see* review by Hicks 1975). When relaxed, the basally situated cells are approximately cuboidal; they are uninucleate (diploid) and basophilic with many cytoplasmic ribosomes. More apically the cells progressively fuse to form larger, binucleate, or uninucleate but polyploid cells. The cells are largest at the surface, where they may even be octoploid, and are bounded over their luminal surfaces by a plasma membrane bearing plate-like aggregates of glycoprotein particles which are embedded in its lipid bilayer. These arrays confer a measure of stiffness on the membrane, so that when the epithelium is in the relaxed state, and the surface area of the cells is reduced, the glycoprotein-lipid plates are partially taken into the cytoplasm within vacuoles or diverticula, re-emerging on to the surface when its area increases once more with the accumulation of urine.

These unusual membranes, together with the tight junctions which surround the apices of the surface cells, form an effective



barrier preventing urine, or its constituents, from passing into the epithelium or beyond into the adjacent tissues. The urothelium therefore creates a protective lining to the urinary system which prevents the rather toxic contents of the urine damaging surrounding structures (Hicks *et al.* 1974).

Normally, cell turnover is very slow in urothelium, and cell divisions, which are restricted to the basal layer, are infrequent. When damaged, however, the epithelium regenerates quite rapidly (Annis 1962).

Pigmented epithelial cells are found in various parts of the body. As layers of columnar to cuboidal cells, they form the external layer of the retina, and are present in the posterior epithelium of the iris. The pigment granules are very small in size, are crowded together within the cells, but do not invade the nuclei. *Melanocytes* of neural crest origin are different in shape, being *dendritic* rather than columnar or cuboidal. They are scattered intermittently, or form small pigmented patches, in the membranous labyrinth of the ear, in the deeper layers of the epidermis, and in hairs. Melanocytes synthesize the pigment

melanin, which is brown-black, and *phaeomelanin* of an orange hue. They will be further discussed in *Section 7* (p. 1219).

Glands

Glands are epithelial derivatives in which the component cells elaborate a secretion. They may lie in and discharge directly on to the epithelial surface from which they originate, for example goblet cells, or be depressed below the surface and discharge on to this by means of a duct. Such glands are termed *exocrine*. In other glands, which are termed *endocrine*, the cells have become detached from the epithelial surface, no duct exists (hence the term *ductless glands*) and the secretion is discharged into the blood and lymph streams.

Exocrine glands may be *unicellular* or *multicellular*. In the former case the secretory cell is incorporated in the epithelial surface on to which it secretes. In *multicellular glands* the cells are usually depressed below the surface, to which they remain connected by one or more ducts. When the glandular epithelium discharges directly into one duct it is called a *simple* gland; when the glandular epithelium discharges through minor into main ducts it is a *compound* gland. The secretory portion can be a *simple*, *straight*, *coiled* or *branched tube* of about the same diameter as the duct, a rounded sac termed an *acinus*, or a flask-shaped sac termed an *alveolus*. Thus there can be distinguished simple and compound tubular, acinar or alveolar glands. Intermediate types, such as tubulo-acinar and tubulo-alveolar, also occur. Glands

1.53C Scanning electron micrograph of the (relaxed) urothelial surface showing the plate-like arrangement of its plasma membrane. Magnification × 6,000.

with highly distended secretory portions (e.g. the prostate) are sometimes called *saccular* glands.

The method whereby the epithelial cells of exocrine glands discharge their secretion varies. In some glands, such as the sebaceous glands in the skin, the cells disintegrate to liberate the secretion. This type of secretion is termed *holocrine*. In others, such as the mammary gland, a small amount of cytoplasm may be released with the secretory vesicles (*apocrine* secretion). More frequently only the secretion is discharged; such secretions are termed *merocrine* or *epicrine*.

Glands are often classified by the type of secretion they produce; a common division of exocrine glands is made into *mucus-secreting* or *mucous* glands, where the cells possess frothy cytoplasm with basal flattened nuclei, and which stain with metachromatic stains and PAS methods, and *serous glands* where the cells have centrally placed nuclei, granular cytoplasm, and which synthesize and secrete proteins (e.g. lysozyme, a bactericide, or the digestive enzymes).

Some glands are entirely mucus-secreting (e.g. the sublingual salivary glands), whilst others are mainly serous (e.g. the parotid salivary glands). The submandibular gland is mixed, some lobules being predominantly mucous whilst others are serous. In some regions mucous acini are capped with crescents of serous cells (*serous demilunes*). The division into mucous and serous types is, however, a rather imprecise one, since even within these categories a wide range of secretory products exist, and such terms are of limited usefulness outside certain narrow contexts (e.g. salivary glands) as considered later in greater detail (p. 1276).

Exocrine glands are usually in part divided by connective tissue septa into *lobules*; small ducts draining the lobules pass to the septa and join to form the major duct or ducts. Glands are characterized by a rich vascular supply, which may be correlated with their high metabolic rate.

Endocrine glands are composed of groups of cells lying in close proximity to vascular channels; they mostly occur in clumps or cords of closely-knit cell groups supported by a network of fine reticulin fibres and associated cells; in the thyroid gland they form hollow balls of cells, or *follicles*, in the centres of which synthesized products can be stored. Endocrine glands have a particularly well developed circulation, and often the capillary vascular endothelium is *fenestrated* (p. 628), presumably facilitating the diffusion of large molecules of hormone into the blood.

The fine structure of gland cells is typified by the presence of an extensive endoplasmic reticulum. In protein-synthesizing cells such as goblet and pancreatic acinar cells, high concentrations of polyribosomes are attached to the rough endoplasmic reticulum, whereas in steroid-secreting cells (e.g. adrenal cortex) the elaborate endoplasmic reticulum is mainly smooth.

In salivary and mammary glands, the *release* of secretion is accelerated by the neurally elicited contraction of *myoepithelial cells* which surround alveoli and the initial segments of their ducts.

The patterns of synthesis and release of secretions by glandular cells varies considerably (Smith 1972). In some, synthesis and release occur continuously (but with quantitative fluctuations) as in the adrenal cortex. In others, synthetic products may be stored for long periods, only being released when suitably stimulated (e.g. pancreatic islet β-cells). A third pattern is seen in goblet cells of the bronchi which undergo repetitive cycles of synthesis and release without the intervention of any external triggering mechanism.

COMPLEX DERIVED STRUCTURES

These include those organs which are derived from epithelia and retain their highly cellular nature; they often possess typical epithelial features as secretory, absorptive and transport functions. Such structures include the liver, placenta, the early tooth germ, and the nervous system as a whole.

THE CONNECTIVE TISSUES

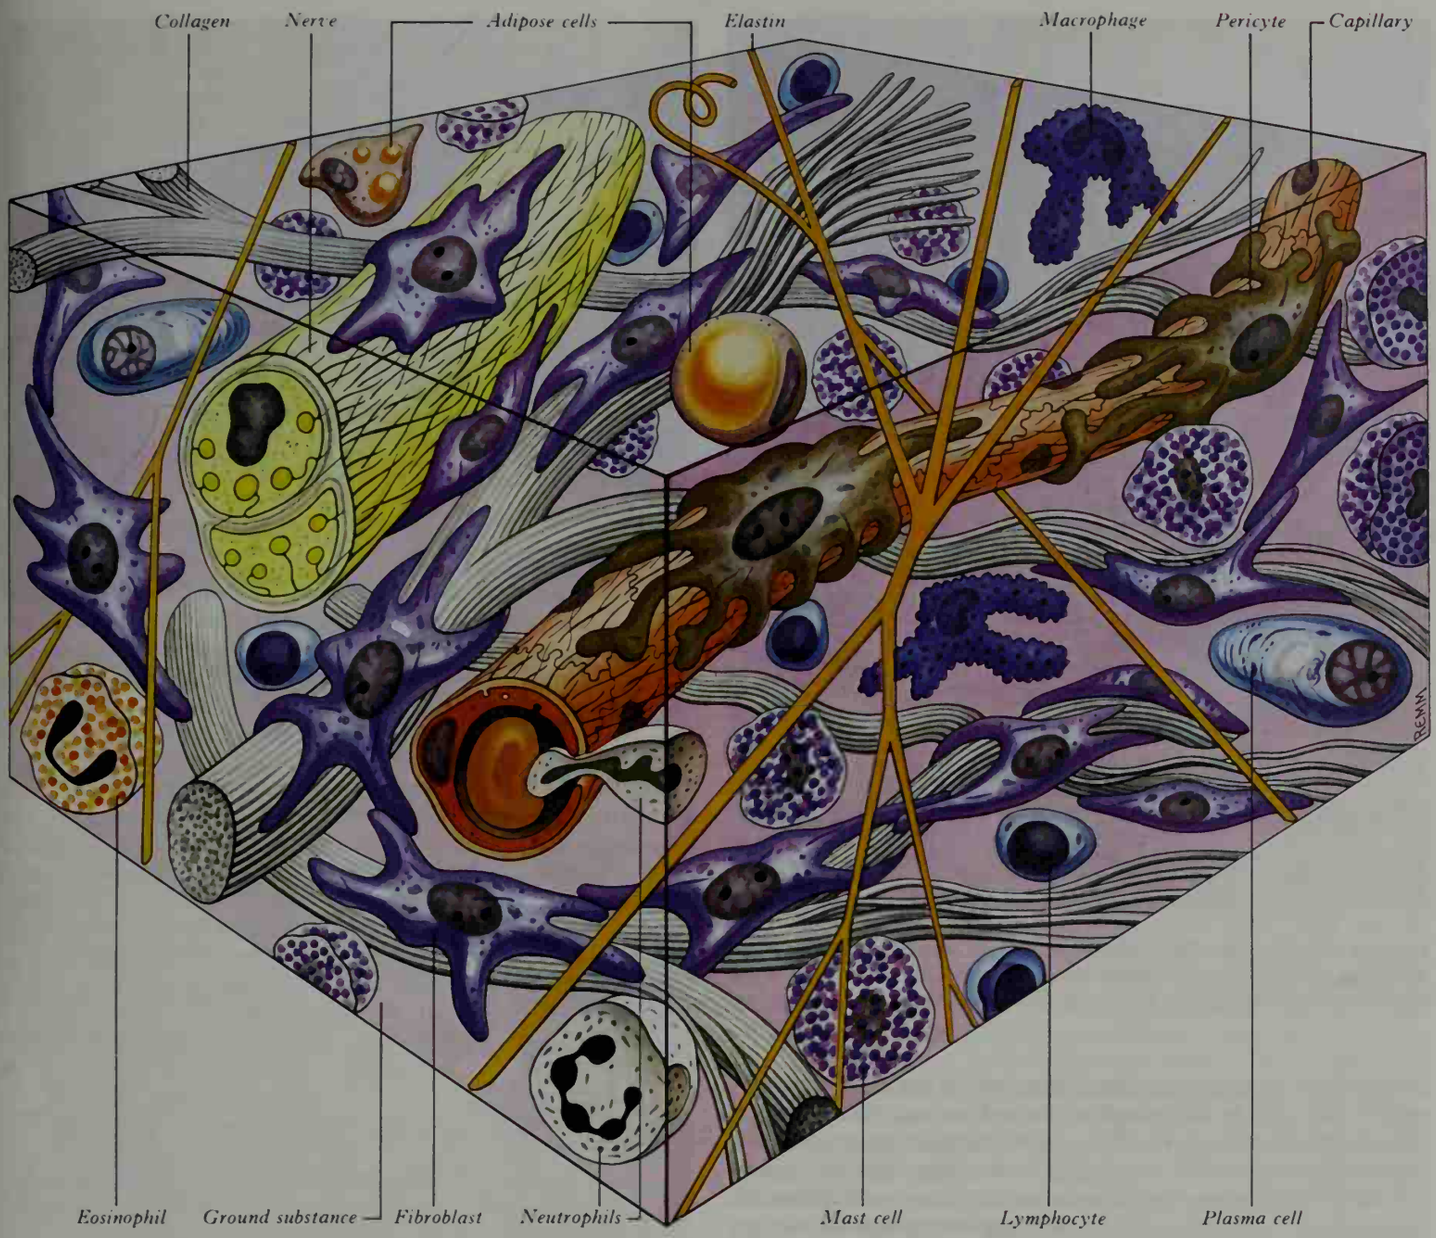
Introduction

The connective tissues may be defined as that group of elements, derived largely from embryonic mesoderm, where there is a considerable proportion of intercellular material secreted primarily by the cells themselves, which are consequently quite widely spaced. Many of the special properties of connective tissues are determined by the precise composition of the intercellular substances, and their classification is also based on its characteristics.

Connective tissues play several essential roles in the body (*see* Wagner and Smith 1967), both *structural*, since many of the extracellular elements possess special mechanical properties, and *defensive*, a role which has a cellular basis (p. 45). Connective tissues are conveniently divided into 'ordinary' types, which are distributed widely throughout the body, and special types, namely cartilage and bone—these are described elsewhere (pp. 238–66), although the same principles apply to both groups.

Connective tissue is thus formed of two components: *cells* and *extracellular matrix*. The matrix in turn is composed of *fibres* and an amorphous viscous *ground substance*. (Some authors apply the term 'matrix' to ground substance alone, but it will not be used in this manner here.) It should also be mentioned that a number of the cell types of connective tissue are also found in the circulating blood and lymph, and there is a dynamic equilibrium between the two.

The Cells of Connective Tissue



Unspecialized connective tissue consists of six principal types of cell and associated matrix—fibroblasts, macrophages, plasma cells, mast cells, fat cells and pigment cells (1.54). In addition, lymphocytes and neutrophil and eosinophil leucocytes form a variable population, which may increase dramatically in various pathological states.

Embryologically most of the cell types arise from relatively undifferentiated mesenchymal stem cells. Some of the latter are believed to remain in the tissues, providing a postnatal source of new cellular elements.

FIBROBLASTS

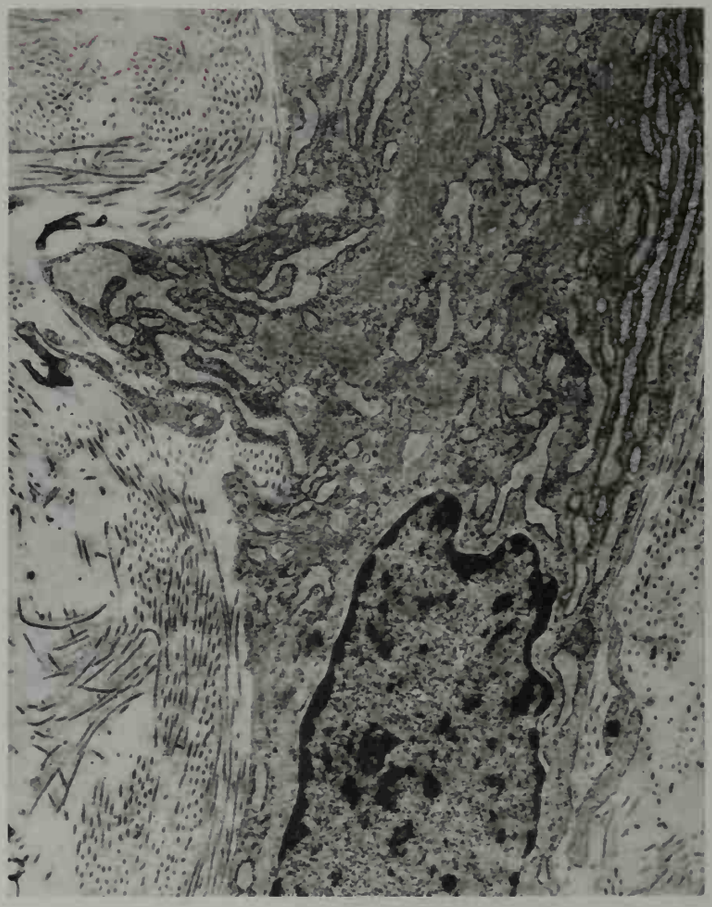
These are usually the most numerous cells. They are flattened and irregular in outline, with branching processes; in profile they appear fusiform or spindle-shaped (1.55). Their nuclei are relatively large, active or euchromatic (open-faced), and possess prominent nucleoli. The cytoplasm is clear, with a few fine granules and occasional fat droplets. In young and active cells the cytoplasm is abundant and basophilic because of the high concentration of rough endoplasmic reticulum (Hall and Jackson 1968). In old and inactive fibroblasts (often termed *fibrocytes*) the cytoplasm is sparse, the endoplasmic reticulum scanty, and the nucleus flattened and heterochromatic (close-faced). In active fibroblasts, mitochondria are abundant and the Golgi complex well represented.

Fibroblasts are concerned with the production of the extracellular materials (*vide infra*), and they are intimately associated with white collagen fibres, to which they often adhere. In some situations, such as glands, fine fibres of *reticulin* are produced instead of collagen. In other situations, such as the spleen, *reticular cells* may lay down reticulin as well as acting as phagocytes; the relationship between such cells, ordinary fibroblasts, and lymphopoietic stem cells (p. 770) is not yet clear.

1.54 A diagrammatic reconstruction of loose connective tissue showing the characteristic cell types, fibres and intercellular spaces.

Fibroblasts are particularly active during wound repair, and they multiply to produce large numbers of cells embedded in fibrovascular *granulation tissue* (*see* Ross 1968). In such situations, mesenchyme cells also may give rise to new generations of fibroblasts and other cell types, although it is thought by some that mesenchyme cells are absent, and that the fibroblasts themselves are capable of acting as stem cells. The contraction of wounds is at least in part caused by the shortening of specialised contractile fibroblasts (myofibroblasts) which arise in such areas (Gabbiani *et al.* 1973). Fibroblast activity is influenced by various factors such as steroid hormone levels, and dietary content. In vitamin C deficiency there is an impairment of collagen formation.

MACROPHAGES (HISTIOCYTES, CLASMATOCYTES)



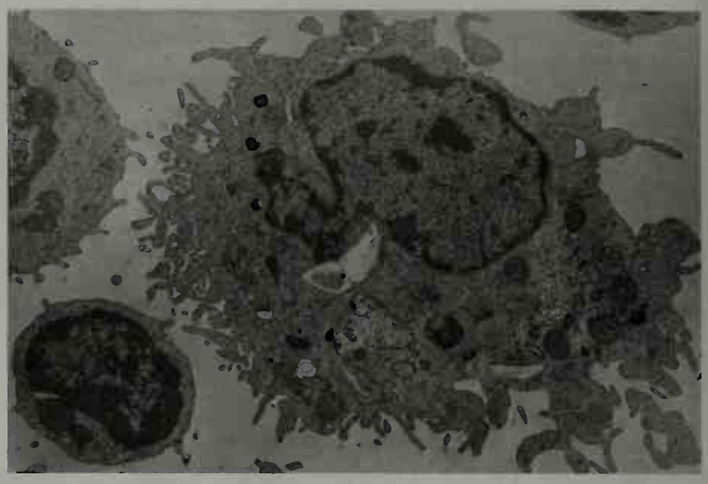
These are also numerous in connective tissues. Their nuclei are smaller and more heterochromatic than those of fibroblasts, and are often indented on one side (1.56, 57). The cytoplasm contains variable numbers of granules and vacuoles. Macrophages may be either attached to the fibres of the matrix (*stationary* or 'fixed' macrophages), when their outlines are irregular and bear numerous filopodia, or they may be motile or *nomadic*, when the cell is more rounded.

Macrophages are, of course, phagocytic, forming part of the *reticuloendothelial* (or *mononuclear phagocyte*) *system* (p. 765). They are capable of engulfing and digesting particulate organic materials such as bacteria and other foreign bodies, and also of disposing of damaged tissues prior to their regeneration.

Ultrastructurally, macrophages contain numerous lysosomes which are active in hydrolysing phagocytosed particles (p. 14). Inert materials such as small particles of carbon or metals may also be taken up. This quality is useful in demonstrating macrophages histologically, since their cytoplasm becomes filled with ingested particles if an experimental animal is previously injected with a suspension of India ink (1.57), trypan blue or lithium carmine (vital staining). Macrophages may also be separated magnetically from mixed cell samples by first treating them with iron carbamyl, which they ingest.

Macrophages are also involved in the immunological reactions of the body (p. 62). Antigens adhering to macrophages may (directly or after modification) be passed to, and thus stimulate, neighbouring immunologically competent cells (p. 265). They may selectively phagocytose particles previously coated by antibodies (*opsonins—see* p. 62) synthesized by lymphocytes, and they are themselves sites for *cytophilic antibody* attachment, which enables them to recognize and attack foreign substances (see also monocytes, p. 59).

Many properties of macrophages are similar to those of a number of specialized cell types in other sites, particularly



1.55 A transmission electron micrograph of a fibroblast. Note the abundant endoplasmic reticulum, and extensive Golgi complex. Some extracellular collagen fibres are also visible. Magnification × 15,000.

circulating monocytes, alveolar phagocytes in the lungs, reticulo-endothelial cells in the lymph nodes, spleen and bone marrow, endothelial (Kupffer) cells of the liver sinusoids, microglial cells of the brain and possibly osteoclasts of the bone marrow. Various cell-labelling experiments have shown that most, or perhaps all, the precursors of these arise in the bone marrow as monocytes which then pass in the circulation to their final destinations, where, however, they continue to divide.

All macrophages are capable of motility, when suitably stimulated. When grouped around a large foreign body, macrophages may also fuse together to form *syncytial giant cells* and *epithelioid cells*.

LYMPHOCYTES AND PLASMA CELLS

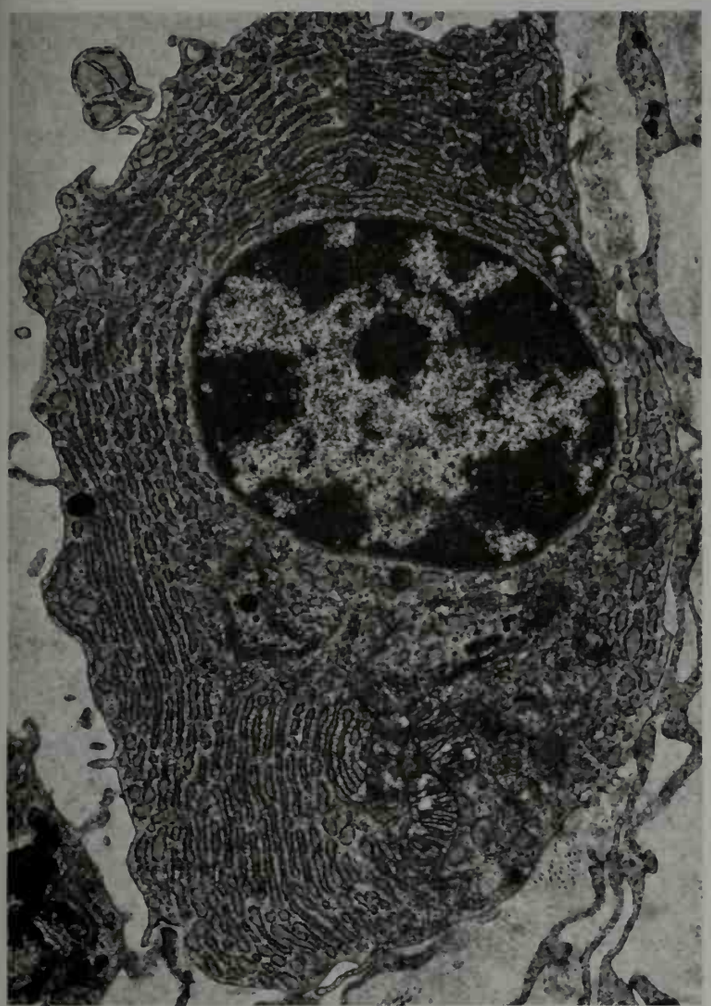
These cells are numerous in connective tissue only in pathological states. *Lymphocytes* may invade an area from adjacent lymphoid tissue or from the circulation. The majority are small cells (6–8 μm) with rounded, highly heterochromatic, often deeply indented nuclei (p. 20, and *see* 1.58, 68, 69). When appropriately stimulated they enlarge, developing numerous ribosomes. *Two* major *functional classes* of lymphocyte exist. The first type is derived from the bone marrow via various lymphoid tissues (*'B' lymphocytes*) and, when antigenically stimulated, synthesizes antibody in the extensive arrays of granular endoplasmic reticulum that it develops as it differentiates and matures into a *plasma cell* (1.58B, C) in lymph nodes and elsewhere. Mature plasma cells, which are incapable of cell division are oval or round in shape, and are virtually filled with rough endoplasmic reticulum except for a well marked Golgi apparatus. They produce large quantities of antibody which may be released locally, or widely dispersed via the circulation, or some may be temporarily stored in large vacuoles clearly visible with a light microscope as *Russell bodies*, which sometimes contain crystalline inclusions. (Some observers consider the presence of such bodies to indicate that the plasma cell in question is ageing and has a low level of functional activity.) The nuclei of plasma cells are spherical and have a characteristic 'cartwheel' configuration of heterochromatin. The prominent Golgi complex is also seen with a light microscope as a pale region to one side of the nucleus, whilst the remaining cytoplasm is deeply basophilic due to the abundant rough endoplasmic reticulum.

1.56 An electron micrograph of a macrophage (right) and a small lymphocyte (lower left). Magnification × 6,000.

The second type is the thymus-derived *'T'-lymphocyte*, which stems from cell stocks initially formed by the bone marrow, but later sojourning in the thymus before passing into the peripheral lymphoid system. When antigenically stimulated, these cells enlarge and their cytoplasm becomes filled with 'free' polysome clusters. The functions of T cells are numerous and incompletely understood, but include the recognition and destruction of virus-infected cells, tumour cells, fungi, tissue and organ grafts, and the modulation of the 'B'-lymphocytes.

Further details of the natural history of lymphocytes may be found on pp. 59–63.

MAST CELLS (MASTOCYTES)



Mast cells occur particularly in loose connective tissues and often in the fibrous capsules of certain organs such as the liver. They are characteristically sited around blood vessels. Mast cells are round or oval, with many filopodia extending from the cell surface (1.59). The nucleus is centrally placed and relatively small, being surrounded by large numbers of prominent vesicles, a well developed Golgi apparatus, but scanty endoplasmic reticulum. The vesicles show a strongly positive reaction with the periodic

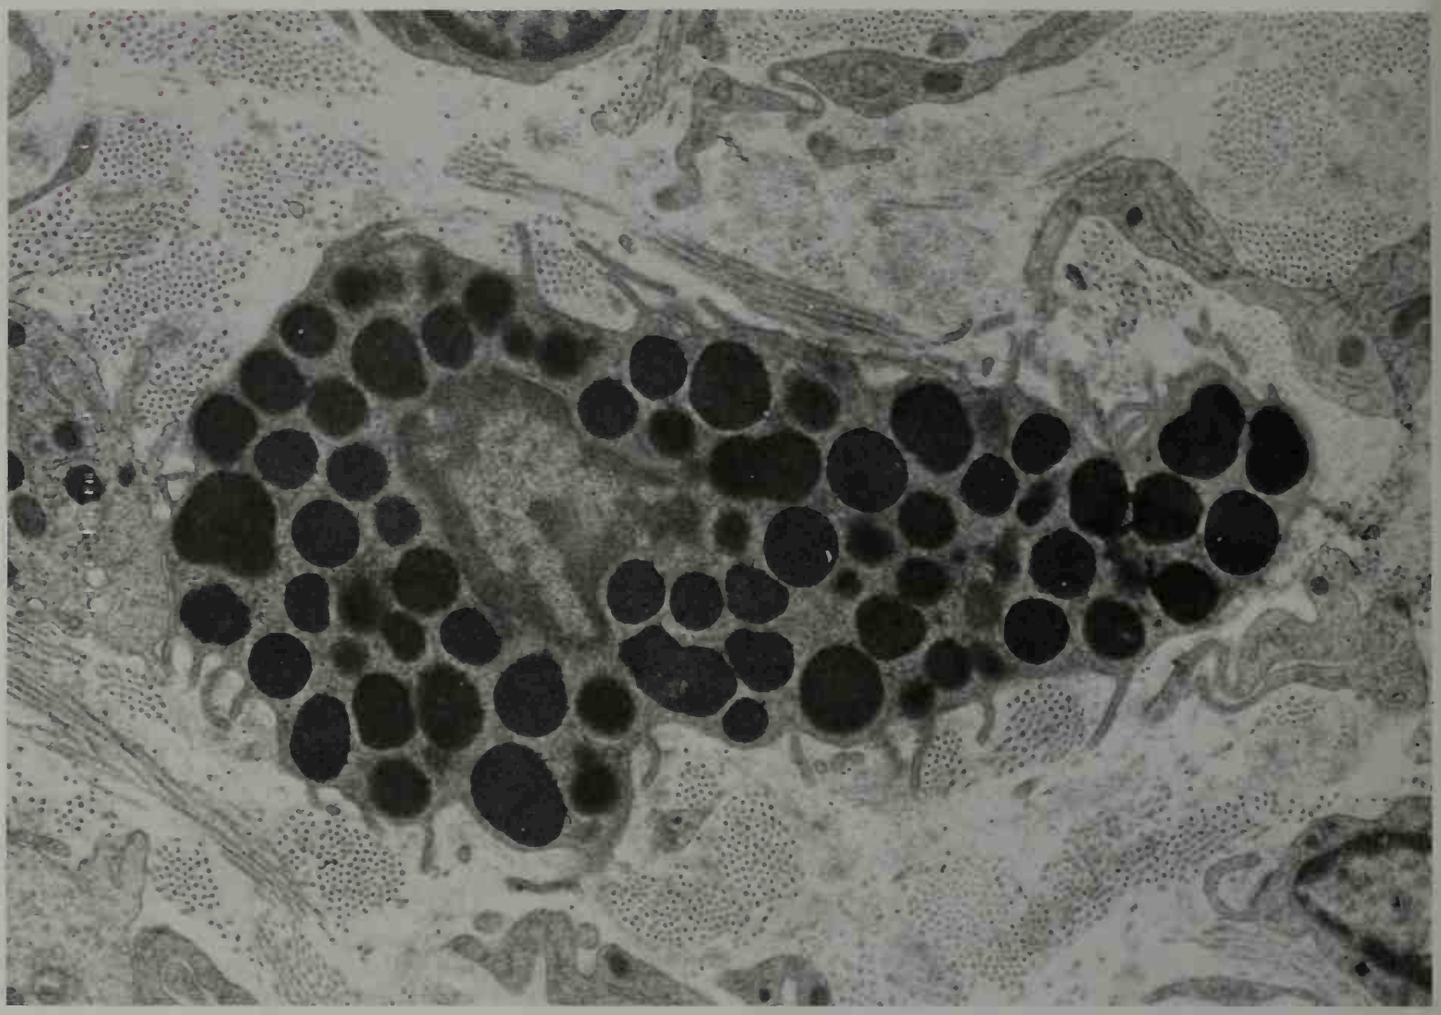
acid-Schiff (PAS) stain for carbohydrates, and with toluidine blue, methylene blue, azure A and alcian blue, they show strong *metachromatic* staining reactions (staining red), also indicating an acid mucopolysaccharide content. Ultrastructurally the vesicles (or 'granules') are seen to vary in size and shape (mean diameter about 0·5 μm), to be membrane-bound and to have a rather heterogeneous content, which varies with the species. In man the vesicles usually contain dense osmiophilic material which may be finely granular, lamellar, or in the form of membranous whorls; these variants may co-exist in the same vesicle, which may also present in places a crystalline substructure. For these reasons they have sometimes been termed *compound granules*.

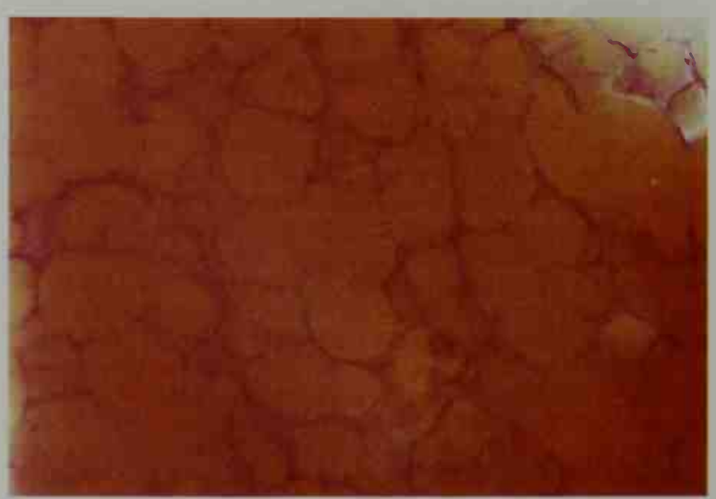


The available evidence points to the presence in mast cells of three active substances: *histamine* and *serotonin* (5-hydroxytryptamine)—agents in inflammatory changes—and *heparin*, a sulphated acid mucopolysaccharide which prevents clotting of plasma, and possibly of proteins which may leak in small quantities from the vascular channels. Mast cells may be disrupted to release their contents either by direct mechanical or chemical trauma, or sometimes following contact with particular antigens to which the body has previously been exposed (p. 62). The latter may result from interaction between the antigen and *cytophilic antibodies* of the IgE class associated with the mast cell plasma membrane, and may give rise to local responses (e.g. urticaria), or generalized ones (anaphylactic shock) following the release of large amounts of histamine and serotonin into the general circulation. They have thus been implicated in many of the phenomena occurring in inflammatory reactions, allergies and hypersensitivity states.

Mast cells closely resemble basophil leucocytes of the general circulation, and it is widely considered that they arise from the bone marrow and pass to the tissues as basophils, migrating through the capillary and venule walls to their final destination. However, there are minor differences between the basophil and the mast cell in terms of their cytochemistry, which suggest either a different lineage for the two, or perhaps more likely, that the basophil matures into a mast cell when it reaches its extravascular environment.

FAT CELLS (LIPOCYTES, ADIPOCYTES)

Fat cells occur singly or in groups in the meshes of many but not all connective tissues, being specially numerous in *adipose tissue* (1.60). When occurring singly the cells are oval or spherical in shape, but when mutually compressed they are polygonal. They vary in diameter, averaging about 50 μm. Each cell consists of a peripheral rim of cytoplasm, in which the nucleus is embedded, surrounding a single large central globule of fat. There is a slight accumulation of cytoplasm around the nucleus, which is oval in shape and appears compressed against the cell membrane by the fat droplet, as does the Golgi complex. In electron micrographs many microfilaments are also seen around the membrane-bound lipid vacuole. (Slavin 1972, Greenwood and Johnson 1977).



In sections not specially prepared to preserve fat this is usually dissolved out by the solvents used, particularly xylol or benzene; only the nucleus and the peripheral rim of cytoplasm surrounding a central empty space are left, so that the cell has a signet-ring

1.59 An electron micrograph of a mast cell showing the large densely staining membrane-bound cytoplasmic granules. Magnification × 6,000.

appearance. The fat consists of glycerol esters of oleic, palmitic and stearic acids.

Doubts exist as to whether fat cells are specifically and exclusively concerned with the storage, and perhaps the synthesis, of fat. Prior to the storage of fat within them they are stellate in shape and difficult to distinguish from fibroblasts and, when depleted of fat, they revert to this appearance. As fat accumulates the cells enlarge and become rounded, the fat first appearing as isolated small globules which later coalesce to form a single large droplet. Conversely, during depletion the single large globule diminishes in size and then breaks up into droplets while the cells become stellate in shape. Fat cells, however, seem to have a well defined distribution within the body and there is evidence that they are indeed specific cells.

1.60 Adipose tissue in frozen section, stained with Sudan red and haemalum. Magnification × 200.

The fat is fixed and stained by osmium tetroxide and specifically coloured by alcoholic solutions of certain dyes, notably Sudan III, Sudan black and Scharlach R, which are more soluble in fat than in the solvent; lipid is conveniently demonstrated in frozen or cryostat sections (1.60).

In some mammals, especially those which hibernate, certain deposits of fat, particularly in the interscapular region, are characterized by the presence of a large, glandular type of cell in which the fat is present as separate droplets and not as a single globule. These deposits of fat are often termed *brown fat* and they are concerned with heat production, mediated by mitochondria.

The mobilization of fat is under nervous or hormonal control, and noradrenalin released at sympathetic nerve endings in adipose tissue is particularly important in this respect (Napolitano 1965; Havel 1965).

Pigment cells (Chromatophores)

These occur in the corium of the skin, especially in dark races, and in the iris and choroid of the eye. They are frequently termed *chromatophores*. They are generally stellate cells with long processes and numerous dark brown or black granules, believed to be melanin, in their cytoplasm. Their origin is considered to be the embryonic neural crest.

Reticular Tissue

In many situations, as in exocrine and endocrine glands, a fine meshwork of reticulin fibres supports the cellular elements (*see* p. 51 and Carr 1970). The cells responsible for forming this are indistinguishable from fibroblasts, but are sometimes termed 'reticular cells'. This term is, however, also used for a variety of

other cells in the reticuloendothelial and haemopoietic tissues (p. 66), where reticulin is also laid down. The nomenclature and proposed relationships between these various elements is somewhat confused, and will not be further explored here.

The Matrix of Connective Tissue

This term is taken here to include all the extracellular materials of connective tissue, and may be divided into two components, the *fibrous elements* and the *ground substance*.

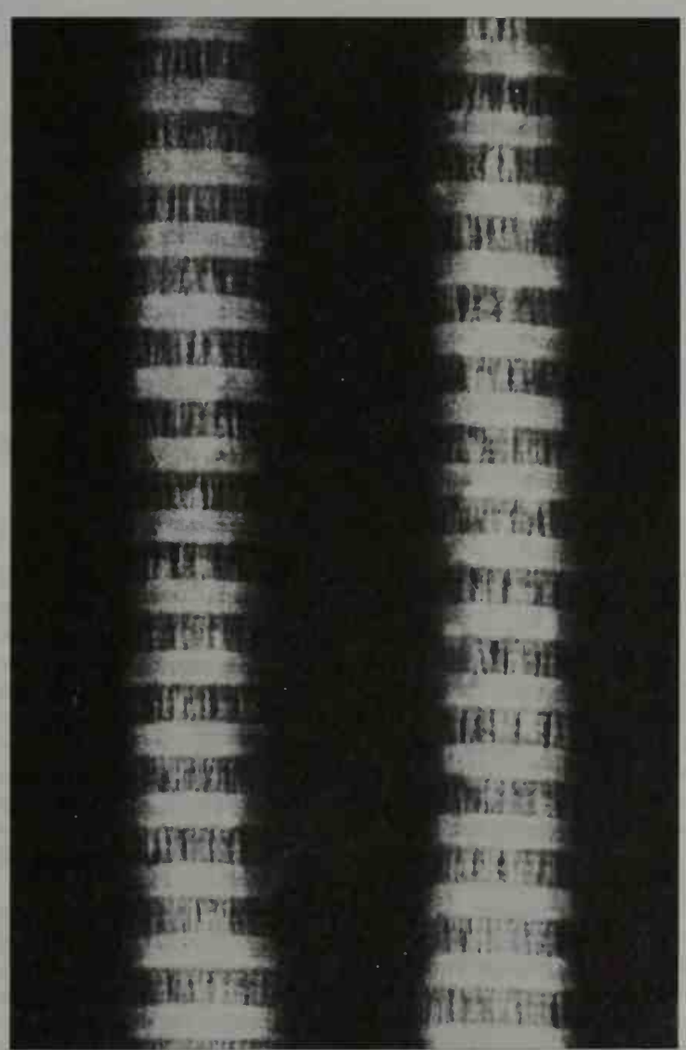
The fibrous elements consist of three types of fibre: collagen, reticulin and elastin.

COLLAGEN FIBRES

White collagen fibres are the most numerous and widely distributed fibrous elements in ordinary connective tissues. They are generally collected into bundles which pursue a straight or sinuous course (1.54) and within which the fibres are more or less longitudinally orientated, giving the bundle a faint longitudinal striation. Within the bundles, the fibres are bound by a small amount of amorphous cement substance, believed to be a mucoprotein. The amount of this material diminishes with age, and the constituent fibres in the bundle thicken.

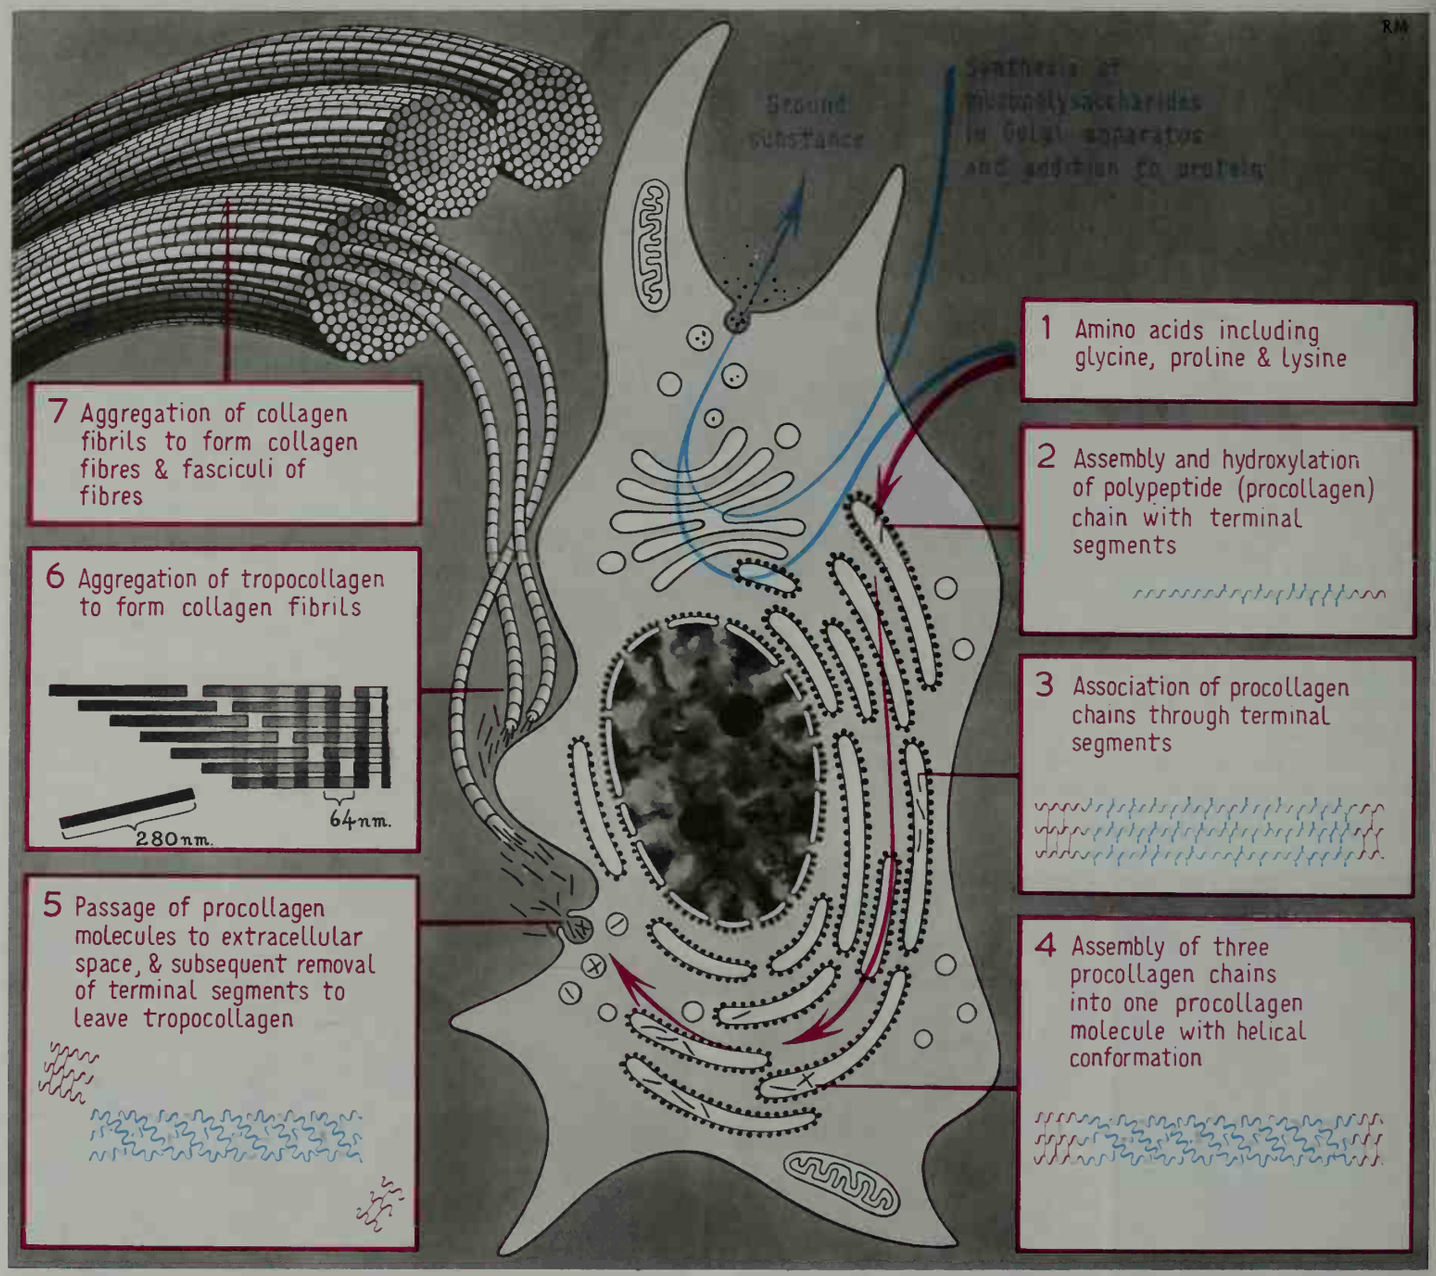
In the fresh state, collagen fibres are soft and flexible; they have a high tensile strength, and are relatively inelastic and inextensible, with a Young's modulus of 10^{10} (Harkness 1961). They are homogeneous, transparent and show a form birefringence, indicating a longitudinal orientation of subunits. The individual fibres are 1–12 μm in diameter and do not branch, although they may, either singly or in small aggregates, pass from one bundle to another. They vary in length and may extend for considerable distances.

Collagen fibres are lightly eosinophilic; they also stain with acid aniline dyes such as aniline blue in Mallory's stain, and with acid fuchsin (red) in van Gieson's stain. They stain only weakly with silver impregnation.



Each fibre consists of bundles of finer parallel fibres, 0·3–0·5 μm in diameter, and these in turn consist of bundles of fibrils each 20–100 nm in diameter (1.61A, C); the latter are joined transversely by regular cross-connexions, probably glycoprotein in nature. These fibrils show a characteristic banding with a periodicity of 64 nm when viewed by electron microscopy. Within the major periodicity, there are several thinner cross striations arranged asymmetrically, so giving the fibril a polarity (1.61A, C).

The foregoing structural appearance is characteristic of fibrils of the protein collagen; when appropriately treated with dilute acids and alkalis, the collagen fibrils swell, and disintegrate into fibrillar units of *tropocollagen*. These units are 240 nm long by 1·4 nm wide, with a molecular weight of 350,000 daltons. *Gelatin*, obtained by boiling collagen, is composed largely of tropocollagen in suspension.



Each tropocollagen molecule can be further subdivided into three polypeptide chains (α-chains) arranged in a triple helix (*see* e.g. Hodge 1967; and 1.62). These chains are rich in the amino acids glycine, which recurs at every third position, hydroxyproline and hydroxylysine, and are bonded by covalent

1.62 A schematic diagram showing the major steps in collagen synthesis by fibroblasts in connective tissue.

linkages at various sites along their length. Two major classes of chain, α_1 and α_2, differing slightly in their amino acid composition, are found in connective tissues; in tendons, for example, tropocollagen molecules are composed of two α_1 chains and one α_2. The lysine and hydroxylysine residues are also able to form strong cross-links between adjacent tropocollagen molecules, and it is the regular arrangement of parallel cross-linked molecules which gives collagen its great mechanical strength. Carbohydrate side-chains are also attached to lysine residues at various positions. The manner in which the tropocollagen molecules are arranged to give the 64 nm periodic bands has received much attention, and a general model has emerged.

The tropocollagen molecules lie parallel to each other in rows (1.62); each molecule, 280 nm long, is in echelon with respect to its lateral neighbour by 64 nm, a distance given by the arrangement of bonding between adjacent molecules. Each molecule thus stretches for four and a quarter period bands. Glycoproteins are important in the stabilization of this structure. The overlapping of these quarter-spaced molecules, when viewed in bulk, gives the characteristic pattern of bands, but only if the aggregations are in a definite geometric relation, possibly with groups of one tropocollagen molecule surrounded by six others as seen in cross-section, limiting the diameter of the fibril to about 100 nm. As intimated above, variations in the amino acid compositions of the α-chains are present in different tissues, and at least four classes of collagen can be distinguished. *Type I* characterizes tendon, bone and much of the dermis; *Type II* pervades the matrix of cartilage; *Type II* is found throughout the cardiovascular system, gastrointestinal tract and in immature dermis; *Type IV* is present in basement membranes. (See also p. 246.)

The Biosynthesis of Collagen

The involvement of fibroblasts in the biosynthesis of collagen (1.62) has been studied biochemically and by autoradiographic electron microscopy. In many respects it appears to be similar to the synthesis of collagen by chondrocytes (p. 245). Amino acids are taken up by the cell and synthesized on the ribosomes of the rough endoplasmic reticulum (1.10A–C) to form long polypeptides, the *procollagen chains* (*see* review by Uitto and Lichtenstein 1976). These are longer than the final α-chains of tropocollagen because extra polypeptide segments (*extension peptides*), which are used to assemble the total molecule, are present at both ends, later to be removed. As chain synthesis proceeds and the polypeptide moves into the cisternae of the endoplasmic reticulum, various enzymes hydroxylate certain proline and

lysine residues to hydroxyproline and hydroxylysine; ascorbic acid (vitamin C), molecular oxygen, and other factors are needed for this step, so that vitamin C deficiency and anoxia result in impaired collagen synthesis. Meanwhile, carbohydrate is attached to some hydroxylysine residues; then the three procollagen chains associate at one end by means of their extension peptides, intertwining as cross-links are formed, to give the triple helix of the *procollagen molecule*. In this form, the molecules are transferred via the Golgi apparatus, or perhaps directly, to the exterior in secretory vacuoles. Once outside, the extension peptides are removed by enzymes released by the cell, so forming tropocollagen which aggregates spontaneously (given the correct ionic environment) to create collagen fibres, cross-linked at the lysine and hydroxylysine residues. Tropocollagen molecules can be re-aggregated from acid solutions, in their characteristic pattern, by raising the *p*H to 7. The 64 nm banding pattern can, however, be altered by changing the glycosaminoglycan concentration.

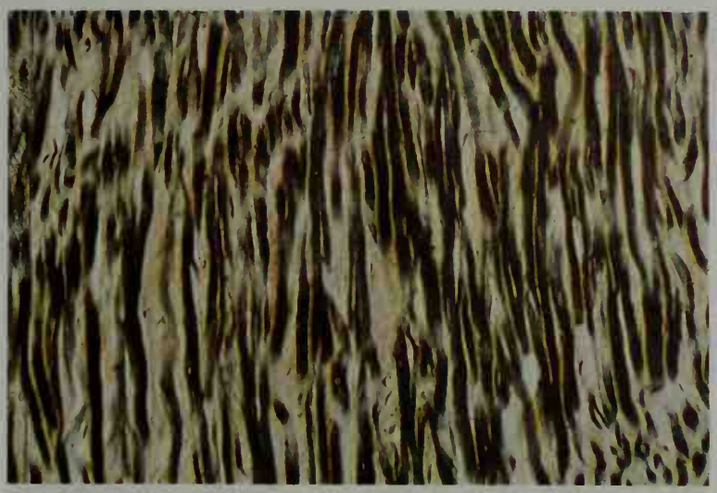
The *direction* of fibre formation, on the other hand, appears to be dependent on the stresses acting in the tissue. The relation between stress on the one hand and the rate and direction of fibre formation on the other is uncertain, but may involve movement of fibroblasts along lines determined by piezo-electric currents consequent upon the deformation of pre-formed collagen fibres.

It is remarkable that in many situations collagen is laid down in a precise geometrical pattern, with successive layers regularly alternating in direction. This occurs in the cornea, where successive layers lie at 90 degrees to each other, helping to provide the cornea with its mechanical and unique optical properties. Regularity of pattern exists also in ligaments, tendons, aponeuroses and connective tissue capsules, etc.

Divergent views have been expressed concerning the role of collagen substructure as an essential determinant of the *pattern* of seeding and crystallite *orientation* during bone formation (*see* pp. 260–66).

RETICULIN FIBRES

Fine branching and anastomosing reticulin fibres form the supporting framework of many glands, the kidney, and the lympho-reticular tissues (lymph nodes, spleen, etc.); also in association with basement membranes, and often in the neighbourhood of collagen fibre bundles. Unlike collagen, reticulin fibres take up silver salts strongly, but do not stain strongly with acid fuchsin.



Ultrastructurally they show a periodic banding which is identical with that of collagen, display the same X-ray diffraction patterns, and exhibit a similar, though not identical, chemical composition (Windrum *et al.* 1955). Reticulin may also form an early framework on which the coarser collagen fibres are laid down during matrix synthesis. Fibroblasts are responsible for their production in most connective tissues, but perhaps other distinctive cells are involved in the various reticulo-endothelial tissues, for example the reticular cells of lymph nodes (p. 768).

ELASTIN FIBRES

These are less frequent than collagen fibres, and are, in contrast, yellowish in colour, and hence so are the tissues in which they abound. Elastin fibres (1.61B; 1.63) branch and rejoin freely, and are usually thinner (1·0–0·2 μm) than collagen fibres, although on occasion they occur as thicker fibres, for example in the ligamenta flava, and sheets, as in the fenestrated elastic laminae of the aortic wall. Such fibres and laminae stretch easily, with an almost perfect recoil, Young's modulus of elasticity being 6×10^6 (Bergel 1961), although with advancing years they may calcify, losing elasticity.

Elastin fibres are highly resistant to hydrolysis in aqueous solutions of high or low *p*H, or boiling water, and to treatment with organic solvents. However, crude preparations of trypsin which contain the enzyme *elastase*, and bacterial elastases, are capable of dissociating the fibre structure.

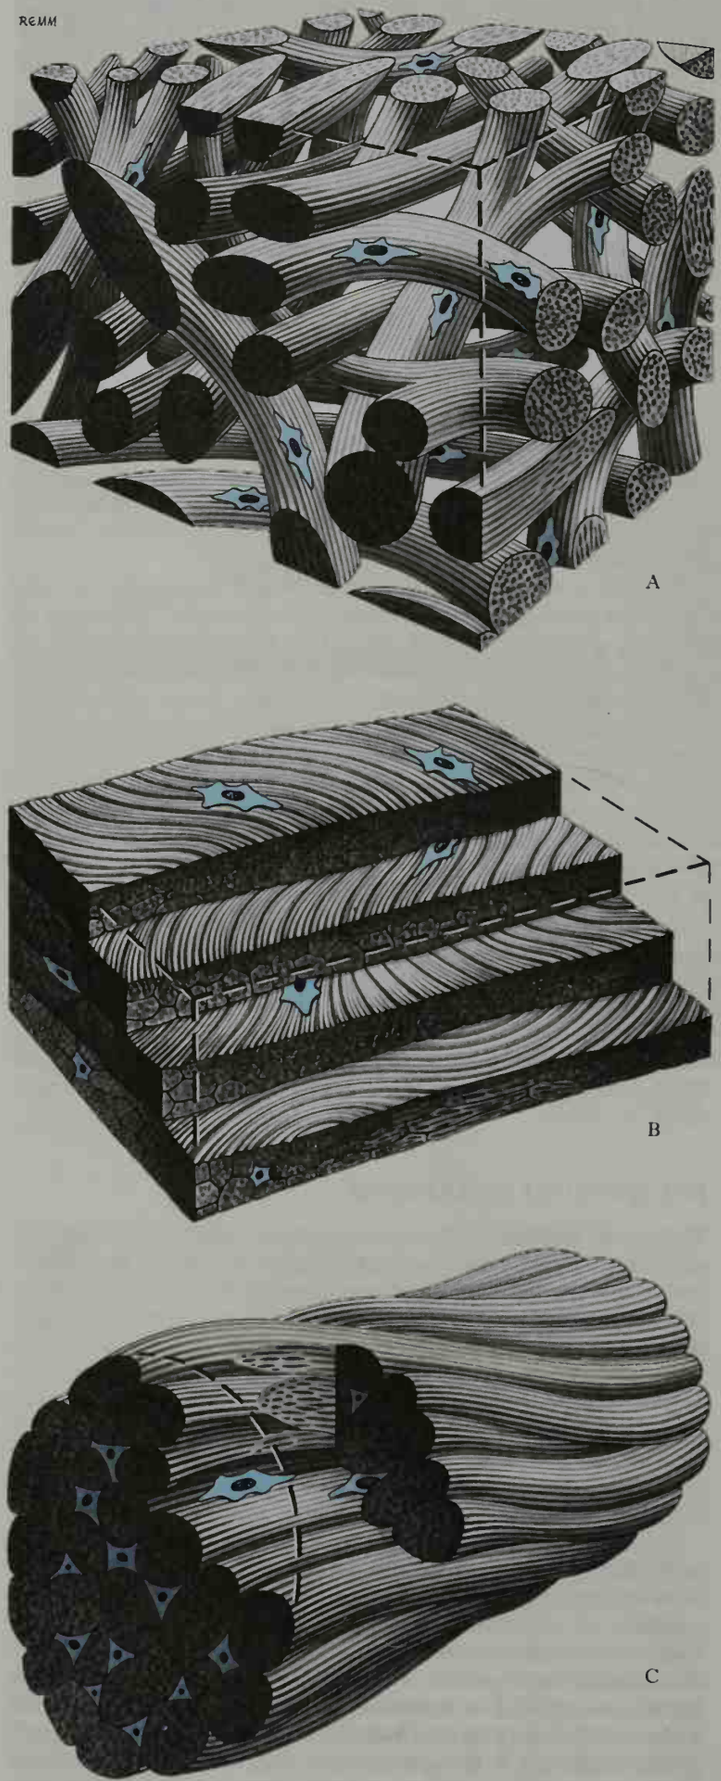
Elastin fibres can be stained with orcein, with Weigert's resorcin-fuchsin and with Verhoeff's stain. The fibres display only weak or no birefringence when unstretched, indicating a lack of regular orientation, but become strongly birefringent when stretched, indicating the rearrangement of its molecules (strain birefringence).

1.63 A longitudinal section through an elastic ligament of an ox showing elastin fibres (black) interspersed with collagen fibres. Verhoeff's and Van Gieson's stains. Magnification × 200.

The fibres are composed chiefly of the protein *elastin*, together with some glycoprotein, in fibrillar form (*oxytalan*), and traces of collagen, ground substance and lipid. Elastin is composed of globular subunits of *tropo-elastin* which have a molecular weight of 67,000 daltons and a diameter of 5·4 nm. These subunits are believed to be arranged regularly in three-dimensional sheets with no directionality, each subunit being linked to the next by bonds capable of deformation. Chemically, elastin contains a high content of the amino acid valine, and another named desmosine, which is apparently unique to elastin. In connective tissue, fibroblasts are responsible for elastin formation, although fibres and sheets of elastin can also be formed by smooth muscle cells.

For a detailed review of the biochemistry, ultrastructure, and biosynthesis of elastin, including an extensive bibliography, *see* Serafini-Fracassini and Smith (1974). For the pre-elastic role of the oxytalan fibrils during elastic fibre synthesis in auricular cartilage, *see* Bradamante and Švajger (1977). The latter consider that the glycoprotein microfibrils are synthesized first, and form a three-dimensional spatial framework, later to become impregnated by elastin.

THE GROUND SUBSTANCE



This forms the non-fibrous element of the matrix, in which cells and other components are embedded (1.54, 62). In ordinary connective tissues it is a viscous gel containing a high proportion of water, bound largely to long-chain carbohydrate molecules and carbohydrate-protein complexes, and some tropocollagen (Balazs 1971).

Where the carbohydrate is a polysaccharide with one or more amino-sugar moieties it is termed a *glycosaminoglycan* (mucopolysaccharide); where the polysaccharide is in association with a protein it is known as a *glycoprotein* or *proteoglycan* depending on the proportion of each.

Various combinations of these molecules may occur at a particular site. Most of them have several features in common; the carbohydrate moiety is always composed of long, unbranched polymers of repeating disaccharides, each chain ranging from 6,000 to several million daltons in molecular weight. The disaccharide units consist of one hexosamine residue bearing an acetyl group, and a hexuronate or galactose residue. The disaccharides may also bear either a carboxyl or a sulphuric ester group, conferring a strong negative charge on the whole polymer which acts as a poly-anion, and therefore can be stained with cationic dyes such as Hale's colloidal iron, alcian blue, and various metachromatic stains.

The compounds present in all ordinary connective tissues vary in amount from one site to another. The principal types are: chondroitin 4-sulphate and chondroitin 6-sulphate (chondroitin sulphates A and C), hyaluronate, dermatan sulphate (chondroitin sulphate B), keratan sulphate, and heparin sulphate (*see* Montagna and Parakkal 1974). All of these, except hyaluronate, which is a huge randomly coiled molecule several million daltons in molecular weight, are normally conjugated with a protein core, from which they extend in rows, like bristles on a brush, being repelled from each other by their negative charges. Such arrangements usually confer a high viscosity on the ground substance because of the formation of complex three-dimensional networks capable of binding water strongly. This water component is of great importance in facilitating diffusion of metabolites, electrolytes and gases, between the capillaries and the cellular elements embedded within the ground substance. The presence of negative charges determines their ion-binding power, and they thus act as selective barriers to the passage of inorganic ions and charged molecules. All of these may be conjugated with proteins.

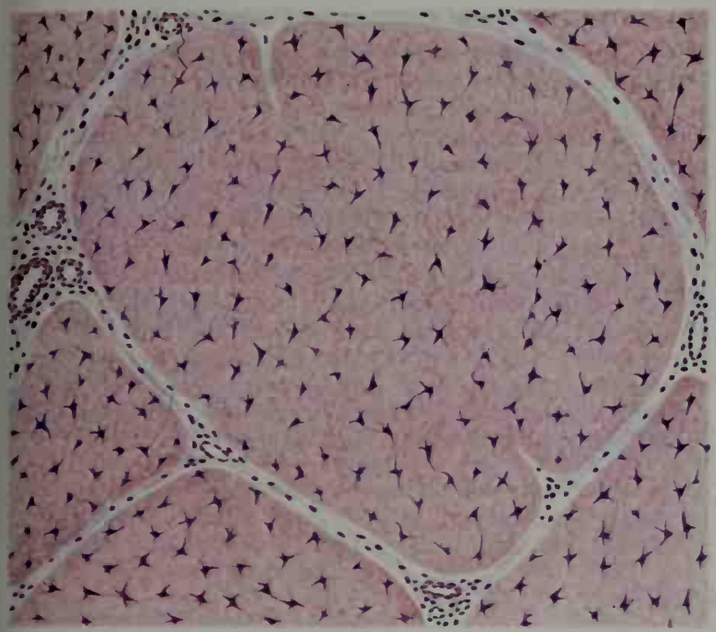
Because of its high viscosity the ground substance also forms a mechanical barrier; some bacteria secrete the enzyme hyaluronidase which decreases its viscosity, so facilitating the spread of the organisms in the connective tissues. The matrix is synthesized chiefly by fibroblasts within the granular endoplasmic reticulum and Golgi complex. Its production may be affected by hormones, as shown for instance in hypothyroidism, when much ground substance may be generated (myxoedema). The ground substance is difficult to demonstrate histologically, since it is highly soluble in water; it can, however, be retained in freeze-dried or freeze-substituted specimens, or after precipitation with cationic detergents such as cetyl pyridinium.

1.64A–C A diagram showing three types of arrangement of collagen fibres in: (A) dense irregular connective tissue; (B) a ligament; (C) a tendon.

BASEMENT MEMBRANES

These are laminae of dense amorphous material which vary in thickness (Kefalides 1970), are associated with many types of cell embedded in or adjacent to connective tissue (e.g. Schwann cells, muscle cells, capillary endothelium, and epithelia in general). In some situations they may be particularly thick, and so, incidentally, easier to investigate, as in the glomerular membrane of the kidney, the lens capsule, the anterior limiting (Descemet's) membrane in the cornea and Reichert's membrane in the placenta of certain mammals.

Such membranes may possess a supporting function, and may be important in selectively altering ionic and molecular diffusion rates. Changes in their thickness are often associated with pathological conditions, as in the thickening of the glomerular membrane in glomerulonephritis and diabetes, although it is difficult to allot causes and effects in such cases.



Ultrastructurally, the basement membrane usually consists of two zones: a thin (50–80 nm) layer of fine (4 nm) fibrils embedded in an amorphous densely staining material, situated near the adjacent cell surface (and often referred to as the *basal lamina*), and a layer of fine reticulin or collagen fibres which merges into the neighbouring matrix. In many sites the basement membrane is continuous with the *glycocalyx* of the neighbouring cells (p. 5).

Basement membranes stain strongly with the PAS technique and with silver methenamine (Rambourg and Leblond 1967). Chemically they are composed chiefly of tropocollagen (80 per cent) with some 10 per cent glycoprotein (Kefalides 1971).

Although at one time basement membranes were thought to be formed as a condensation of the general connective tissue ground substance, recent immunological evidence shows that they are in part formed by the cells which they adjoin. For example, basement membranes of several types of epithelia have antigenic properties in common, which are, however, distinct from those of connective tissue; furthermore, endothelial basement membranes also have a distinct antigenic nature.

CLASSIFICATION OF CONNECTIVE TISSUE

The connective tissues differ considerably in appearance, consistency and composition in different regions according to the local functional requirements. These differences are related to the predominance or otherwise of one or other of the cell types, the concentration, arrangement and types of fibre, and the character of the ground substance. On these bases, *ordinary*

1.65 A transverse section of a tendon showing fibrocytes enclosed between bundles of collagen fibres.

connective tissues can be classified into *irregular* and *regular* types, distinguished by the absence or presence of a high degree of orientation in the fibrous elements.

Irregular Connective Tissue

This can be further subdivided into *loose*, *dense* and *adipose*.

Loose connective tissue (1.54, 57) is the most generalized form. It is extensively distributed and its chief use is to bind parts together, though allowing, by virtue of its extensibility and elasticity, a considerable amount of movement to take place. It occurs as the subcutaneous tissue in animals which possess a hairy coat, as the submucous coat in the digestive tract and as subserous tissue. In man it forms the subcutaneous tissue in regions where this is devoid of fat as in the eyelids, penis, the scrotum and labia. It is also found between muscles, vessels and nerves, forming investing sheaths for them and connecting them with surrounding structures. It is present in the interior of organs, binding together the lobes and lobules of the compound glands, the various coats of the hollow viscera and the constituent fibres of muscles and nerves.

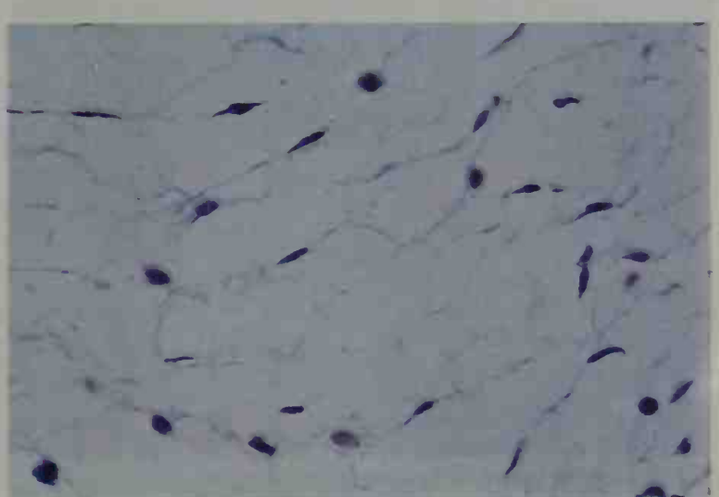
Loose connective tissue consists of a meshwork of thin collagen and elastin fibres interlacing in all directions to give a measure of both elasticity and tensile strength. The large meshes contain the soft, pliable semifluid ground substance in which occur all varieties of connective tissue cells except reticular cells, scattered along the fibres or in the meshes. Occasional fat cells, usually in small groups, are seen.

Dense irregular connective tissue is found in regions which experience considerable mechanical stress and where protection is given to ensheathed organs. The matrix contains a high proportion of collagen fibres which form thick bundles (1.64A) interweaving in three dimensions, and giving considerable strength. Active fibroblasts are few in number and most are flattened with heterochromatic nuclei. The vascular supply, in accord with this, is limited.

Examples of this type of tissue may be found in the reticular layer of the dermis, the connective tissue sheaths of muscle and nerves, and the adventitia of large blood vessels. The capsules of various glands, the coverings of various organs such as the penis and testes, the sclera of the eye, and periostea and perichondria are all composed of dense irregular connective tissue.

Adipose tissue. A few fat cells occur in loose connective tissue in most parts of the body. However, in adipose tissue (1.60) these occur in great abundance and constitute the principal component. Fatty tissue occurs only in certain regions and this selective distribution suggests that the fat is deposited in genetically determined sites. It occurs in abundance in subcutaneous tissue, which is sometimes referred to as the *panniculus adiposus*, around the kidneys, in the mesenteries and omenta, in the marrow of bones and as localized pads in the synovial membrane of many joints. Its distribution in subcutaneous tissue shows characteristic age and sex differences.

Adipose tissue consists of fat cells embedded in a vascular areolar tissue which is usually divided into lobules by stronger fibrous septa carrying the larger blood vessels, whence each lobule receives an independent blood supply. Within the lobules the fat cells are round or, when mutually compressed, polygonal. Areolar tissue and septa both contain the other cellular components of fibrous tissue. These fat deposits serve not only as stores but in some situations have mechanical functions such as in the soles of the feet, palms of the hand and in synovial membranes. In these regions the connective tissue framework of the fatty tissue often contains large amounts of elastic tissue and in emaciation these deposits tend to be spared until a late stage. Elsewhere they help to conserve the body heat.



Regular Connective Tissue

This includes those highly fibrous tissues in which the fibres are regularly orientated with respect to one another, either to form sheets such as fasciae and aponeuroses, or thicker bundles as ligaments or tendons (1.64). The direction of the fibres within such structures is related to the stresses which they experience, but there is considerable interweaving of fibrous bundles, even within tendons, which increases their structural stability and perhaps elasticity.

The fibroblasts which secrete the fibres may eventually become trapped within the fibrous structure, where they are compressed, and present highly angular outlines. Cross-sections of tendons (1.64C, 1.65) show inactive fibroblasts with stellate profiles and small heterochromatic nuclei. Fibroblasts on the external surface may be active in continued fibre formation, and they afford a pool of cells from which repair after damage may stem (*see* McMinn 1969).

Regular connective tissue is predominantly collagenous, but elastic components also occur, as in the ligamenta flava of the vertebral laminae, and in the vocal folds. A smaller proportion of elastic elements is also present between the collagen lamellae of many other ligaments and fasciae. In other sites, the collagen fibres may form precise geometrical patterns, as in the cornea (*see* p. 1154).

Mucoid tissue is a fetal or embryonic type of connective tissue (1.66), found chiefly as a stage in the development of connective tissue from mesenchyme. It exists in the 'jelly of Wharton', which forms the bulk of the umbilical cord, and consists of a copious matrix, largely made up of hydrated 'mucosubstances' and a fine meshwork of collagen fibres, in which nucleated cells with branching processes (probably fibroblasts) are found (Boyd and Hamilton 1970). However, it has been demonstrated (Parry 1970)

1.66 A section of fetal mesenchyme showing mucoid tissue sparsely populated with cells. Magnification × 500.

that the stellate appearance of the cells in Wharton's jelly probably results from fixation and staining of excised cords which have suffered a haemodynamic collapse. When this is avoided the cells are aligned and strap-like. Such findings may well apply to other situations in which mucoid tissue is found. Usually few fibres occur in typical mucoid tissue, though at birth the umbilical cord shows a considerable development of perivascular collagen fibres; after birth it is still to be seen in the pulp of a developing tooth. In the adult the vitreous body of the eye is a persistent form of mucoid tissue in which the fibres and cells are very few in number.

Pigmented connective tissue, such as occurs in the choroid and in the lamina fusca of the sclera of the eye, is composed of loose connective tissue, in which large numbers of pigment cells (melanocytes) are also present.

Vessels and Nerves of Connective Tissue

The *blood vessels* of connective tissue are very few—that is to say, few are supplied to the tissue itself, although many carrying blood to other structures may permeate one of its forms, viz. areolar tissue. In dense fibrous tissue the blood vessels usually run parallel to and between the longitudinal bundles, sending communicating branches across the bundles; in some of its forms, as in the periosteum and dura mater, they are fairly numerous. In yellow elastic tissue the blood vessels also run between the fibres. *Lymphatic vessels* are very numerous in most forms of connective tissue, especially in the loose tissue beneath the skin and the mucous and serous surfaces. They also occur abundantly in the sheaths of tendons, as well as in the tendons themselves. *Nerves* are found ending in dense connective tissues (p. 839); it is doubtful whether any nerves end in loose irregular tissue; at all events, they have not yet been demonstrated.

THE BLOOD

Introduction

All cells live within the body in a fluid environment upon the stability of which, in terms of physico-chemical characteristics, each cell is dependent for its normal functioning. This fluid environment, whilst being maintained at a steady state within certain limits, also allows for the diffusion of metabolites between cells and between the external and internal environments. In small animals with a relatively simple type of organization, unaided diffusion is rapid enough for nutrients, gases and waste materials to pass to and from the individual cells to satisfy their metabolic demands. In more complex animals diffusion is assisted by the muscular movements of the body, and in larger and yet more complex forms, particularly those with a coelom which interrupts the continuity of the tissues, a system of cell-lined tubes separates the body fluids into blood, confined within the tubes and able to circulate by muscular propulsion, and tissue fluid lying in the extracellular spaces outside the tubes. The coelom forms a third compartment which also possesses the function of a circulatory system in some groups of invertebrates. In the vertebrates a fourth division is added in the form of the medullary cavity of the central nervous system which contains the cerebrospinal fluid (p. 1050). A fifth compartment is provided by a system of further vessels which are cell-lined lymphatics, returning some of the tissue fluid to the blood circulation.

In animals with a true blood vascular system (p. 622) a high level of circulatory efficiency is possible. The system of cell-lined tubes also allows for the segregation within the circulation of some elements such as respiratory pigments able to store and carry oxygen and often carried within special cells as in vertebrates, various types of defensive cell, many of which can actively migrate into the tissues when required, so achieving rapid access to all parts of the body, and other large molecules such as polysaccharides and proteins, which may gain only limited entry to the tissues. With the development of a pumped circulation the hazard of leakage from damaged vessels is increased; various cellular and chemical *haemostatic* mechanisms ensure that such blood loss is limited.

In mammals most tissues are served by an extensive blood supply circulating by way of the heart through arteries, arterioles, capillaries, venules and veins (p. 622) The capillaries form the main site of exchange and diffusion between blood and tissues. Most cells lie within a few tens of microns of a capillary, active tissues receiving a richer and more intimate supply than less active ones. Some tissues, however, are not penetrated directly by capillaries, and diffusion gradients may be several hundreds of microns in length; such tissues are cartilage, some epithelia, and the connective tissue of the cornea and dentine.

Tissue Fluid and Lymph

The walls of the vascular system are lined by endothelial cells (p. 629) which allow the free diffusion of water, ions, gases in solution and small organic molecules. Large molecules are mostly retained within the blood, although some leakage does occur. Water and dissolved substances pass into the extravascular space which lies between the tissue cells, being termed *tissue fluid*. Because of the relatively high pressure at the arteriolar ends of the capillaries tissue fluid is constantly being formed; some of this passes back into the venous end of the capillary and the post-capillary venules, which are at relatively low pressure, but the remainder passes into the neighbouring lymphatic vessels as *lymph*. The lymphatic vessels eventually return the lymph to the blood circulation via the thoracic duct or the right lymphatic duct; *en route* to these ducts, the lymph is filtered by its passage through successive lymph nodes (p. 765), and whilst in them it picks up a population of lymphocytes and macrophages. Blind-ending lymphatics in the villi of the small intestine contain lymph which picks up great quantities of lipid (chyle) absorbed across the intestinal mucous membrane during alimentation. This is added to the lymph (and eventually to the blood) as minute lipid droplets (*chylomicrons*) each about 0·2–1·0 μm in diameter, which may be seen using light microscopy with dark field illumination. The lymphoid tissue also adds proteins in the form of antibodies (*immunoglobulins*) to the lymph and hence to the bloodstream.

Characteristics of Blood

Blood is an opaque turbid fluid with a viscosity somewhat greater than that of water (mean relative viscosity 4·75 at 18 °C), and a specific gravity of about 1·06 at 15 °C. When oxygenated, as in the systemic arteries, it is bright scarlet, and when deoxygenated, as in systemic veins, it is dark red to purple.

Blood is a heterogeneous fluid consisting of a clear liquid, *plasma*, and formed elements, *corpuscles*; because of this admixture it behaves hydrodynamically in a complex fashion, and belongs to that class of fluids termed non-Newtonian. This characteristic has important consequences in the physical study of blood flow in vessels (haemorrheology).

Plasma

This is a clear, slightly yellow fluid which contains many substances in solution or suspension; the *crystalloids* give a mean freezing-point depression of about 0·54 °C. Plasma is rich in sodium and chloride ions and also contains potassium, calcium, magnesium, phosphate, bicarbonate and many other ions, glucose, amino acids, etc. The *colloids* include the high molecular weight plasma proteins, composed chiefly of those associated with clotting, particularly prothrombin, the immunoglobulins, and complement proteins, involved in immunological defence (p. 61), and glycoproteins, polypeptides and steroids concerned with hormonal activities. Since most of the metabolic activities of the

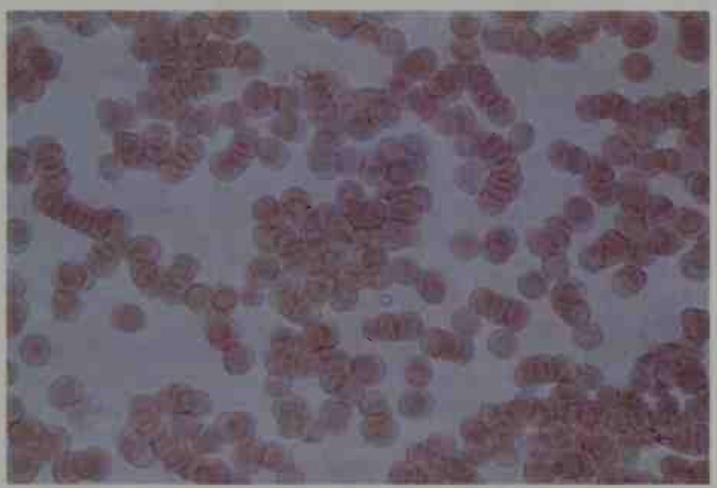
body are reflected in the composition of the plasma, routine chemical analysis of this fluid has become of great diagnostic importance and a considerable body of information on its chemistry is available.

The formation of clots by the precipitation of the protein fibrin from the plasma is initiated partly by the release of specific materials from damaged cells and blood platelets (p. 63) in the presence of calcium ions. If blood or plasma samples are allowed to stand, clot formation occurs to leave a clear yellowish fluid, the *serum*. Removal of the available calcium ions by means of citrate, various organic calcium chelators (EDTA, EGTA), and oxalate, prevents clot formation.

Blood as a Tissue

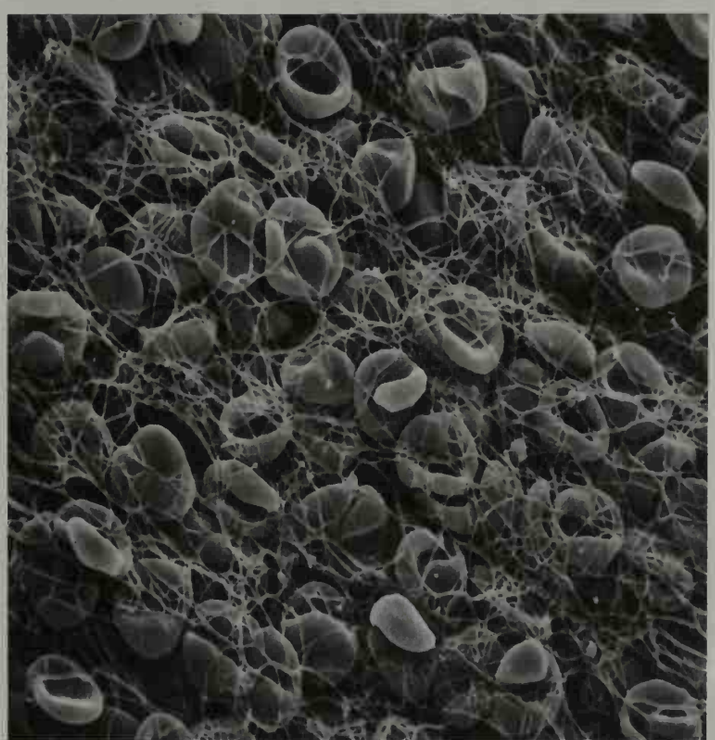
Blood has many affinities with connective tissue, as, for instance, in the mesenchymal origin of its cells, the free exchange of leucocytes with the connective tissues, and the relatively low cell:matrix ratio. Many of the plasma substances and some of the cells, however, arise from a variety of sources (e.g. the proteins associated with clotting are formed in the liver), and so blood is really a composite tissue pool.

The Formed Elements of Blood



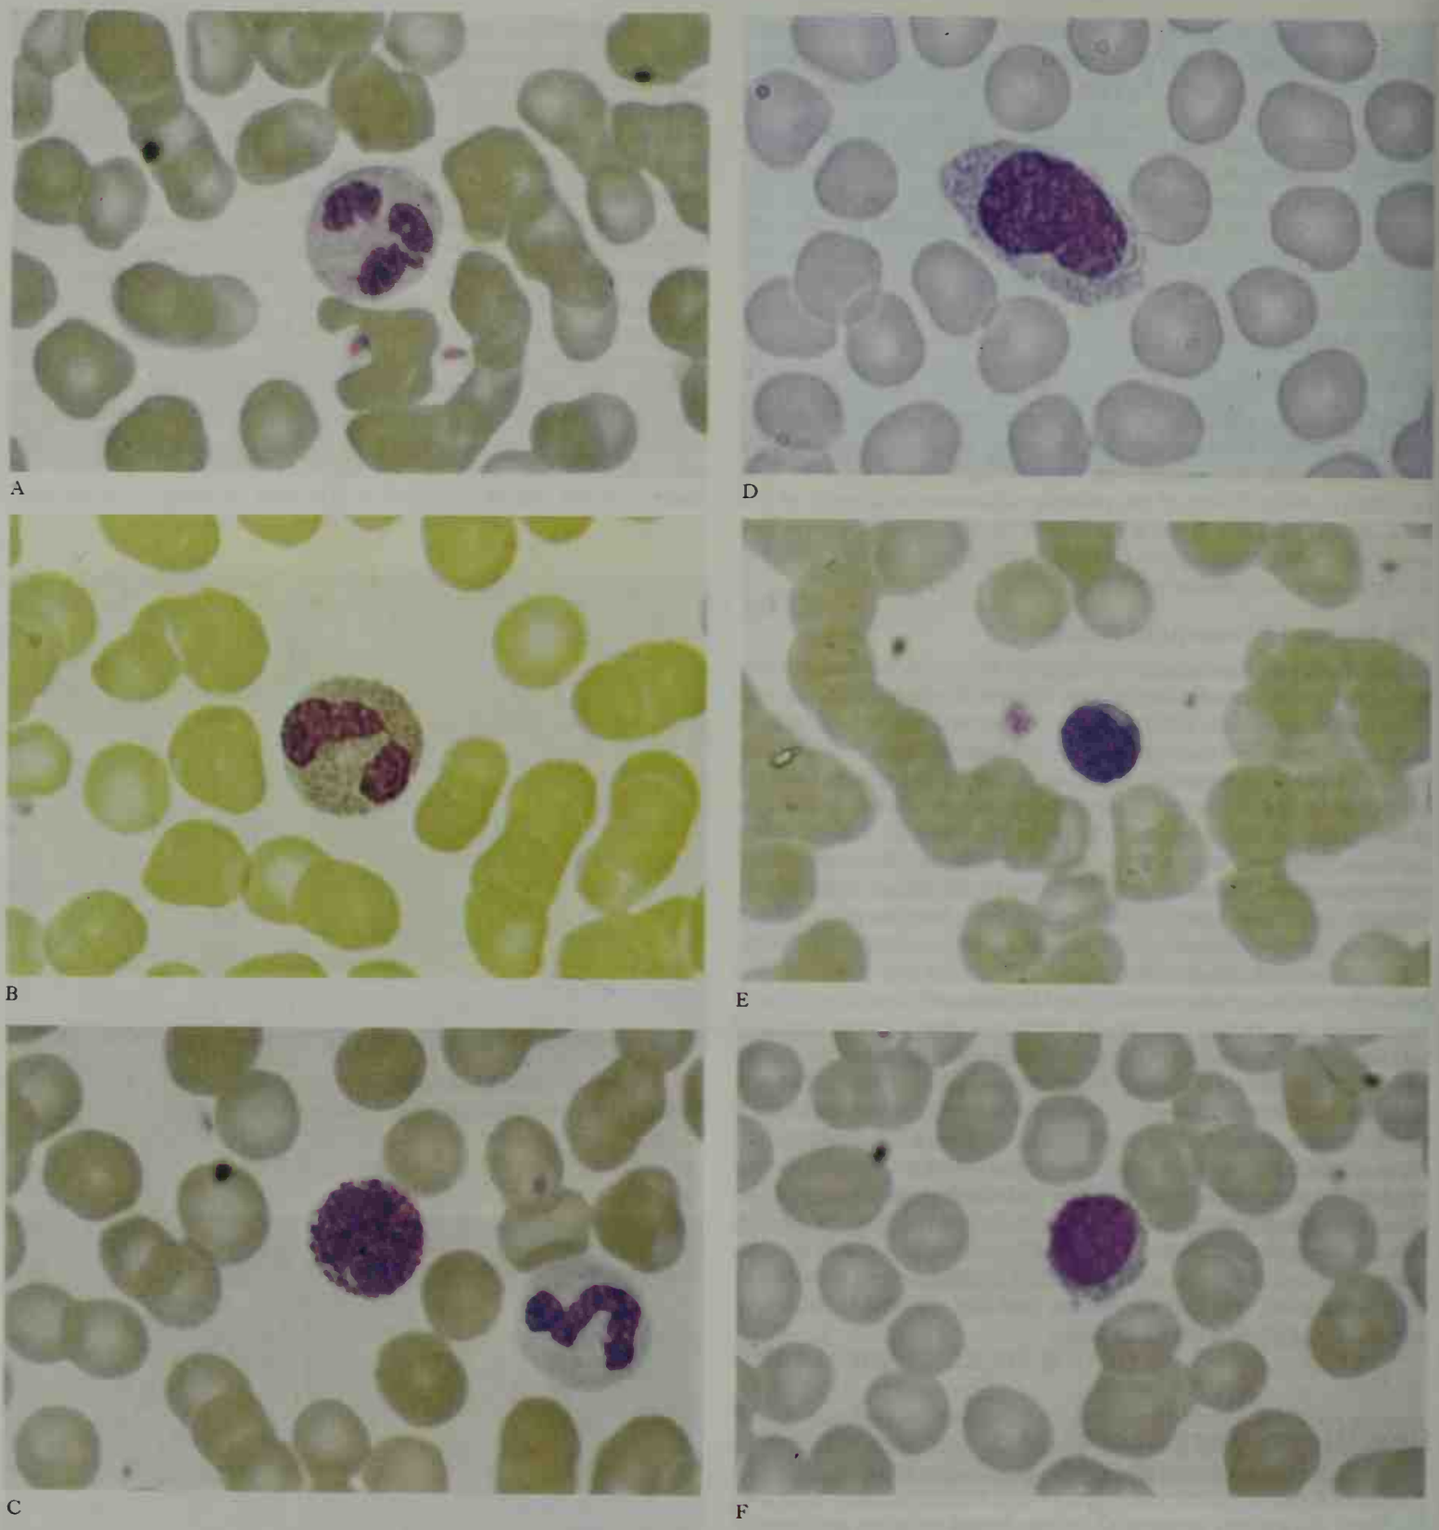
Blood contains three groups of formed elements: red and white blood corpuscles, and platelets (*see* Wintrobe 1974, for a detailed description of these cells). Some structural aspects of these elements are visible in fresh blood, but many others are seen only in fixed and stained specimens. The examination of blood cells is of considerable clinical importance since their numbers, proportions of different cell types, and structure are valuable indicators of pathological changes in the body. Amongst other techniques, the Romanowsky methods of staining are particularly valuable and are widely used in clinical laboratories. These methods involve staining in aqueous solutions with methylene blue-eosin mixtures which colour both acidic dye binding and basic dye binding structures. The Giemsa and Leishman stains belong to this group. (It should be noted that throughout this section, the figures given for cell dimensions and numbers are approximate ranges only. The data provided by different authorities vary somewhat; further, the dimensions of some cells when measured in the fresh state are substantially smaller than when measured in a dried smear—with erythrocytes the converse applies. In particular the upper limit for the diameter range of the small lymphocyte given here—10 μm—is rather higher than that chosen by some workers, who hold that cells over 8 μm in diameter should not be so classified. The differences stem from methodological and site variations, and the somewhat arbitrary nature of the chosen dividing line.)

Red Blood Corpuscles



The red blood corpuscles (*erythrocytes* or *red blood cells*) (**1**.67, 68, 69) form the greater proportion of the blood cells (99 per cent of the total number), with a count of $4{\cdot}1–6{\cdot}0 \times 10^6/mm^3$ in adult males and $3{\cdot}9–5{\cdot}5 \times 10^6/mm^3$ in adult females. Each cell is a biconcave disc with a diameter of 6·3–7·9 μm (mean 7·1 μm) and a rim thickness of 1·9 μm; in wet preparations the mean diameter is 8·6 μm. Erythrocytes lack nuclei and are pale red by transmitted light with paler centres because of their biconcavity. They show a tendency to adhere to one another by their rims to form loose piles of cells (*rouleaux*), a character probably determined by the properties of their cell coat. In normal blood a few assume a shrunken star-like, *crenated* form (**1**.67A), a shape which can be reproduced by placing normal biconcave erythrocytes in a hypertonic solution, which results in osmotic shrinkage. Such cells are called *echinocytes* (Bessis 1973). In hypotonic solutions erythrocytes take up water and become spherical and may eventually lyse to release their haemoglobin (*haemolysis*); they are then termed *red cell ghosts* (erthrocytic umbrae).

Erythrocytes are bounded by a plasma membrane and consist internally of a single protein, haemoglobin, apart from a few remnants from their initial development. The plasma membrane of erythrocytes has received much attention because of the ease with which it can be obtained for analysis in quantity (Bretscher and Raff 1975). It is about 60 per cent lipid and glycolipid, and 40 per cent protein and glycoprotein. More than 15 classes of protein are present, including two major types. Firstly, the glycoprotein *glycophorin* (of about 50,000 daltons molecular weight) spans the membrane, and its negatively charged carbohydrate chains project from the outer surface of the cell, conferring most of the fixed charge on the cell exterior by virtue of its sialic acid groups. Secondly, the 'Band 2' protein which may bear some antigenic groups; the ABO antigens (p. 68) are all glycolipids (Race and Sanger 1975). Other proteins include several enzyme systems, some concerned with ionic regulation, others with the addition of lipid to the cell membrane from serum lipid (this is necessary because the cell does not possess its own synthetic apparatus).



The shape of the erythrocyte is largely determined by the protein *spectrin* (a name which reflects its biochemical preparation from red cell 'ghosts') which is attached to integral membrane

1.67A Fresh preparation of living erythrocytes showing rouleaux formation and red pigmentation. Magnification × 500.

1.68A–F Blood cell types stained in smeared preparations by the Giemsa method. Erythrocytes are shown in all figures which also demonstrate other cell types: (A) neutrophil leucocyte and platelets; (B) eosinophil leucocyte; (C) basophil leucocyte with prominent densely staining cytoplasmic granules, and neutrophil leucocyte; (D) monocyte; (E) small lymphocyte and (F) medium-sized lymphocyte. Material kindly provided by Dr. J. P. Black of Guy's Hospital Haematology Dept.

proteins on the inner surface of the cell membrane, so forming a stabilizing network of attachments. This considerably stiffens the membrane, an effect which is aided by the large amount of cholesterol in the membrane itself. Red cells can thus regain their shape and dimensions after passing through the lumina of the finest ramules of the blood-vascular system; microscopic examination has shown that erythrocytes often pass through capillaries flattened face-first, buckling somewhat to a shield-like shape (Brånemark 1972) rather than rolling up, as might be expected.

Haemoglobin is a globular protein with a molecular weight of 67,000, consisting of *globulin* molecules bound to *haem*, an iron-containing *porphyrin* group (Perutz *et al.* 1960). Each molecule is made up of four subunits, each in turn consisting of a coiled polypeptide chain with a cleft holding a single *haem* group. In normal blood, four types of polypeptide chain can occur, namely: α, β, γ and δ. Each haemoglobin molecule contains two α-chains and two others, so that several combinations, and hence a number of different types of haemoglobin molecule are possible. Haemoglobin A (HbA) which is the major adult class, contains 2 α- and 2 β-chains. Haemoglobin A_2 (HbA2), a minor component in adults, is composed of 2 α- and 2 δ-chains. Haemoglobin F (HbF), found in fetal and early postnatal life consists of 2 α- and 2 γ-chains. In the pathological condition *thalassaemia* only one type of chain is synthesized, so that a molecule may contain 4 α-chains (α-thalassaemia) or, more commonly, 4 β-chains (β-thalassaemia)—Haemoglobin H (Wintrobe 1974).

Each polypeptide chain is determined by a separate gene; a number of variant haemoglobins are known in which only one or a few amino acid residues are abnormal, reflecting slight alterations in the corresponding genes. In the Haemoglobin S of sickle-cell disease a single alteration in the β-chains (valine substituted for glutamine) causes a major alteration in the behaviour of the red cell and its oxygen-carrying capacity which, however, may confer some protection against malarial infection, where the disease is endemic. Other common variants include Haemoglobins C and D (*see* Williams *et al.* 1977). The oxygen-binding power of haemoglobin is provided by the iron atoms of the haem groups, and these are always maintained in the ferrous (Fe^{++}) state by the presence of glutathione.

In addition to haemoglobin, erythrocytes possess a number of enzyme systems, notably those concerned with glycolysis and ionic transport, which together maintain low sodium levels within the cell against diffusion gradients, and thus create the appropriate conditions of *p*H and ionic strength for the normal functioning of haemoglobin. As intimated above, glutathione metabolism is also active. Although, of course, in the absence of a nucleus and ribosomes, no protein synthesis takes place in mature erythrocytes, lipid in the plasma membrane can, however, be replaced to some extent from circulating serum lipids, by the activity of membrane enzyme systems.

The iron-containing compound *ferritin* is also often present in newly formed erythrocytes, as are also persisting remnants of the apparatus of protein synthesis (ribosomes and other RNAs) from the stage of differentiation of the cell in the bone marrow. After Romanowsky staining, the residual RNA of young erythrocytes causes a slight bluish tinge; with the supravital stain brilliant cresyl blue it forms a reticulum, giving the name *reticulocyte* to this type of cell. Later in maturation such evidences of basophilia disappear. Other inclusions may be present in red cells, particularly in pathological conditions; amongst these are nuclear remnants (*Howell-Jolly bodies*) and altered haemoglobin (*Heinz-Ehrlich bodies*).

Life Span and Destruction

Erythrocytes which have been labelled radioactively or antigenically and then injected into the circulation, have been shown to last between 100 and 120 days before being destroyed (Berlin *et al.* 1959). As erythrocytes age they become increasingly fragile and their surface charge changes as their content of negatively charged membrane glycoproteins are progressively reduced (Marikovsky and Daron 1969). Perhaps as a result of the changes in charge they are eventually ingested by the macrophages of the spleen and liver sinusoids without previous lysis, and are then hydrolysed (Harris 1963). Here, the haemoglobin is broken into its globulin and porphyrin moieties; the globulin is then further degraded into its constituent amino acids which pass to the general amino-acid pool of the body. The iron is removed from the porphyrin and can be used either directly in the synthesis of new haemoglobin in the bone marrow, or stored in the liver as ferritin or haemosiderin; the remaining haem portion is converted in the liver to bilirubin and is then excreted in the bile.

Red cells are produced by the bone marrow (p. 66) and are destroyed at the rate of about 5×10^{11} cells a day.

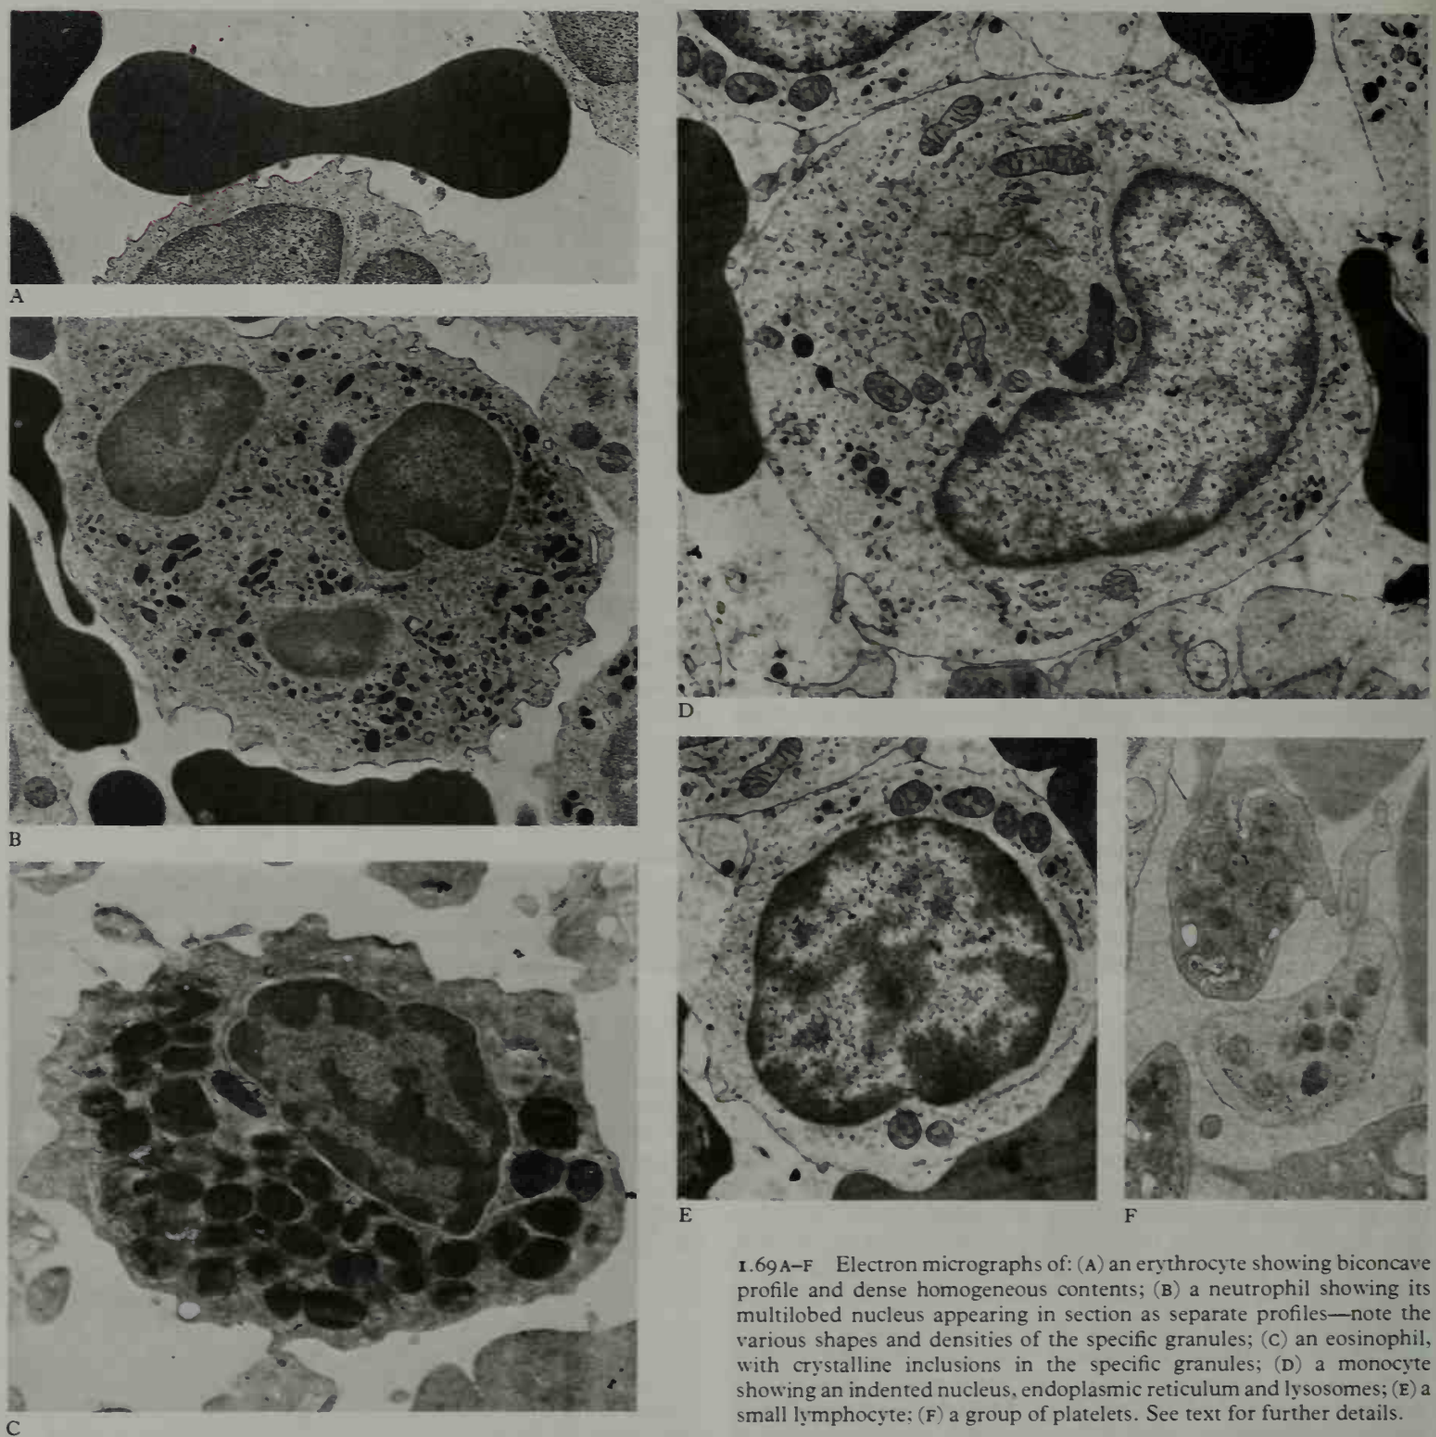
Fetal erythrocytes differ markedly from those of adults, up to the fourth month of development, in that they are larger (10 μm), are nucleated, and contain a somewhat different type of haemoglobin (Hb-F). From this time they are progressively replaced by the adult type of cell.

The Leucocytes

Leucocytes (*white blood corpuscles* or *cells*) belong to at least five different categories, distinguishable by their size, nuclear shape and cytoplasmic inclusions (1.68, 69, 72). These types of cell fall into two main divisions, namely those with prominent stainable cytoplasmic granules, the granulocytes, and those without, the agranulocytes.

The granulocytes or *granular leucocytes* are all closely related developmentally; all possess irregular or multilobed nuclei and are often termed **polymorphonuclear leucocytes** for this reason. This group is comprised of three types of cell, the granules of which give different staining reactions with the Romanowsky dyes: they are *acidophil* (or *eosinophil*) leucocytes with granules which bind acidic dyes such as eosin, *basophil* leucocytes the granules of which bind basic dyes (methylene blue) strongly, and *neutrophil* leucocytes whose granules stain weakly with both elements by a different type of reaction (*see* Wintrobe 1974).

NEUTROPHIL LEUCOCYTES



Neutrophil polymorphonuclear leucocytes (*neutrophils*, *neutrophiles*, *heterophile leucocytes*, or '*polymorphs*') form the largest proportion of the leucocytes (60–70 per cent, with a count of 3,000–6,000/mm^3). In dried smears, where the cells have flattened, they have a circular profile with a diameter of 10–15 μm. In the living state the cells may be spherical whilst passively circulating, but can flatten and become actively motile on contact with a suitable surface.

Within the cytoplasm the numerous granules give a variety of colour shades ranging from violet to pink when stained with Romanowsky stains such as Wright's and May-Grünwald-Giemsa, which are commonly employed in haematology. Under the electron microscope, too, the *granules* are heterogeneous in size, shape, and content (*see* e.g. Zucker-Franklin 1967), but all of them are membrane-bound bodies containing hydrolytic enzymes, that is, they are various species of lysosome. Two major categories can be distinguished according to their developmental origin (Bainton *et al.* 1971). Firstly, *non-specific* or *primary granules* which are formed early in neutrophil genesis (p. 67); these are relatively large (0·5 μm) spheroidal bodies containing peroxidase, acid phosphatase, and several other enzymes. With light microscopy they stain strongly with neutral red and azure dyes. Secondly, *specific* or *secondary granules*, formed a little later, and which assume a wide range of shapes including spheres, ellipsoids and rods. These contain alkaline phosphatase, collagenase, and aminopeptidase, all of which are lacking in the primary granules. The secondary granules, however, lack peroxidase and acid phosphatase. Some enzymes such as lysozyme are present in both. The presence of these lysosomes correlates well with the phagocytic activity of neutrophils.

In *mature neutrophil* granulocytes the nucleus is characteristically multilobate with up to six segments joined by narrow nuclear strands (the *segmented* stage). Less mature cells have fewer lobes, the earliest to be released under normal conditions being *juveniles* (*band*, or *stab cells*) in which the nucleus is an unsegmented crescentic band. In certain clinical conditions, even earlier stages in neutrophil formation, with indented or rounded nuclei (*metamyelocytes*, or *myelocytes*—p. 64) may be released from the bone marrow. In mature cells the edges of the nuclear lobes are often irregular; in females about 3 per cent (range 1–17 per cent) of the nuclei of neutrophils show a conspicuous 'drumstick' formation which represents the sex chromatin of the inactive X chromosome (*Barr body*)—see also p. 34.

Mitochondria, a Golgi complex, a sparse endoplasmic reticulum, and glycogen are present in the cytoplasm. A conspicuous array of microtubules is often seen between the 'arms' of the nucleus, and it is interesting that locomotion of neutrophils is in the direction in which the free arms point.

Neutrophils form an important element in the defence systems of the body (*see* Wintrobe 1974); they can engulf microbes and particles in the circulation and, after squeezing between the endothelial cells lining capillaries or venules, can perform local phagocytosis in the extravascular tissues, wherever it is needed. The engulfing of foreign objects is followed by digestion through fusion of the phagocytic vacuole, first with primary granules (the *acid phase* of hydrolysis), then with the secondary granules (the *alkaline phase*), any undigested remains being finally either egested, or stored. Although phagocytosis is supported by anaerobic glycolysis, lysosome action requires oxygen, so that neutrophils that are active in defence have a high oxygen demand. Phagocytosis, or the release of granules, may be enhanced by the

See text for further details.

presence of antibodies attached to the surfaces of neutrophils, and which can bind specifically to target antigens, for example, a type of bacterium to which the body has previously been exposed. Opsonizing antibodies (*opsonins*—p. 62) coating the antigenic target may also promote phagocytosis. The antibodies in both cases are secreted by transforming lymphocytes (p. 61), and the neutrophil granulocyte is just one in a series of defensive cells which form an interrelated system for the elimination of foreign materials from the tissues (1.71).

After phagocytosis, the neutrophil's cytoplasmic granules gradually become used up, so that a marked reduction in their number (degranulation) occurs. Granules may also be discharged from the surface of the cell when it is suitably stimulated, to damage or kill neighbouring organisms or cells.

The numbers of neutrophil granulocytes in the blood vary considerably, often rising during episodes of acute bacterial infection, as they are released earlier in their formation by the bone marrow, and as granulocyte production rises. Once released into the blood they may circulate freely (the *circulatory pool*), or they may adhere to the walls of post-capillary venules and other vessels (the *marginal pool*) to re-enter the circulation when suitably recruited, for example, by brief exercise, or by exposure to noradrenalin. However, neutrophil granulocytes do not remain long in circulation since, after a short time (half-life 7·5 hours), they may either be destroyed, or pass through the endothelial walls to the extravascular tissues, engaging in defence; alternatively, after entering various secretory ducts, such as the bronchi, salivary gland ducts, and the urinary tract, they are lost to the body.

EOSINOPHIL LEUCOCYTES

These cells (*acidophil leucocytes*) are similar in size, shape and motile capacity to neutrophils; they number 100–400/mm³. The granules of the cytoplasm are uniformly large (0·5 μm) and give the living cell a slightly yellowish colour. With Romanowsky stains they are uniformly orange to red. The nucleus has two prominent lobes connected by a thin strand. Ultrastructurally, the cytoplasm is seen to be packed with specific granules (1.69C) which are spherical or slightly ellipsoidal. Each of these bodies is

bounded by a membrane and contains an amorphous material in which is embedded a prominent crystal; in man these crystals show a square lattice structure with a periodicity of about 4 nm. In other mammals the details of the granules vary somewhat. Several enzymes have been demonstrated cytochemically within the granules, including acid phosphatase, peroxidase, ribonucleases and cathepsin. They therefore appear to have a similarity to lysosomes. Mitochondria, endoplasmic reticulum and other cell organelles are similar to those of neutrophil granulocytes.

Eosinophil granulocytes are able to pass into the extravascular tissues from the circulation in the same way as neutrophils, when suitably stimulated. The total lifespan of the eosinophils is a few days, of which about 30 hours is spent in the circulation, and the remainder in the surrounding tissues.

The functions of the eosinophils are not yet fully understood, but since their numbers rise disproportionately to other leucocytes (an *eosinophilia*) in certain allergic disorders, and also in worm infestations, they seem to play a part in the immune system. They may be important in phagocytosing antibody-antigen complexes and fibrin, to concentrations of which they are attracted. They are also capable of engulfing bacteria and fungi, although this does not seem to be a major function. Recently, it has been shown that eosinophils can attach themselves to parasitic worms by cytophilic antibodies, and cause their destruction by liberating lysosomal enzymes on their surfaces.

BASOPHIL LEUCOCYTES

These are similar to neutrophils in size (10–15 μm) and shape, but form only a small proportion of the leucocytes (0·5–2 per cent) in normal blood, numbering from 25 to 200/mm^3 (**1**.68 c).

They are distinguished from the other leucocytes by their large (0·5–1·5 μm) basophilic granules, which vary greatly in number (10–100 in each cell), but they are usually conspicuous. The nucleus is less irregular than in other granulocytes and often presents an S-shaped form. Ultrastructurally, the basophilic granules appear as membrane-bound vesicles with densely stained contents showing a variety of crystalline, granular and lamellar inclusions. With light microscopy basophil cells are periodic acid-Schiff (PAS) positive, and with some dyes such as Azure A, they are *metachromatic* (i.e. they stain a different colour from that of the dye), both reactions indicating the presence of polysaccharides. Heparin, histamine and serotonin have also been shown to be present. All these features indicate a close relation to, or identity with, mast cells of the connective tissues, and it is probable that basophils are mast cells derived from bone marrow, although, since some histochemical findings suggest slight differences, definitive evidence is lacking. In normal blood the turnover time of basophils is long (9–18 months in mice), but like other leucocytes they can migrate from the circulation to the extravascular tissues when antigenically stimulated; under these conditions they release histamine and other inflammatory agents from their granules (p. 47).

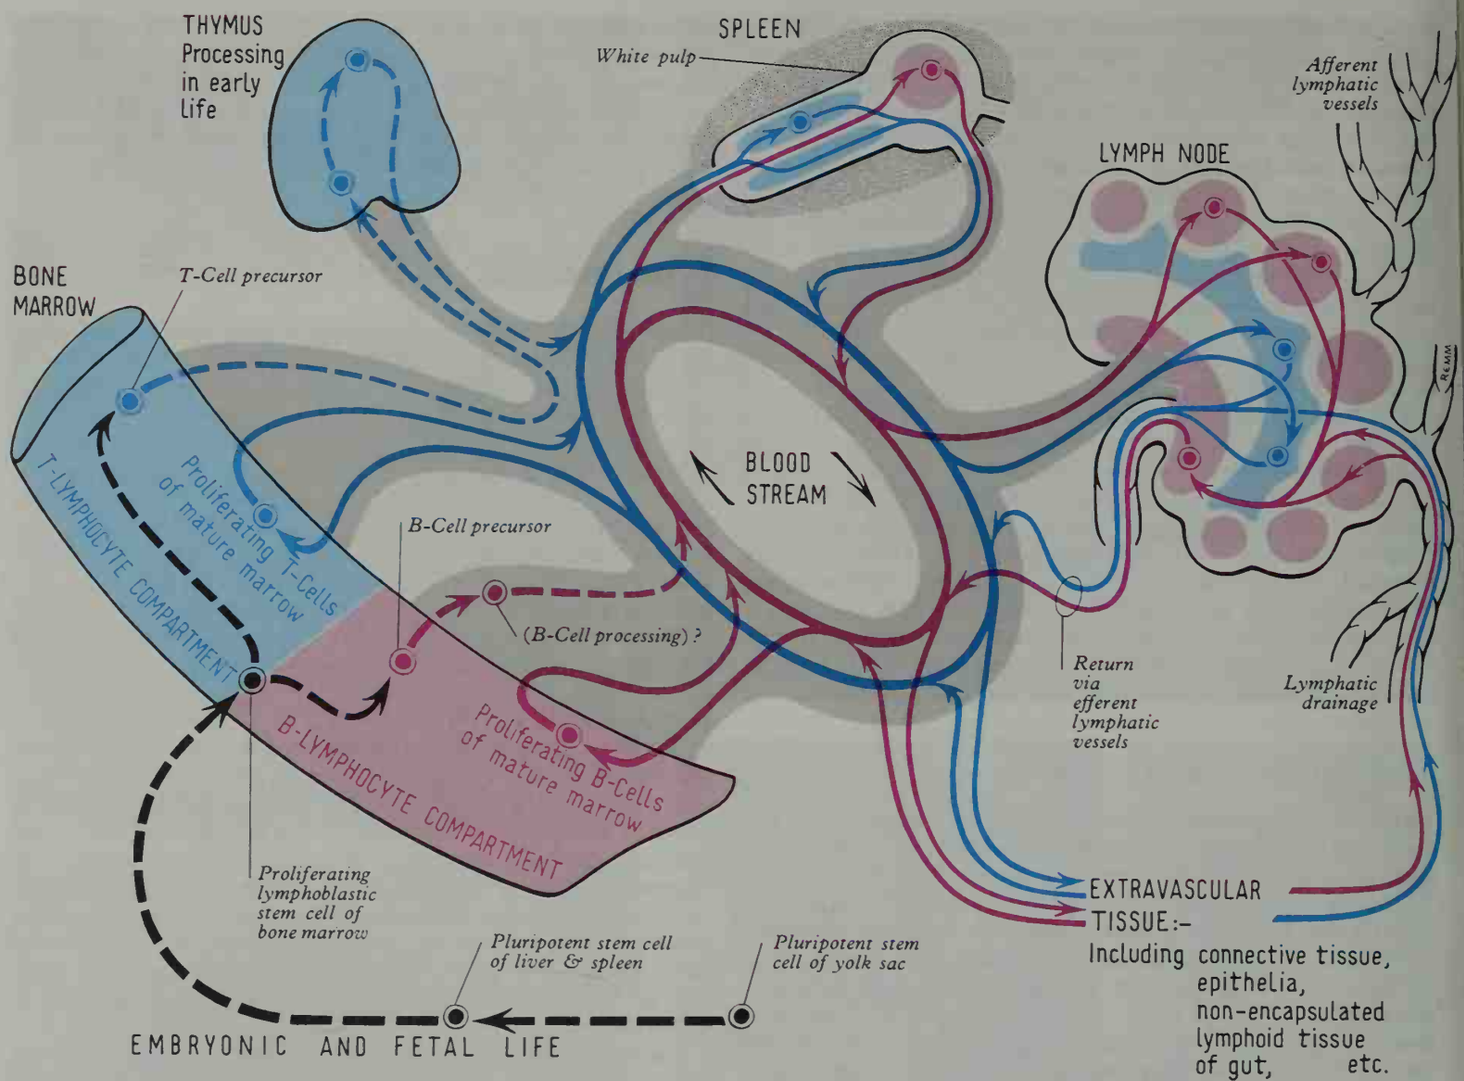
The agranular leucocytes are divided into two distinct groups, monocytes and lymphocytes, distinguishable on structural and functional grounds. Their nuclei are not lobulate, and both possess a moderately basophilic cytoplasm.

MONOCYTES

These are the largest of the agranular leucocytes (15–20 μm in diameter in smears) but they form only a small proportion of the leucocytes (2–8 per cent with a count of 100–700/mm^3 of blood). The nucleus, which is euchromatic, is relatively large, and has a characteristic indentation on one side. The cytoplasm forms a wide rim around the nucleus, near the indentation of which lies a prominent Golgi complex and vesicles stainable with neutral red. Ultrastructurally (Cawley and Hayhoe 1973), many lysosomes are seen to be present, together with some peripheral rough endoplasmic reticulum. Mitochondria are quite abundant, reflecting the highly motile nature of the cell. Monocytes are actively phagocytic.

All of these characteristics are similar to those of macrophages of connective tissues, spleen, liver, lung, peritoneal cavity, and nervous tissue; this series of related cells is known as *mononuclear phagocytes* (corresponding approximately to the reticulo-endothelial system of former times) with which they are believed to be identical (p. 765), the circulating monocytes becoming macrophages in the extravascular tissues.

Lymphocytes



These cells (**1**.68, 69) are the second most numerous type of leucocyte, forming 20–30 per cent of all white cells and giving a total count of 1,500–2,700/mm^3. Like the other leucocytes already described, they are also found in extravascular tissues; however, they differ in being formed in large numbers outside the bone marrow as well as within it and, accordingly, constitute a widely distributed *lymphoid system* which will be described in detail in *Section VI* p. 766.

Until relatively recently, lymphocytes were regarded as cells of little functional importance and, perhaps, representing degenerative stages of some other type of blood cell. The work of Miller, Yoffey, Gowans and others in the 1950s, however, showed that these cells play a vital part in the body's defences, and since that time they have come to be the focal point of modern immunology (*see* e.g. Roitt 1977).

The term 'lymphocyte' is customarily reserved for agranular leucocytes in the 5–15 μm diameter range, but they do not show the phagocytic activities characterizing monocytes, and the granular leucocytes. They are often classified as 'small' or 'large' although there is a continuous spectrum of sizes between these extremes, reflecting the ability of the small cells to transform into the large ones. Besides those cells engaged in defence, some of the small elements of similar appearance, are known to be circulating *stem cells* for other cell lineages of the haemal series, which can only be distinguished from the 'true' lymphocytes by methods of tissue culture.

Small lymphocytes, which are in the great majority in normal blood, have a rounded, densely-staining nucleus containing coarse strands of heterochromatin (a *leptochromatic nucleus: leptos*=threadlike) and one or more inconspicuous nucleoli. The cytoplasm forms a narrow rim around the nucleus and stains light blue with Romanowsky dyes. Under the electron microscope, few organelles appear in the cytoplasm, which contains only a small number of mitochondria, single, unattached ribosomes (monosomes), and occasional elements of agranular or granular endoplasmic reticulum; all of these features are signs of low metabolic activity. Small lymphocytes are, however, freely motile and can pass between endothelial cells to escape from (or enter) the vascular system, so that they are frequent in extravascular tissues where they may make extensive migrations, even passing into the body's secretions such as saliva.

Larger lymphocytes in the circulation, sometimes known as *lymphoblasts*, are a mixture, firstly, of *immature cells* capable of becoming small lymphocytes—a step which usually occurs in the lymphoid system—and secondly, of *transforming lymphocytes* which are formed when small lymphocytes become functionally active after antigenic stimulation. Both types of large lymphocyte are actively engaged in synthesizing protein, and hence possess a partly euchromatic nucleus with a prominent nucleolus, and a wide perinuclear zone of strongly basophilic cytoplasm. Ultrastructurally, polyribosome groups are numerous; in B-lymphocytes (*see* p. 61) these are chiefly attached to the endoplasmic reticulum, in which antibodies are synthesized prior to their secretion. In T-lymphocytes, and immature lymphoblasts, ribosomes are mostly unattached. The nuclei of both B- and T-lymphocytes, although more euchromatic than those of small lymphocytes, still retain a peripheral rim of heterochromatin, usually arranged in blocks not unlike the figures around a clock face, or the spokes of a wheel (the 'radkern' form), indicating that only a small part of the genome is active, as one might expect in a cell synthesizing a restricted range of specific proteins. In the most *immature* cells the nucleus is evenly euchromatic, reflecting the wide variety of proteins being made.

1.70 A diagram depicting current views of the origins and circulation of the two major classes of lymphocyte from the bone marrow to the peripheral lymphoid tissues. B-lymphocytes are shown in red, T-lymphocytes in blue.

The lifespan of lymphocytes varies from a few days to many years, and so we can distinguish between *short lived* and *long lived* lymphocytes. Those with long lives are almost certainly of great significance in *immunological 'memory'* (*see* p. 62).

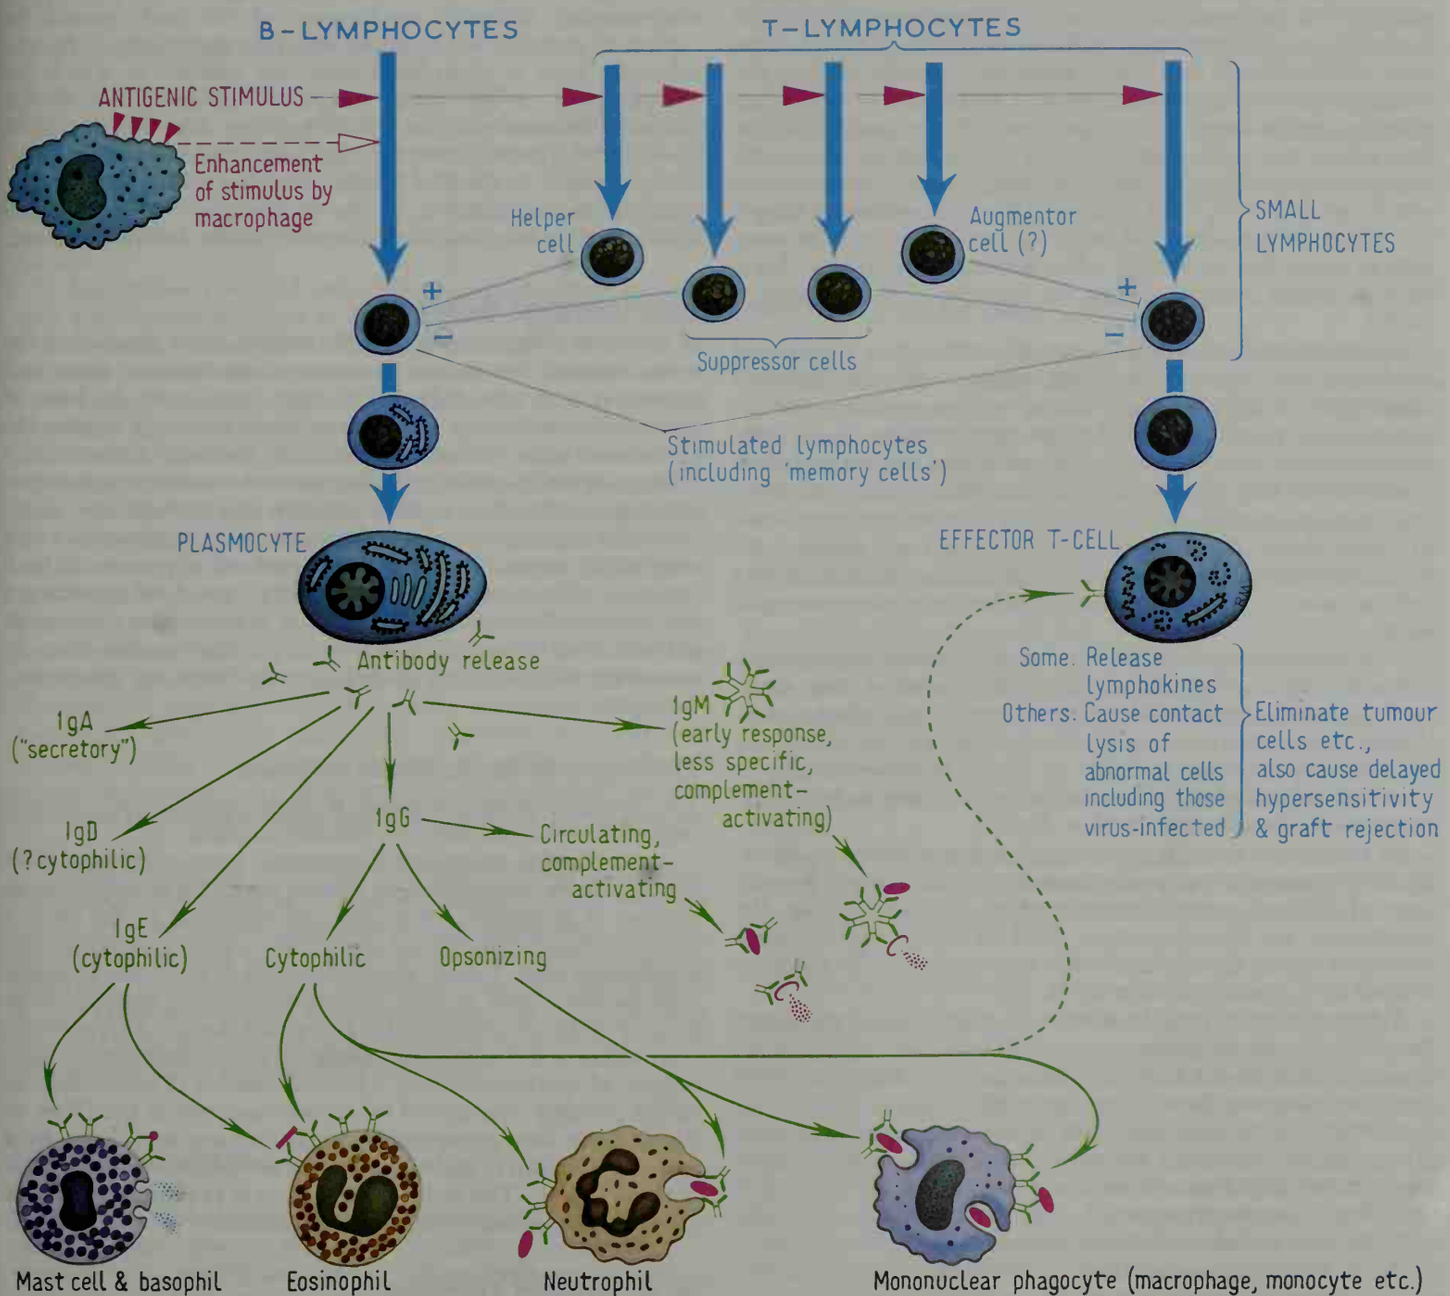
Origins of Lymphocytes

Much of the knowledge of lymphocyte life history (1.70, 71) has come from experimental situations which include the tracing of radioactively or genetically labelled cells—the latter involving transfusion of lymphocytes with chromosomal abnormalities into normal but inbred strains of laboratory animals. Other experiments are based on the sensitivity of lymphocytes to ionizing radiation, the various components of the lymphocytic system being eliminated by selective irradiation, accompanied by appropriate transfusions or transplants of lymphopoietic tissue from bone marrow, lymph nodes, thymus and so forth. Thirdly, selective surgical removal of various lymphopoietic components and the removal of lymphocytes from the lymphatic channels has been carried out. In addition to these, a whole battery of immunological techniques has been brought to bear on the problem, including immunoassay, tissue culture methods, techniques for the localization of antibodies by their reactions with antigens or antigen-antibody complexes previously labelled with fluorescent compounds or electron-dense atoms (or enzymes) with subsequent examination by fluorescence and electron microscopy respectively.

The picture which has emerged is still far from clear; nevertheless tentative views can be expressed at this stage.

Lymphocytes originate in the embryo from mesenchymal cells of the yolk sac initially, and later in the liver and spleen. These primitive *stem cells* subsequently take up residence in the bone marrow, which becomes the only site of stem cell proliferation after birth. Similar considerations apply to the haemopoietic *colony-forming units* (*see* p. 66). Such stem cells divide unequally to throw off lymphoblasts which again divide and transform into small lymphocytes. Some of these pass in the blood circulation to the thymus where they migrate into the lobules and divide repeatedly (p. 780); the resulting small thymus-processed *T-lymphocytes* then re-enter the bloodstream and can return to the bone marrow or to the *peripheral lymphoid tissues* (tonsils, lymphoid tissue of the alimentary and respiratory tracts, lymph nodes, spleen), which they enter by migrating through the walls of the capillaries or post-capillary venules. Here, the cells are found in the sinusoids of the lymph nodes and in the loose superficial tissue of the lymph nodes (i.e. paracortical areas), and *periarteriolar white pulp* of the spleen, that is, in both cases, tissue neighbouring the *germinal centres* (p. 768). They can enter the general flow of lymph, returning to the bloodstream via the thoracic and right lymphatic ducts and the brachiocephalic veins, and so eventually back to the lymphoid tissues again. This *circulation of lymphocytes* (see also p. 773), first established by Gowans, is responsible for the large number of lymphocytes found in the blood (1.70). When stimulated antigenically such lymphocytes enlarge and multiply, and their progeny are capable of interacting with tissue cells (*vide infra*).

The *B-lymphocytes* do not pass through the thymus, but move directly via the circulation to the general lymphoid tissues, where they settle down. *En route*, they may undergo a phase of differentiation similar to that of the T-lymphocytes in the thymus, although it is not clear where this step might take place. Various sites have been suggested, including the intestinal lymphoid tissue, but as yet conclusive proof is not available. In



birds, B-lymphocytes are derived from a specialized diverticulum of the cloaca, called the *bursa of Fabricius* (giving this type of lymphocyte its title—the *bursa equivalent*—or *B*-lymphocytes, although subsequently it appears that such a prefix can be even more appropriately applied to denote the bone marrow origin of the B-cell class in mammals). On antigenic stimulation they multiply to form the *germinal centres*; such lymphocytes can, while still within the lymphoid tissues, or after further migration, transform into the large pyroninophilic (i.e. RNA-rich) plasma cell series, which produce antibodies in their extensive rough endoplasmic reticulum.

FUNCTIONING OF THE LYMPHOCYTIC SYSTEM

The lymphocytic cells, together with the phagocytes of the reticulo-endothelial system, are responsible for the defensive reactions of the body, the former by antibody formation, the latter by phagocytosis. These defences are directed against foreign invasion by bacteria, viruses, fungi, protozoa, helminth worms, etc., or their metabolites (toxins), and against any unwanted or abnormal materials within the body such as proteins and effete, neoplastic, or virally transformed cells.

B-lymphocytes can, when antigenically stimulated, proliferate and their progeny transform to larger cells (*plasmocytes*) which synthesize and secrete *circulating antibodies*; the latter chemically 'recognize' and bind specifically to foreign chemical substances (*antigens*) so as to inactivate them, or cause their destruction. Antibodies may circulate freely in the body fluids (*soluble antibodies*) or may be secondarily attached to a variety of defensive cells (*cytophilic antibodies*) to enhance their activities, or to enable them to carry out a wider range of functions (1.70, 71).

Chemically, **antibodies** (or *immunoglobulins*) are proteins with a molecular weight of 150,000–950,000 daltons. Each antibody molecule consists of four polypeptide chains, two of them long (about 15 nm: the *heavy* chains) and two shorter (*light* chains) all joined together by sulphydryl links. The whole molecule is Y-shaped, two of the arms of the Y being able to swing around a central hinge. One end of the molecule (the *Fab* fraction) is highly variable in its amino-acid sequences, and since this end is responsible for specific binding to antigens, there is a vast number of possible antibody varieties, each type being able to bind a specific antigen in a manner closely analogous to enzyme-substrate binding. The other end of the molecule, the *Fc* portion, is much less variable and can attach to certain cells if they possess

1.71 Schema of the origins and functions of the various subclasses of lymphocyte, including the role of antibodies (green) in inactivating antigens (red) and in initiating defensive activities in other classes of cell. A further subclass of defensive 'killer cells', active against virally transformed cells, has been demonstrated to act cooperatively with effector T-cells.

specific *Fc* receptors on their surfaces, thus conferring antigen-binding properties upon them by virtue of the free *Fab* ends of the bound antibodies.

At present, five classes of antibodies are distinguishable in the blood plasma and elsewhere. These are: Immunoglobulin G (IgG), which forms the bulk of circulating antibodies; Immunoglobulin M (IgM), which is often formed early in the immune response and is usually present as a pentamer, the monomers joined at the *Fc* ends into a star-like aggregate; Immunoglobulin A (IgA), which is present in secretions of the body, particularly saliva and other fluids of the alimentary tract; Immunoglobulin E (IgE), which is a cytophilic antibody found on the surface of mast and perhaps other cells; and finally Immunoglobulin D (IgD) of uncertain significance, although believed to be important in the ontogeny of the immune system. All classes can be soluble antibodies, and IgG and IgE can also be cytophilic (*vide infra*).

The defensive functions of antibodies are numerous. They can *agglutinate* antigens by forming cross-links between them, so rendering them inactive as infective agents (e.g. viruses). After binding an antigen they may also co-bind *complement*, a protein complex in plasma, which punctures cell membranes, so causing the lysis of bacteria and other cells attacked by antibody. They may also bind to antigens after attachment by their 'safe' *Fc* ends to other defensive cells which are thus armed to detect, adhere to, and ingest or enzymatically damage foreign bodies; examples are macrophages and neutrophils both of which bear *Fc* receptors on their surfaces. Such cell-bound antibodies can also activate the complement complex to cause lysis of bacteria, etc. Antibodies may first coat an antigen (*opsonizing antibodies* or *opsonins*) before they attach to a macrophage, thereby stimulating its phagocytic capacity. Cytophilic antibodies may cause the activation of cells in other ways when they bind antigens. Thus, IgE antibodies trigger the release of histamine and other vasoactive agents from mast cells to which they are bound, when activated by antigens; this is seen in certain types of allergy, for example to the proteins of pollen.

B-lymphocytes, themselves, can be activated to divide and transform into antibody-secreting plasma cells by antigenic stimulation of cytophilic IgG bound to their surfaces, and T-lymphocytes are also activated in the same manner. In all these cases it should be emphasized, the antibodies are derived from transforming B-lymphocytes (including plasma cells) and come to be attached to other cells only after passing into the tissue fluids or blood. Some B-lymphocytes may also act to *'suppress'* the transformation of other types of B-lymphocyte, whilst yet others carry a *'memory'* of previous reactions of the immune system (*vide infra*).

When circulating antibodies bind to antigens they form *immune complexes* which, if present in abnormal quantities, may cause pathological damage to the vascular system and other tissues either, as in some types of glomerulonephritis, by interfering mechanically with permeability to fluids; or alternatively, by causing local activation of the complement system to attack cell membranes, thus causing vascular disease.

In pregnancy some IgG is transferred across the placenta, conferring a measure of *passive immunity* on the fetus; but in the case of Rhesus factor incompatibility, it brings about the destruction of Rhesus-positive fetal erythrocytes. In some mammals (oxen, sheep), antibodies are transferred in the first-formed milk (colostrum) after birth.

T-lymphocytes include subclasses of cell, all of which are derived from thymus-processed precursors. These cells carry out a number of distinct activities, including a type of defence which does not depend directly on antibody attack (*cell-mediated immunity*), and various *controlling roles* in the immune system. Those engaged directly in defence (termed by some, *effector cells*) are stimulated by a suitable antigen to reproduce and then grow into large lymphocytes which may either release cytotoxic substances.(*lymphokines*) into the neighbourhood of the antigenic body, or, alternatively, cause its destruction by cellular adherence to it with the subsequent release of toxic materials at short range. They may also in some way 'arm' other cells (e.g. macrophages, or the recently described *'killer cells'*) to carry out a similar aggressive, cytotoxic operation. Lymphokines are non-antibody substances with a molecular weight of from 20,000 to 80,000 daltons, and appear to consist of several types of molecule. In addition to their cytotoxicity they can also affect the migration of macrophages, neutrophils, and eosinophils, stimulate the mitosis of other lymphocytes, and also increase capillary permeability: all these activities of lymphokines enhance the effectiveness of defensive responses.

The type of immunity mediated by T-lymphocytes thus appears to be chiefly concerned with the elimination of foreign or abnormal eukaryote cells, including virus-infected cells, fungi, some protozoa (e.g. trypanosomes), neoplastic cells, and, unfortunately for medicine, foreign tissues in grafts (if their antigens are not sufficiently closely matched with those of the recipient). Cell-mediated immunity is also seen in such responses as delayed hypersensitivity.

Controlling functions of T-lymphocytes include *'helper'* actions to enhance the responses of B-lymphocytes and other T-lymphocytes, and *'suppressor'* effects which may inhibit the transformation of some classes of B- and T-cells. Finally, a proportion of T-lymphocytes are *memory* cells, able to respond rapidly to those antigens to which the body has previously reacted, as also in the case of some B-lymphocytes noted above.

Although the plethora of activities carried out by lymphocytes seems highly complex, it is to be expected that the potent and wide-ranging defensive mechanisms of the body should be subject to multiple strict checks, controls and balances. As yet, relatively little is understood about the manner in which the various parts of the whole system of cellular and chemical defences are *integrated*, but it is increasingly clear that they must be viewed as a *single system* of great efficiency and elegance. When, however, such integration breaks down, the effects may be far-reaching as, for example, in the wide variety of *auto-immune diseases*, and in neoplasia of the immune system, such as myeloma.

Immunological Memory

If after one antigenic response the body is again exposed to the same antigen, the second response is much more rapid and extensive, even after a period of years; this forms the basis of clinical immunization. This phenomenon evidently implies the presence of some type of immunological 'memory'. Experiments with isotopically labelled materials show that macrophages ingest antigens or bind them to their surfaces, and perhaps alter them, thereafter passing the processed antigen on to lymphocytes which may either respond immediately or, perhaps as progeny of such activated cells, remain as 'memory cells' capable of mounting a much more efficient defensive train of reactions on subsequent antigen stimulation. Over-reactivity of this system may be associated with various types of hypersensitivity, e.g. anaphylactic shock.

The Nature of the Antigenic Response

The antibody-antigen reaction is *highly specific*, each antigen requiring its own antibody for binding to occur.

In the life of an individual an enormous range of antigens must impinge on the immunological system, requiring an equally large number of antibodies. How these are coded for by the limited genome of each lymphocyte constitutes a severe problem; two possibilities exist. Firstly, that the antigen in some way interacts with the cell's DNA or RNA to dictate the type of antibody to be formed by the lymphocytes (the *instructive theory*). Alternatively, it is proposed that from a wide range of types of lymphocyte, each capable of synthesizing only a limited number of antibodies (an ability possibly determined by *somatic mutation* of the DNA or RNA), only the appropriate lymphocytes are stimulated by a particular antigen to multiply and synthesize antibody (the *clonal selection theory*). The weight of evidence is at present greatly in favour of the second of these two possibilities.

Immunological Tolerance

Since lymphocytes react to foreign antigens and not usually to the proteins and carbohydrates of the body itself, there must be some mechanism which ensures the distinguishing of *self* from *non-self*,

that is an *immunological tolerance* to self. This may break down in auto-immune diseases such as Hashimoto's syndrome—self-immune destruction of the thyroid gland—and perhaps in disseminated sclerosis which causes demyelination of tracts in the central nervous system. Self-tolerance is achieved during fetal development in man, involving perhaps the action of the thymus (p. 782). Burnet has widened the theory of selective antigenic response (*vide supra*) to attempt an explanation for the mechanism of self-tolerance (the *clonal theory*), suggesting that those cell lines (*clones*) of lymphocytes which produce antibodies to the body's own tissues are suppressed in fetal life and are then no longer available to multiply at a later stage (*see* Burnet 1969; Edelman 1974). Self-tolerance may be extended to the antigens of a genetically identical or closely similar individual, so that grafts of tissue between monozygotic twins or inbred strains of animals may be accepted.

All tissues from within a particular species show antigenic classes similar to those seen in the erythrocytes (p. 68), and in man a number of *histocompatibility* tissue antigen groups have been recognized (p. 69). The success or failure of *isologous grafts* (i.e. grafts between genetically dissimilar members of the same species) depends largely on the degree of matching of these antigens between donor and recipient.

PLATELETS (THROMBOCYTES)

Blood platelets, also known as *thrombocytes*, (1.68, 69), are relatively small (2–4 μm), irregular or oval discs (Hovig 1968), present in large numbers (250,000–500,000/mm^3) in blood. In fresh blood samples they rapidly stick to one another, and to all available surfaces, unless the blood is previously treated with citrate or other substances which reduce the availability of calcium.

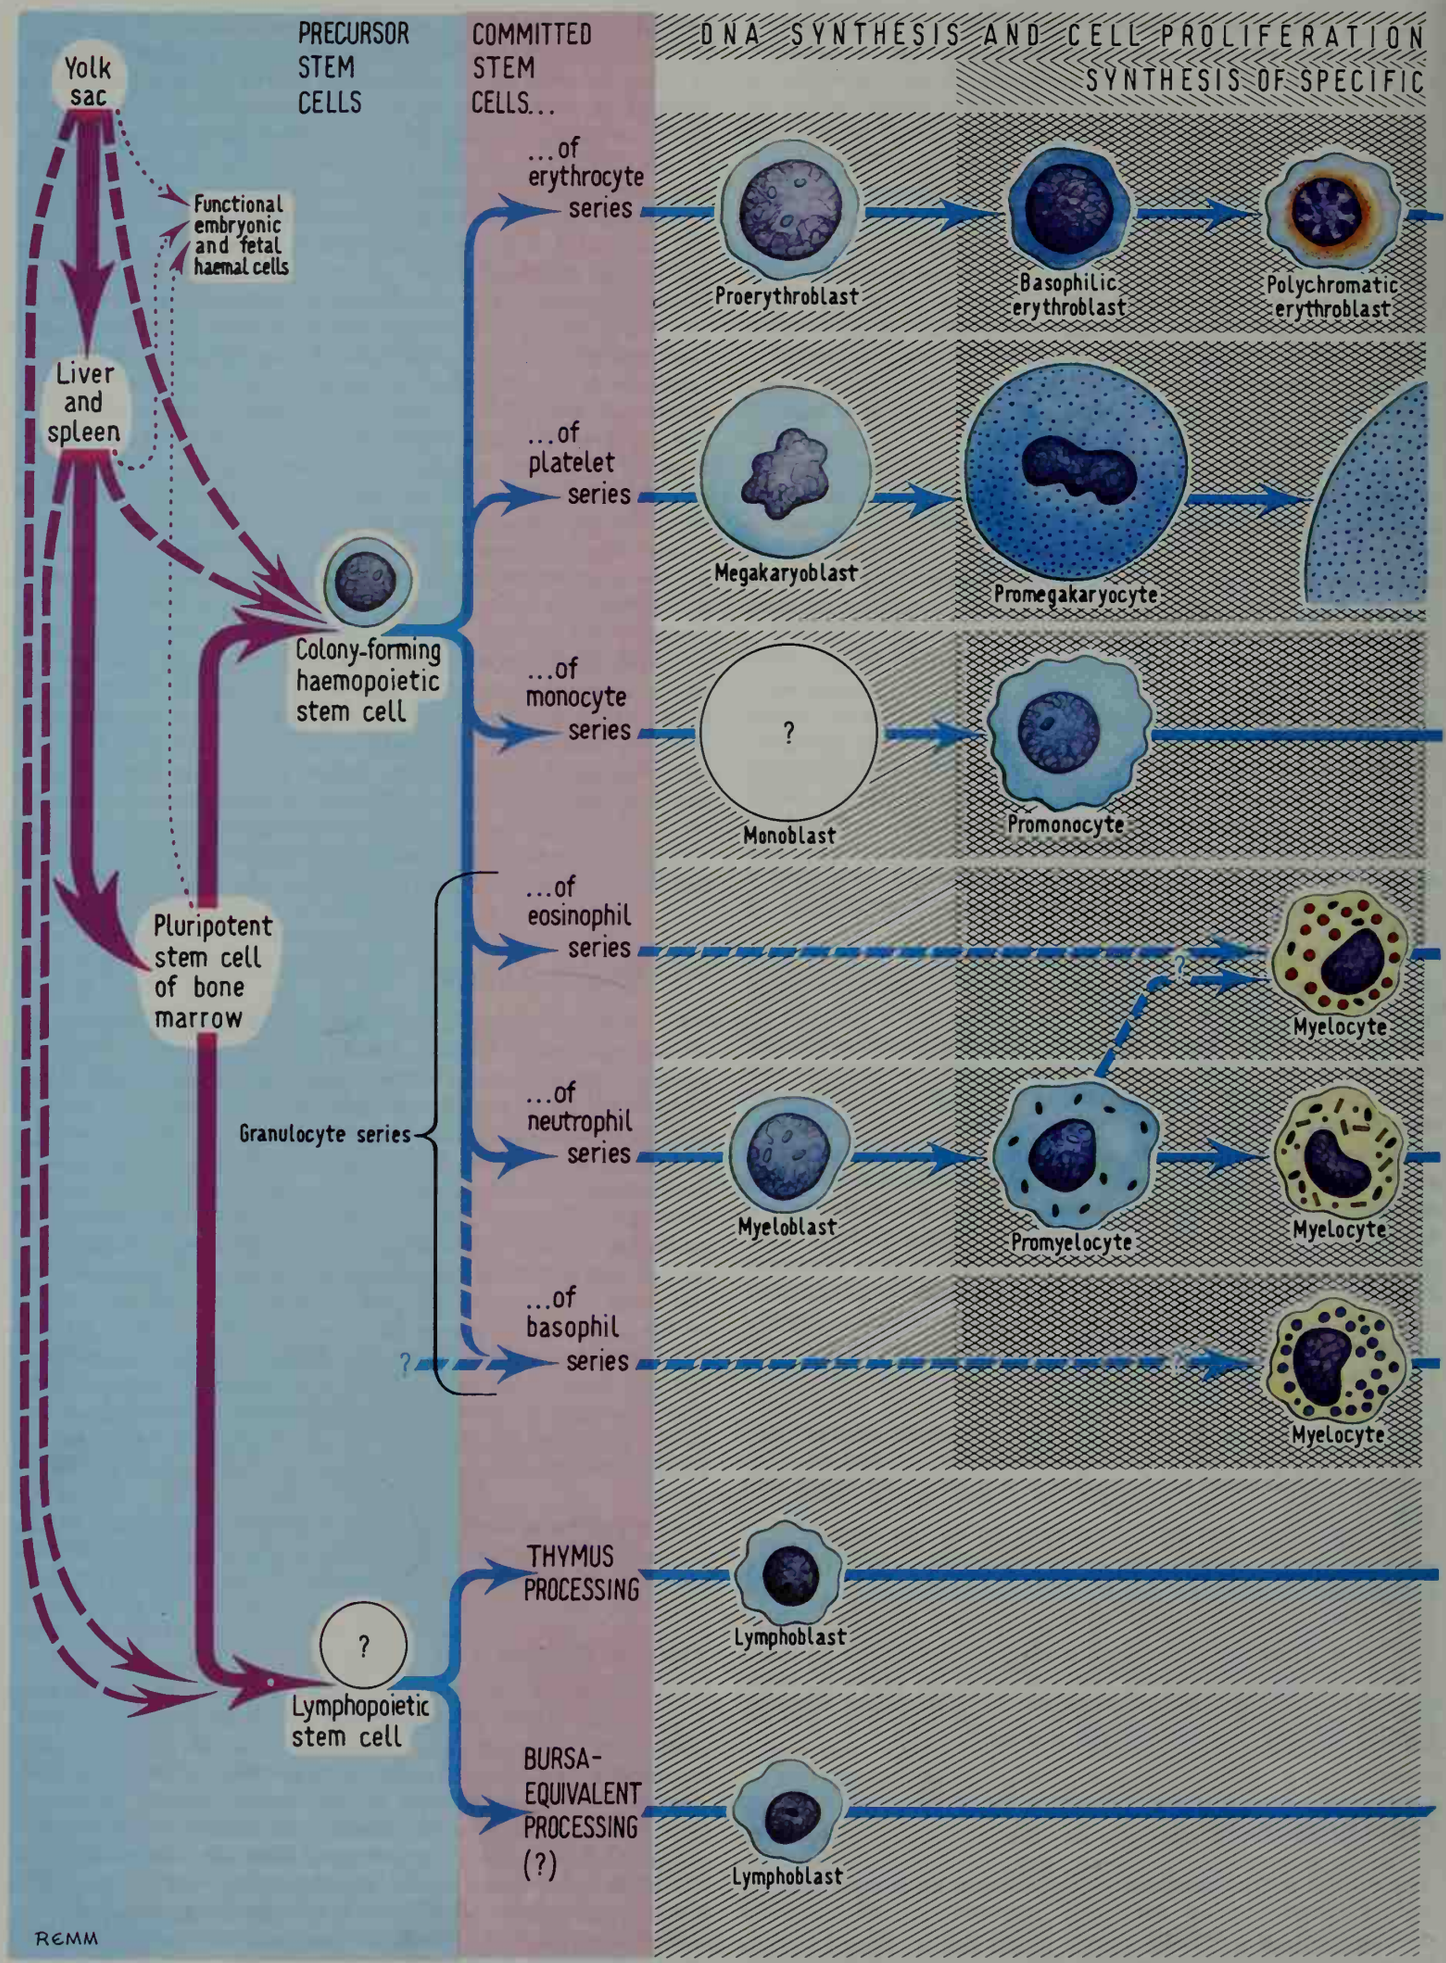
In Romanowsky-stained preparations, platelets show an outer clear zone (*hyalomere*) and an inner basophilic granular region (*granulomere*). Ultrastructurally each platelet is seen to be anucleate, unlike similar cells in submammalian groups of vertebrates (for which the term thrombocyte is perhaps best reserved). Each platelet is surrounded by a plasma membrane with a thick cell coat; the latter is probably the basis of the adhesive properties of platelets. Beneath the surface is a band of about ten microtubules which runs around the perimeter of the cell and probably gives rise to its characteristic shape. Associated with the microtubules are microfilaments of an actin-like protein, *thrombosthenin*, responsible for platelet contraction (Zucker-Franklin 1969). Within the cytoplasm are mitochondria, some endoplasmic reticulum, glycogen, and membrane-bound vesicles of varying density. These include large lysosomes rich in acid phosphatase, large dense-cored vacuoles containing acid muco-substances, and small osmiophilic granules of 5-hydroxy-tryptamine (Day *et al.* 1969). Narrow, agranular endoplasmic reticulum, tubules, and a wider system of channels and vacuoles connected to the surface have also been described (*see* Cawley and Hayhoe 1973).

Platelets form an important element in the haemostatic mechanism by initiating thrombus formation due to their adhesion to each other (*agglutination*) and to damaged surfaces, and by the release of factors which assist in the formation of the fibrin clot. The contraction of individual platelets is also involved in clot retraction. Details of clot formation are given in many standard texts and will not be considered further here. The life span of platelets is 8–14 days (Heyssel 1961).

Haemopoiesis (1.72)

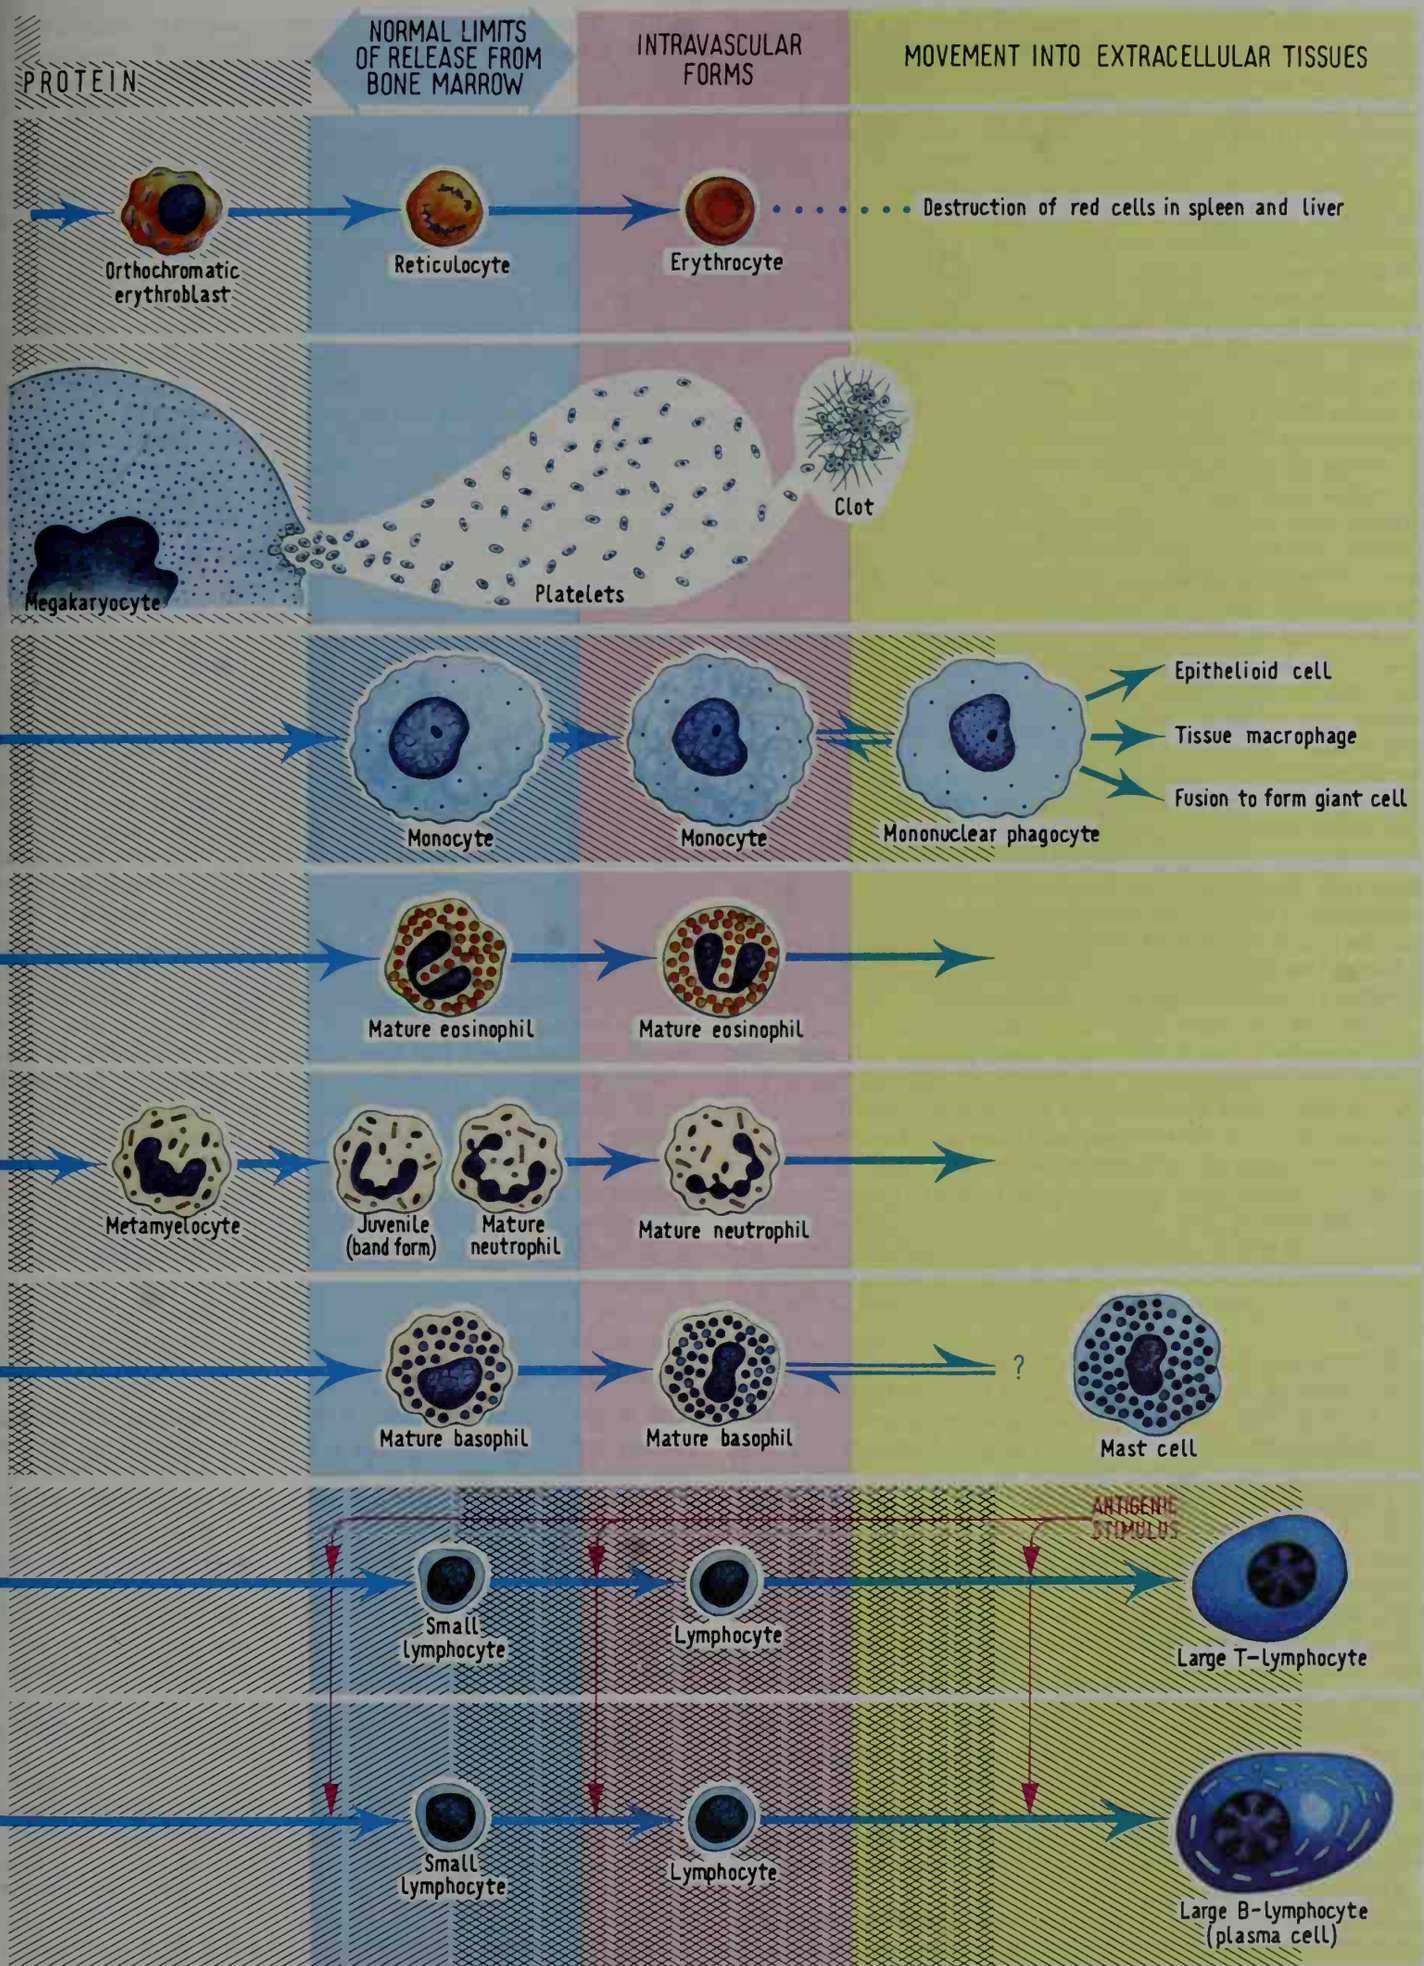
The earliest sign of blood *vessel* formation in the human embryo occurs when, during the early primitive streak stage of development, angioblastic tissue differentiates almost simultaneously in various extraembryonic sites, namely, in the mesenchyme of the yolk sac wall, and in similar tissue of the connecting stalk and chorion (p. 180). The earliest formation of blood *cells* (1.72), however, appears to be confined to the wall of the secondary yolk sac, where they differentiate from deeply placed mesenchymal cells which lie next to the yolk sac endoderm. Whilst a mesodermal or endodermal origin for these cells is still debated, they are unquestionably mesenchymal in character, and differentiate into the primitive *stem cells* of the haemopoietic line, which give rise directly to fetal blood cells. Beginning in the second month, a number of intraembryonic sites of haemopoiesis appear and slowly replace the earlier sites. These intraembryonic sites *succeed, but overlap*, each other in time, each site gradually increasing in importance and then waning. Initially, the intraembryonic sites are broadly *intravascular*, but soon *extravascular* loci of haemopoiesis supervene. Rapidly the *liver* becomes the dominant organ of embryonic blood formation, its activities continuing until about the seventh month. Lagging somewhat behind the liver, the *spleen* is then added, its haemopoiesis continuing from the third to sixth months. From later in the third month, an additional source of blood cells emerges, namely the *bone marrow* (*myeloid tissue*) where *all blood cell types* are formed, and later the peripheral lymphoid tissues, where only lymphocytes are produced (lymphopoiesis). The *thymus* is an active lymphopoietic organ from this stage (whilst initially it also has some general haemopoietic functions). The myeloid and lymphoid tissues become the dominant source of supply by the seventh month, and shortly after birth all other sites have regressed completely (*see* Wintrobe 1974). Occasionally, clumps of tissue capable of total haemopoiesis are found outside the bone marrow (*extramedullary tissue*) in paravertebral sites; in pathological cases, where there is more demand for haemopoiesis, and especially during early childhood, complete haemopoiesis may also occur in the liver, spleen and lymph nodes, and infrequently, also in the kidneys, adrenals, adipose tissue, general connective tissue, and even in cartilage.

THE BONE MARROW



This is a soft pulpy tissue which is found not only in the cylindrical marrow cavities of the long bones but also in the spaces between the trabeculae of all bones and even in the larger Haversian canals. It differs in composition in different bones and at different ages, and occurs in two forms, *yellow* and *red marrow*.

During fetal life and at birth there is red marrow throughout the skeleton. After about the fifth year the red marrow is gradually replaced in the long bones by yellow marrow. The replacement commences earlier and is more advanced in the more distal bones. Further, in each bone the replacement, in general, proceeds from the distal to the proximal end, though some maintain that it commences in the centre of the shaft and extends in both directions, but more rapidly in the distal. By 20 to 25 years of age the red marrow persists only in the vertebrae, sternum, ribs, clavicles, scapulae, pelvis, cranial bones and in the proximal ends of the femora and humeri. In old age the marrow of the cranial bones undergoes degeneration and is then termed *gelatinous marrow*.



The yellow marrow consists of a basis of connective tissue, supporting numerous blood vessels and cells, most of which are fat cells, although a small population of typical red marrow cells persists.

The Red Marrow (1.74)

This consists of a framework of reticular connective tissue with argyrophilic reticulin fibres and attached phagocytic cells, containing in its meshes a variety of blood cells and their precursors, and a few fat cells. Small nodules of lymphoid tissue are also scattered through it. No lymph vessels have been demonstrated, however, in yellow or red marrow. The vascular supply of the bone marrow is derived from the nutrient artery to the bone and drained by the accompanying vein (p. 257). The artery ramifies in the bone marrow; its branches terminate in thin-walled arteries from which an extensive plexus of cell-lined sinusoids arises. These, in turn, drain into disproportionately large veins (Brookes and Harrison 1957). Many of these blood sinusoids are collapsed at any instant and are frequently but erroneously referred to as intersinusoidal capillaries. The marrow

1.72 Haemopoiesis: a schema of the origins, developmental stages, and fates of the different classes of haemal cells. Where details of development are uncertain, putative routes are shown in broken lines. Developmental pathways of the prenatal period are indicated (left) in red, and different

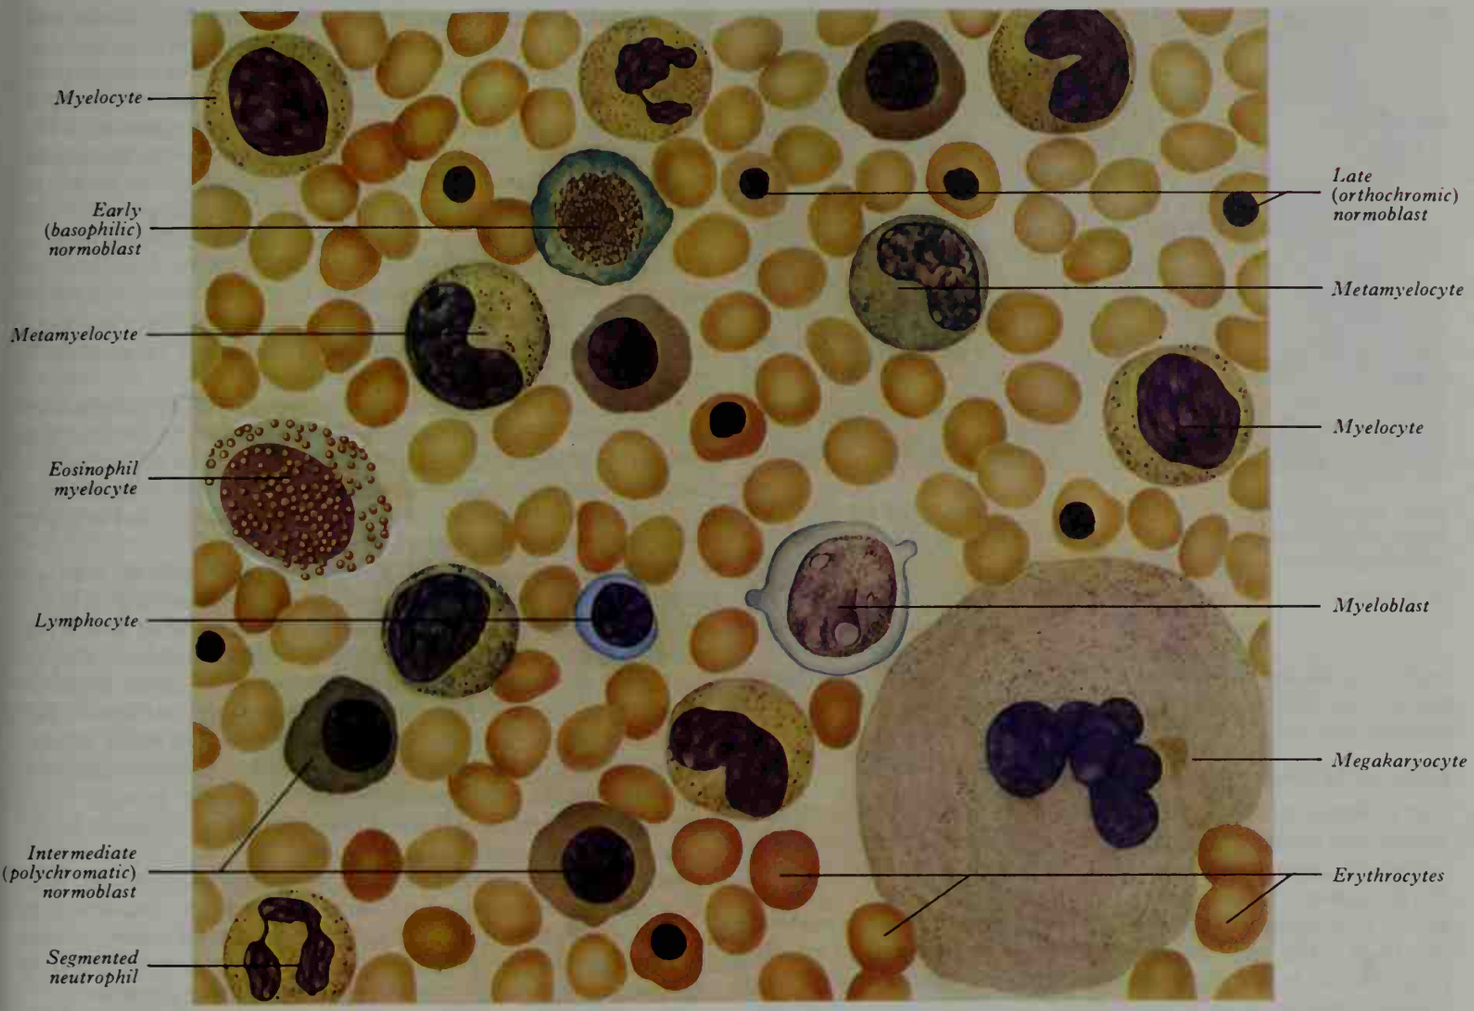
stages of cellular development are hatched diagonally according to the column headings. It should also be noted that there is evidence for macrophage proliferation in the extravascular tissues, a finding not indicated in this scheme.

sinusoids are irregular in outline and are lined by flattened, phagocytic, reticulo-endothelial cells, which under the light microscope appear to provide a complete endothelium. Their oval nuclei follow the curves of the sinusoidal wall, when seen in profile, and from the perinuclear region the cytoplasm spreads outwards as a thin veil, with marginal pseudopodial projections which overlap those of adjacent cells. The nucleus carries prominent nucleoli, and the cytoplasm is well provided with mitochondria, but granular endoplasmic reticulum is minimal. Phagosomes containing ingested particulate matter are common. Externally the endothelial cells are supported by a delicate mesh of reticulin fibres, a few of which pass through the extrasinusoidal cellular cords and become continuous in places with the perivascular reticulin of the smaller marrow arteries. The reticulin fibres are in part clothed by the cytoplasmic process of extravascular fixed macrophages, and, it is claimed, similar processes of primitive, relatively undifferentiated, *reticular* or *reticulum cells*. Islands or cords of haemopoietic tissue cluster around such cells, each group probably belonging to a single haemal cell line (Weiss 1977). Reticulum cells appear to be responsible for phagocytosing cell débris and for laying down a reticulin fibre support for the cells.

The initial stages of differentiation of haemal cells in mature marrow are far from clear. Early attempts to trace cell lineages in bone marrow preparations solely by histological examination of normal and abnormal tissue, led to much controversy about the origins and relationships of the various types of cell which could be observed. Some investigators considered it likely that all cell lines arose from a single type of stem cell (*haemocytoblast*) in adult tissues (the *monophyletic theory* of Maximow and others), whereas others favoured a multiple origin from many different types of stem cells (the *polyphyletic* theory, propounded by Ferrata and colleagues). Yet others have suggested compromise solutions (see Hardisty and Weatherall 1974). For many years it was also assumed that the lymphocytes arose exclusively in the peripheral lymphoid system and not in the bone marrow.

More recently, many experimental methods have been devised in an attempt to settle this issue; these include cell and organ culture, the replacement or transfusion of radiation-inactivated bone marrow with genetically or radioactively labelled haemal cells, and the separation of stem cells from peripheral blood. The picture emerging still presents many uncertainties, and applies mainly to rodent experimental models, rather than directly to man. However, a brief outline of some recent findings will be attempted. It will be seen that haemopoiesis can best be described as a limited polyphyletic system, depending upon the stage in embryogenesis that is considered the starting point of differentiation.

Haemopoiesis in embryonic life commences in the mesenchymal *blood islands* of the yolk sac, where giant nucleated erythroid cells are formed. But these are soon replaced by *nucleated fetal erythroblasts*, and these, in turn, are replaced by moderately large *anucleate, biconcave fetal erythrocytes* by about the fourth month of gestation. The adult type of erythrocytes are present by full term. Megakaryocytes, then granulocytes, lymphocytes and monocytes, appear in that order between the second and fourth months of gestation. During the earlier developmental stages, stem cells occurs in the yolk sac, liver, spleen and early bone marrow (p.180), and these tissues can give rise to *all haemal cell lines* if they are transplanted to adult spleens (i.e. they are haemally 'totipotent'). Meanwhile, the lymphoid organs start to be colonized by stem cells which, however, under normal circumstances only give rise to lymphocytes, and hence appear to be already committed to that particular line of cells. However, the ability of these lymphoid tissues to carry out full haemopoiesis under certain pathological conditions suggests that some uncommitted stem cells have been retained in these sites, but are normally suppressed.



In the *bone marrow* two types of *stem cell* have differentiated by early postnatal life; one type forming lymphocytes, whilst the other gives rise to erythrocytes, platelets, monocytes, neutrophils, eosinophils, and possibly basophils. The second of these stem cell types readily forms *haemal cell colonies* when transplanted to spleen cultures and each such cell is termed a *colony-forming unit* (CFU). The pluripotent CFUs are not numerous (about 0·5 per cent of all haemopoietic cells in marrow), but they can circulate freely in the blood, where they appear as small lymphocyte-like cells, 7–10 μm across, with a large pale nucleus containing one or two nucleoli, and bearing a narrow rim of cytoplasm.

Next, we turn to the problem of the differentiation of such stem cells into the various cell lines of the blood. The early stages of these lines are difficult to distinguish since usually they cannot be recognized until well after they have begun to differentiate. In each cell line, however, a definite sequence of major stages can be recognized (or ascribed)—*see* **1**.72. These stages are: (1) the *final commitment* of a stem cell to a particular line of differentiation; (2) early cell *proliferation* to form a large pool of dividing cells; (3) *differentiation* as specific proteins characterizing the particular line are synthesized, accompanied by the gradual cessation of cell division; (4) final *maturation*, marked by the gradual closure of protein synthesis; (5) *release* of the cells from the bone marrow parenchyma into the circulation. In the case of some cell lines, cell division may continue outside the bone marrow (e.g. monocytes or macrophages), and maturation may also be completed after release (e.g. erythrocytes).

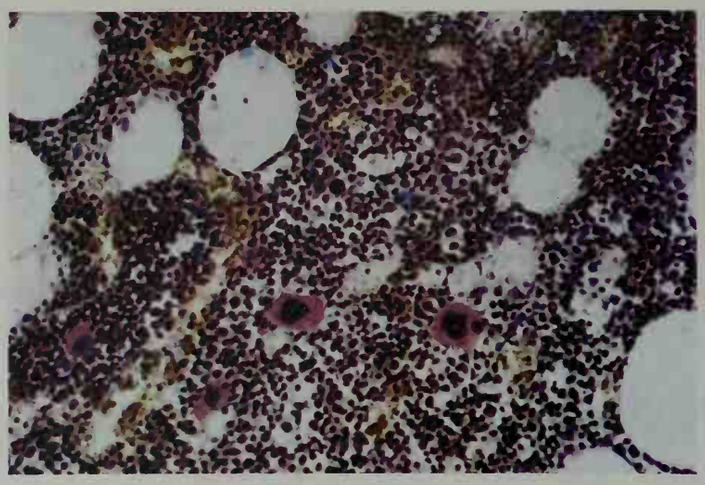
The earliest 'committed' stages of each cell line are outwardly similar to the CFU, but at the next proliferative stage, differences begin to emerge. In all, however, the initial picture is that of a rapidly dividing, relatively undifferentiated cell, in which the nucleus is large and euchromatic, with prominent nucleoli, the moderately basophilic cytoplasm contains unattached polyribosomes and the total cell size is large. As proliferation proceeds, the size of the cell usually diminishes as cell division outstrips cell growth. As the phase of final differentiation continues, the ribosomes become numerous, and the cytoplasmic basophilia increases, as the specific proteins begin to be synthesized, whilst the nucleus gradually becomes more heterochromatic and smaller, as DNA synthesis ceases, and ultimately the nucleus becomes multilobed or pyknotic as RNA synthesis terminates. The completed cell is then ready to be released, although the precise timing of its passage from the bone marrow varies with metabolic conditions and the 'demand' for more cells, so that relatively immature types of cell may be found in the circulating blood under abnormal conditions. This 'shift to the left' (a graphic convention of haematologists in which the cell is represented as maturing from the left to the right) is a useful concept in diagnostic haematology. These general features of development can be seen in several lines of haemal cells, and help to unify what appears at first sight to be a highly divergent series of progressions.

Erythropoiesis (1.72, 73)

The first identifiable cell of the erythroid series is the *proerythroblast* (*pronormoblast*), a large (14–20 μm) cell with a large euchromatic nucleus and moderately basophilic cytoplasm. The latter already contains small amounts of ferritin and contains some of the protein spectrin in its surface; both are characteristic of this cell line which must have been preceded by an erythropoietic stem cell sensitive to stimulation by erythropoietin (*see* p. 68). Proerythroblasts proliferate, and haemoglobin-RNA synthesis begins, as the smaller (12–17 μm) *basophilic* or *early erythroblast* (*basophilic normoblast*) appears, rich in ribosomes; shortly afterwards, haemoglobin synthesis commences so that the cytoplasm becomes partially eosinophilic (the *polychromatophilic*, or *intermediate erythroblast/normoblast*) which has a diameter of some 12–15 μm. As the cytoplasm becomes fully eosinophilic the cell is transformed into an *acidophilic erythroblast* (*orthochromatic* or *final erythroblast/normoblast*) which has a diameter of 8–12 μm. At this stage, most of the RNA is lost and the nucleus, becoming intensely pyknotic, is finally extruded from the cell, thus forming the anucleate *reticulocyte*. At this point the cell is released into the circulation, losing its residual RNA in a few days to become a mature *erythrocyte*. The whole process of erythropoiesis takes 5–9 days; after release, reticulocytes typically sojourn for up to 2 days in the marrow sinusoids, and then for an equal time in the spleen, perhaps because of their particularly adhesive cell coat.

1.73 A smear preparation of normal human red bone marrow, obtained by sternal puncture. This is a composite figure, drawn from a number of normal smears prepared by the late Dr. R. L. Waterfield, Guy's Hospital, and stained with a modification of Leishman's stain.

The cell lineage of normal erythrocytes is often called the *normoblastic series* to distinguish it from abnormal erythroid lines; too few divisions of the early proliferative stages may give rise to abnormally large erythrocytes (*macrocytes*), whereas too many divisions, or insufficient early growth, can lead to *microcyte* formation. Disturbances in haemoglobin synthesis can also give rise to a variety of anaemias and other pathologies.



Granulocytopoesis (1.72, 73)

The details of this process are best known for the *neutrophil*, which will be described in some detail. Initially, the putative stem cells transform into the large (10–20 μm) *myeloblasts* which are similar in general size and appearance, though not in internal details, to the proerythroblast (*vide supra*). These proliferative cells differentiate into the larger *promyelocytes*, in which the first group of specific proteins is synthesized in the granular endoplasmic reticulum and Golgi apparatus, both of these organelles being quite prominent. The proteins are stored in large (0·3 μm) *primary* ('*non-specific*') *granules*, that are large lysosomes containing acid phosphatase and having azurophilic staining properties (p. 57). Next, in the smaller *myelocyte*—the last proliferative stage—the smaller *secondary* ('*specific*') *granules*, which contain a slightly different enzyme array, are formed in a similar manner. The nucleus is typically indented on one side in myelocytes (1.72, 73). Subsequently, in the *metamyelocyte* stage the cell size decreases further, the nucleus becomes heterochromatic and horse-shoe shaped, and protein synthesis practically ceases. Finally, as the neutrophil is released, the nucleus becomes heavily indented (the *juvenile* or '*stab*' form) and then partially divided into up to six lobes (the *segmented* or *mature neutrophil*).

Eosinophils pass through a similar sequence except that their nuclei never become as highly irregular as that of the neutrophil, and only one set of lysosomal granules is synthesized. It is not known whether the eosinophil differentiates from the same myeloblast (or promyelocyte) stock as the neutrophil, or whether it is distinct from the colony forming unit (CFU) stage. In the case of *basophils*, it is not certain that they follow this general sequence at all; they may not even share the CFU as an ancestor.

Monocytes are also formed in the bone marrow, from stem cells of unknown structure; subsequently they pass through a proliferative *monoblast* stage, and then form differentiating *promonocytes* in which small lysosomes begin to be formed—these may be demonstrated by neutral red staining. After further divisions, monocytes are released into the general circulation, and then pass to perivascular and extravascular sites, which they populate as *mononuclear phagocytes* or *macrophages*.

Platelets, being fragments of cells, arise in a most unusual manner by the division of the cytoplasm of huge cells into many portions. The first detectable cell of this line is the highly *basophilic megakaryoblast* (15–50 μm); this is followed by a *promegakaryocyte* stage (20–80 μm) in which synthesis of granules begins; finally, the fully differentiated *megakaryocyte*—a giant cell (35–160 μm) with a large, dense, *polyploid*, *multilobate* nucleus—emerges. Once differentiation has commenced, mitoses proceed without cytoplasmic division, and the chromosomes are retained within a single polyploid nucleus containing 8n, 16n or 32n chromosomes, depending upon how many nuclear mitoses finally occur. Under the electron microscope, the cytoplasm is distinguished by numerous centrioles and spindle microtubules, both of which reflect the repetitive *mitotic* activity. Meanwhile, differentiation proceeds in the cytoplasm with the production of free polysomes, smooth endoplasmic reticulum, and fine basophilic granules. Cytomembranes within the cell fuse with one another, and, with invaginations of the plasma membrane and cell

1.74 A photomicrograph of a section of bone marrow from a fetal human long bone. Note the heterogeneous collection of cell types including four large megakaryocytes. Magnification × 150.

coat to cut off portions of cytoplasm, which then break away from the parent cell to form platelets. The nucleus of the megakaryocyte eventually disintegrates.

Control of Haemopoiesis

The numbers of cells in the circulation are closely regulated, cell destruction being counterbalanced by cell replacement. How this system operates is known, at least in part, only for erythrocytes. Erythropoiesis is stimulated by a circulating protein *erythropoietin* synthesized by the tissues of the kidney and other parts of the body. The rate of erythropoietin synthesis is inversely proportional to the oxygen content of the tissues, hence low oxygen tensions, usually consequent upon lowered erythrocyte numbers, stimulate erythropoiesis, whereas high oxygen tensions cause the withdrawal of the stimulus. At high altitude the lowering of the partial pressure of oxygen in the atmosphere leads to a raised erythrocyte count.

Many other factors also affect the rate of haemopoiesis, for example thyroid hormones, somatotrophic hormone, androgenic steroids and other hormones. The numbers of cells in the blood show a *diurnal rhythm*, probably because of hormonal fluctuations. Infection, haemorrhage and other clinical disturbances also affect the pattern of cell production, as do cytotoxic chemicals and ionizing radiations, to which the dividing cells of the bone marrow are particularly susceptible.

Blood Groups

Early attempts at transfusion of blood led to the discovery that erythrocytes bear antigens on their surface (*see* Race and Sanger 1975) which can interact with naturally occurring antibodies in the plasma of other individuals, causing agglutination and lysis of the erythrocytes. Such antigens, which are not shared with all members of a particular species, are termed *iso-antigens*; other iso-antigens are found amongst cells of other tissues (*vide infra*). Erythrocyte antigens are known as *agglutinogens* and the corresponding antibodies as *agglutinins*.

Erythrocytes from an individual can bear several different types of antigen, each type belonging to an antigenic system in which a number of alternative antigens are possible in different persons. So far at least fifteen groups have been identified, which vary in their frequency of distribution amongst the various races of mankind, including the A B O , Rhesus, M N S , Lutheran, P, Kell, Lewis, Duffy, Kidd, Diego, Yt, Auberger, Ii, Xg and Dombrock systems. Clinically, only the A B O and Rhesus groups are of major importance. For a full description of blood groups in man, see the comprehensive account by Race and Sanger (1975).

All of these antigens are determined by genes carried by autosomes except Xg, which is borne by the X chromosome. Within each group the antigens are determined by alleles and inheritance is in accordance with simple mendelian principles (p. 101). Thus, in the A B O system the genome may be homozygous and carry the A A complement, the blood group being A, the B B complement giving blood group B, or may carry neither (O O), the blood group consequently being O. In the heterozygous condition the following combinations can occur: A B (blood group A B), A O (blood group A), and B O (blood group B). In Caucasians and Negroes group O is the commonest, being present in about 50 per cent of the population, followed in frequency by groups A, B and AB in that order (Mourant 1975). In West Africans the Duffy determinant (Fy) is almost always absent, a lack which may confer resistance to *Plasmodium vivax* malaria (Miller and Carter 1976).

The plasma in each case carries naturally occurring antibodies specific to the antigens which are not present on the erythrocytes in the same blood, so that in group A blood, anti-B antibodies are found. Similarly, present in group B blood are anti-A antibodies, in group O blood both anti-A and anti-B antibodies, and in group AB blood there is neither type of antibody.

Transfusions succeed only if the recipient's antibodies do not correspond to the donor's antigens, and cross-matching of blood antigens is therefore vitally important. Persons with group AB blood, lacking antibodies to both A and B antigens, can be transfused with blood of any group and are termed *universal recipients*; conversely, those with group O, *universal donors*, can give blood to any recipient, the donor's antibodies being diluted to insignificance. Normally, however, blood is only transfused between persons with precisely corresponding groups, since anomalous antibodies of the A B O system are occasionally found in blood, and may cause agglutination.

Within the A B O system several subgroups exist (A_1, A_2, A_1B, etc.); the cross-matching of some of these is important in transfusions. The anti-A B O agglutinins, like all others (except those of the Rhesus system), belong to the immunoglobulin M (IgM) class, and do not cross the placenta during pregnancy.

The Rhesus antigen system, so-called because of its presence also in the erythrocytes of the Rhesus monkey, is determined by three sets of alleles, namely, Cc, Dd and Ee, the most important clinically being Dd. The commonest condition in Britain is CDe and about 83 per cent of the population is Rhesus-positive. Inheritance of the Rh factor obeys simple mendelian laws, and it is therefore possible for a Rhesus-negative mother to bear a Rhesus-positive child. Fetal Rh antigens can, under these circumstances, stimulate the production of anti-Rh antibodies by the mother, and since these belong to the immunoglobulin G group of antibodies they are able to cross the placental barrier and cause agglutination of fetal erythrocytes. In the first of such pregnancies little damage is usually caused, but in subsequent Rh-positive ones, massive destruction of fetal red cells may ensue, causing fetal or neonatal death. Treatment is by exchange transfusion of the neonate infant, or by desensitizing the mother after the first Rh-positive pregnancy with Rh-immune serum, which appears to destroy the fetal Rh antigen in the maternal circulation before the processes of immunological memory (p. 62) can be entrained (*see* Clarke 1975).

Of the other antigenic systems known, some of which are occasionally of clinical importance, many are restricted to individual genic groups or even families; they can be of great value to anthropologists when tracing demographic relationships, as of course are the major systems described above.

Other antigenic systems such as M N S (shared with other tissues in the body) can be used in medico-legal investigations to establish identity of blood, or in parental identification. These antigens can remain intact long after death, and have been detected even in mummified tissues from Egypt over 4,000 years old (Harrison *et al.* 1969).

The genetics of blood groups is complicated by gene linkage with other characters which may be of some clinical importance; duodenal ulcers show a higher incidence in those with group O blood than in the general population, for example.

Leucocytes also bear antigens, and about twelve such groups have so far been identified, ten of them belonging to the same complex system. These are similar to the *histocompatibility*

antigens involved in graft rejection (*vide infra*), and they form the basis of possible *immunosuppressive* measures by means of *antilymphocytic sera* which contain specific antibodies to the lymphocyte antigens.

Histocompatibility antigen system. Amongst important components constituting the cell membranes of all cells except erythrocytes, are factors which are responsible for determining the individuality of tissues from different persons, termed collectively the *histocompatibility* or HLA system (Bach and van Rood 1976). Various subdivisions of this system can be detected serologically, and four major subgroups, HLA-A, -B, -C, and -D, are known. Great variation of composition occurs within these subgroups, providing an enormous number of permutations amongst the human population. The HLA system has attracted much attention, lately, because of its importance in transplant surgery, and, in a quite different way, because of the association between certain of its subgroups and some types of disease. For example, the subtype HLA-B27 is present in nearly all cases of ankylosing spondylitis; the condition of haemochromatosis, a disturbance of iron metabolism, is strongly associated with HLA-A3, and rheumatoid arthritis with HL4-D4. Other conditions that display a statistical correlation with the HLA system include diabetes in juveniles, Hodgkin's disease, and multiple sclerosis. The reasons for these associations are not clear, but are thought to represent some type of loose *genetic linkage* between the HLA determinants and other alleles predisposing the body to a range of diseases. In mice, where this system has been widely investigated, genes that apparently control the responsiveness of the immune system to infection (the Immune related, or Ir genes) are situated between those genes that determine the major histocompatibility (H2) factors. In humans, where the HLA determinants are carried on the short arm of chromosome 6 (in a sequence A, C, B, D), genes coding for some of the serum complement factors, and those controlling antibody production, are also present in the same chromosomal region, and may therefore segregate with the HLA determinants during gamete formation.

Apart from these considerations, the HLA system is of great importance in the defence of the body against viruses and cancer. The HLA factors are integral proteins or glycoproteins of the plasma membranes of all nucleated cells (although the HLA-D subgroup appears to be specific to B-lymphocytes). Their main function is, apparently, to provide the means by which the immune system, particularly that associated with T-lymphocyte activity, can distinguish between normal cells and those which, like virally infected or neoplastic cells, bear alien or abnormal antigens, causing their subsequent elimination. Unfortunately, the same surveillance system applies to organ transplants and tissue grafts, for which procedures, recipient and donor histocompatibility subtypes must be matched as closely as possible to avoid immune attack and rejection. It is interesting that chemically the HLA factors have many features in common with antibodies, and it is feasible that they originated from a common cell-surface ancestor molecule, which provided a system of recognition between self and non-self, and which in the case of antibodies, later became adapted for specifically attacking foreign antigens (Cunningham 1977).

EMBRYOLOGY

Introduction

To distinguish between that which is living and that which is inanimate seems intuitively simple, and is a commonplace of everyday existence; but such a distinction continues to defy concise scientific definition. This question is obviously central to any study of living forms, and biological texts conventionally open by considering a series of attributes displayed by organisms, such as irritability or responses to environmental change, motility, ingestion followed by transformation (metabolism) of foodstuffs and excretion of end products, growth, reproduction, maturation and so forth.

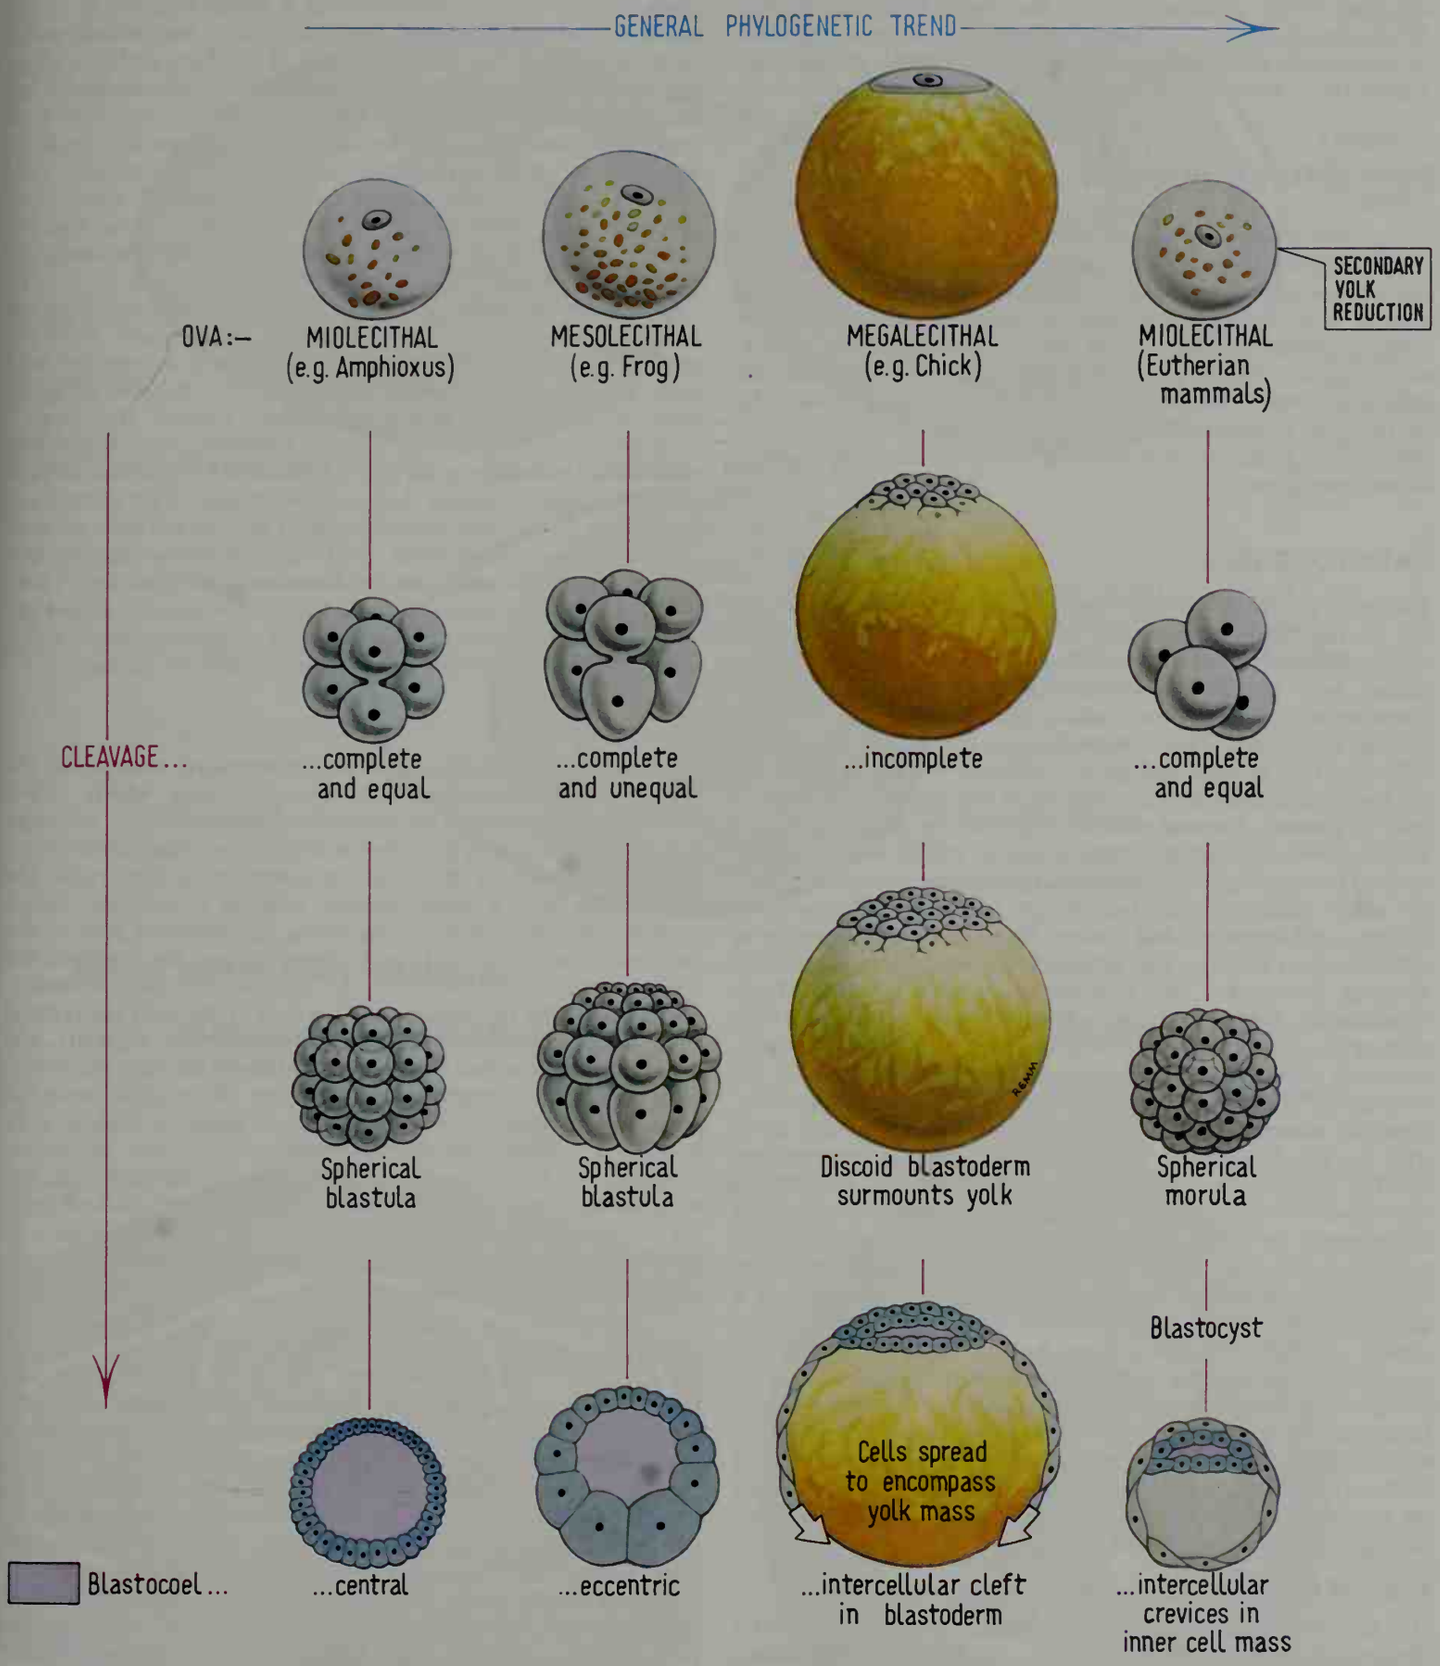
However, the basic building blocks of living things, sub-atomic particles, atoms and molecules are common to all materials known to man; in this context the attributes listed above are seen to be the inevitable consequences of particular arrays or *organizations* of the building units.

THE DYNAMISM OF LIVING ORGANISMS

To date, our examination of both the physical universe and the biosphere has led to fundamental generalizations, firstly concerning the relativistic nature of all forms of observation, and secondly, the interrelation between matter and energy. Aspects of the latter are stated explicitly in the various *laws of thermodynamics*, which for our present purposes hold that the total energy content of the universe is constant, and that overall, the proportion of disorganized, randomized or dissipated energy (the *entropy* level) is steadily increasing. Living systems, however, appear to reverse this trend by their growth, reproduction and increasing structural complexity, that is to say, their entropy level is *decreasing*. This apparent paradox is only answered by considering life forms as interlocked structurally, functionally, and energetically with their environment, from which they are supplied by a constant flow of energy which is essential for their maintenance (Schrödinger 1967; Lehninger 1965; Young 1964). The ultimate source of this energy on earth is the structural degradation of materials in the sun with the emission of radiant energy partly as light. This is trapped by green plants and used in photosynthetic processes whereby simple substances, with the addition of energy, are transformed into complex molecules which are incorporated into the plant tissues and eventually provide a source of chemical energy, or food, for the animal kingdom. This absolute dependency upon supplies of environmental energy reflects the *dynamic* nature of life processes, which constantly undergo change. Further, the continued success of an organism in any habitat implies that its structural and functional organization is complementary to features of its environment, and they can only be meaningfully studied together, that is, as one system. Indeed, some observers hold that the various control systems of an organism necessarily embody a 'model' of their environment for effective responses to occur (Young 1971).

That living organisms are dynamic, of course, implies a changing state with the passage of time, but the time scale chosen for study may vary from millions of years to fractions of milliseconds. Examples of the latter include such rapid biochemical and biophysical interactions as the activation of visual pigments by photons, conformational changes in cell membranes with consequent changes in permeability, as during the transmission of a nervous impulse or the release of a neurochemical transmitter, and the formation and breaking of linkages between actin and myosin subunits during muscle contraction. A relatively short time scale is also involved in the multitude of feedback systems whereby the state of the internal and external environment is constantly monitored and appropriate adjustments are made to preserve the internal environment within the fairly narrow range of values necessary to the continued life of cells. Such a preservation of internal constancy, or *homeostasis* (p. 802), despite *short-term* fluctuations in the surroundings, is a central feature of the operation of all the principal organ systems, for example, the regulation of temperature, blood pressure, hydration, osmolarity, electrolyte and hydrogen ion concentrations, glucose and oxygen levels, etc. To these may be added somewhat *slower homeostatic cycles* of endocrine secretory control systems, the varying rates of cell growth, death and replacement in various tissues, the behaviour patterns associated with mating, rearing of young, searching for and securing food, and also the ill-understood processes which lead to the laying down of short- and long-term memory traces.

REPRODUCTION AND EVOLUTION



Contrasting with these short-duration changes, all extant organisms have an ancestry which stretches back over hundreds of millions of years, a period which involved great changes in the natural environment. The latter were paralleled by a gradually increasing diversity of form and complexity of organisms, each more or less well adapted to life in some particular pocket of the changing environment. The *long-term homeostatic mechanism* which emerged and led to this diversification is intimately connected to another aspect of the dynamism of living organisms. Thus, in addition to securing an adequate flow of solar or chemical energy to drive its cellular machinery and continually replace its substance, each organism also passes through stages of *growth*, increasing *maturity* and, in complex forms, eventual *senescence* and *death*. Continuing life of the species is therefore dependent upon some mode of *reproduction*. Elementary life forms increase their mass and maturity until, at a critical point, they reproduce by simple equating division of their substance. Each successive organism has the same essential physicochemical constitution as the parent, and part of its structure operates as an information store, that is, a chemical (or genetic) *memory system*, so that the offspring grow into identical replicas of the parent. Occasionally, however, apparently spontaneous changes occur in the organization of the genetic memory store, and such *mutations* lead to the emergence of organisms with altered characteristics. Often such *mutants* are less well fitted for survival under environmental stresses and they succumb, but sporadically a favourable mutation occurs. The transmission of this to succeeding generations leads to the establishment of a species with an enhanced probability of survival and, occasionally, the ability to populate new or changing environments.

Such **asexual** methods of reproduction are seen in many relatively simple extant forms of life, but the great diversity and complexity of the remainder followed the emergence of **sexual** methods of reproduction in which each offspring is the result of welding of half of the genetic memory of *two* parents. In essence each parent *segregates* certain specialized *reproductive cells* in which there is a *rearrangement* of the genetic material, and a *reduction* to half the quantity found in the general cells of the body (p. 27). Two reproductive cells, one from each parent, approach and *fuse*, and their genetic material intermingles in a specific manner (p. 99). The resulting offspring, whilst in part possessing certain characteristics which resemble those of one or other parent, and of course those of the species in general, also possesses unique features due to the new genetic combination and the previous genetic rearrangement. When the effects of occasional favourable mutations are added to the infinitely varied genetic combinations resulting from sexual reproduction over countless generations, the opportunities for the initiation of altered species are vastly increased. It is on such a wide range of variants that the forces of *natural selection* operate and result in the endless array of life forms which populate all corners of the earth's surface, the oceans and the skies.

Any organism, therefore, including mankind, is not only interlocked structurally and energetically with its environment, exhibiting transient homeostatic responses and rhythmic variations, but is also at some point in its individually unfolding life history (*ontogeny*). It is progressing towards senescence, and possesses a unique genetic apparatus, the result of countless generations of diversifying, sexually reproducing ancestors (*phylogeny*). All these grades of dynamic change should be considered when any study of the fabric and behaviour of mankind is undertaken.

The present section is concerned with certain aspects of the development or ontogeny of the human body. However, in a volume such as this, which deals primarily with the general

EARLY DEVELOPMENT OF CHORDATA

2.1 Variations in the patterns of cleavage in *Chordata* associated with differences in oöcyte size, yolk volume and distribution. Note that the overall phylogenetic trend is from left to right, and the progression of cleavage from above downwards. Note also the morphological *differences* and '*homologies*' between the various groups. Consult text for further comment.

anatomy of the body, a comprehensive treatment of human development cannot be entertained. What follows is a concise summary of the principal events, and those requiring further details should consult one of the excellent texts devoted to general developmental principles or specifically to human embryology (Patten 1953; Arey 1974; Hamilton *et al.* 1977).

Sexual Reproduction

Sexual reproduction can conveniently be divided into several chronological stages, namely *gametogenesis, fertilization, cleavage, gastrulation,* and *organogenesis,* whilst to the latter three stages the general term *embryogenesis* may be applied. This essentially reflects orderly temporal and spatial variations in *growth, morphogenetic movement,* and *patterned differentiation,* balanced against *regional degeneration* and *death* of cells and tissues. An abbreviated, preliminary description of these phases of development will be given before proceeding to a more specific account of human ontogeny

GAMETOGENESIS

The body of a multicellular organism which reproduces sexually can be regarded as consisting of general body (*somatic*) cells which, although exhibiting extreme ranges of variation in size, shape, and specific functional as well as morphological characteristics, all possess certain common features of their genetic apparatus. This contrasts with the highly distinctive differentiation process and genetic changes which occur within the *gonads* and result in the formation of mature *generative* (*germ*) cells or *gametes.* General somatic cells usually possess a full or *diploid number* of chromosomes, a half of which was originally derived from each parent. However, the *activity,* and *expression* of the many different gene loci on the chromosomes varies in different cell types in adult tissues, and during development as differentiation occurs. The somatic cells which are capable of dividing do so by the process of mitosis (p. 29). Each chromosome, having first made a faithful replica of itself and thus of its genes, divides longitudinally and each resultant cell is again equipped with the diploid number of chromosomes which are replicas of those in the parent cell. During gametogenesis, however, a complex series of changes termed *meiosis* are set in train (p. 30). Essentially, during this, the original chromosome number is reduced to a half, the *haploid number,* in which a *recombination* of the genetic material has occurred (the details of this process are considered on p. 99). The male gonad or *testis* produces many small motile gametes or *spermatozoa* in which the cytoplasmic machinery is much reduced; each consists of a nucleus bearing the genetic apparatus, the chromosomes, with a closely applied acrosome derived from a Golgi apparatus and succeeded by a long flagellum which is partly ensheathed by an energy-transforming mitochondrial sheath (for details see p. 95). In contrast the female gonad or *ovary* produces fewer, larger non-motile *ova,* their cytoplasm containing a variable quantity of food reserves (*yolk* or *deutoplasm*) and exhibiting regional variations of the cortex (*oöplasmic segregation*) which are of importance in the initial stages of differentiation (p. 76).

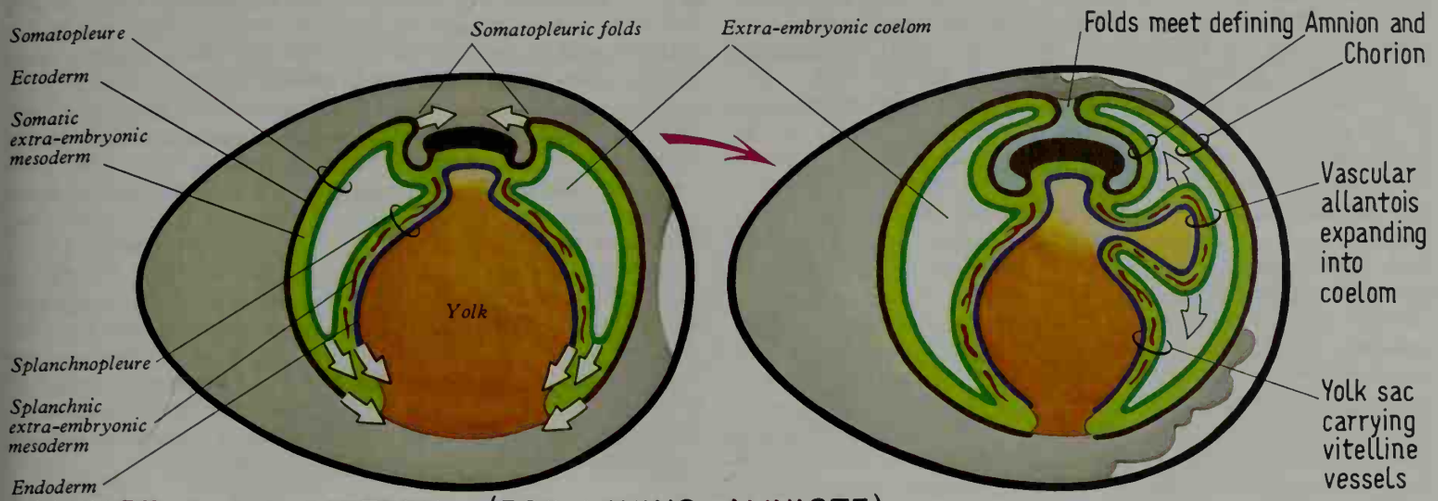
Types of Ova and their Influence on Development

Ova vary enormously in their size, amount of yolk, and number shed, throughout the animal kingdom, and within the *Chordata* a broad evolutionary trend can be recognized (**2**.1). Elementary aquatic forms usually produce many small *miolecithal* (yolk-poor) ova, which, after fertilization, rapidly develop into independent larvae, many of which succumb to predators and other inhospitable features of the environment. The larger ova of the amphibia are *mesolecithal* (with greater reserves of yolk), but again, are *wholly* transformed into aquatic larval stages which usually live and forage for food independently, and exhibit a long period of growth, differentiation and metamorphosis before the mature state is reached.

Colonization of dry land by forms not restricted by a periodic return to the water for reproductive purposes was, of course, necessarily paralleled by drastic evolutionary modifications in their ontogeny. Reptiles, birds (and prototherian mammals) are characterized by the production of a small number of large, heavily yolked (*megalecithal*) eggs enclosed by membranes and a hard shell, which may be laid on land. They have no larval stage and much of the fertilized ovum does not contribute directly to the body of the embryo, but is concerned with the elaboration of various *extraembryonic membranes.* The latter provide mechanisms for the mobilization and transport of the massive yolk reserves to the developing embryo, deposition of waste end-products of metabolism, the provision of a local aquatic environment for the embryonic tissues, and to allow exchanges of carbon dioxide and oxygen across the porous shell (**2**.2).

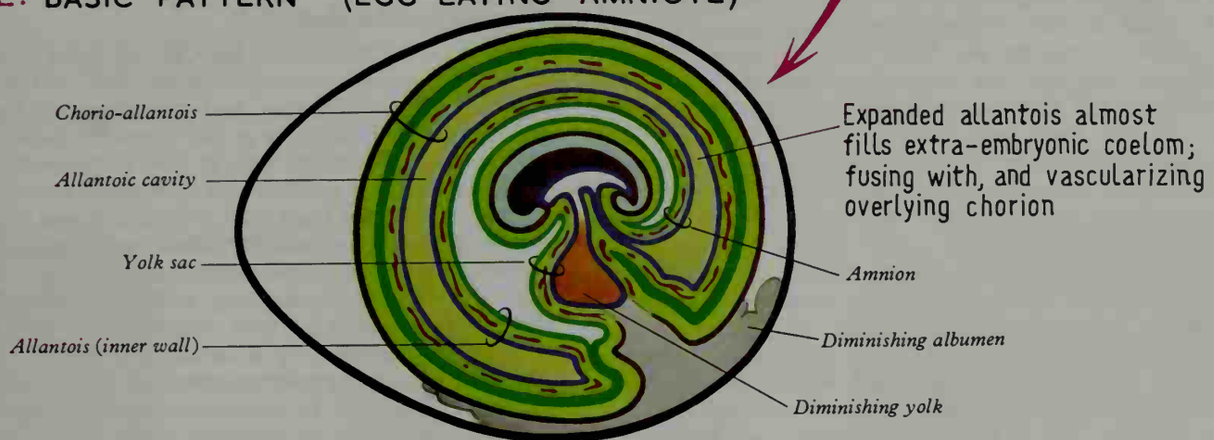
Eutherian mammals, including man, although derived from such ancestors with heavily yolked eggs, again produce miolecithal eggs, but these are few in number, possess no hard shell, and development proceeds within the controlled environment of the female genital apparatus. Despite this drastic secondary reduction in yolk content, however, many features of mammalian development are only explicable by reference to such ancestry. Thus, although there are differences of detail between the various groups of mammals, they all develop the same array of extraembryonic membranes (yolk sac, allantois, amnion and chorion), with broadly similar functional associations. These membranes are, of course, modified in various ways for *viviparity,* that is, development *in utero,* with nutritive, respiratory, excretory and immunologic dependency upon the mother.

Recapitulation



Similarly, within the body of the mammalian embryo all the principal organ systems pass through stages which reflect fundamental patterns in the *ontogeny* of their ancestors, although these may be variously modified or abbreviated. Such patterns are particularly clear in the basic metamerism of the trunk, the progression from a simple tubular heart to a complex, folded, double pump with intervening septa, the common plan of the early nervous system and special sense organs, the craniocaudal sequence of nephric tubules, the plan of the early chondrocranium and the succession of gill arches in the early pharyngeal wall. Such *recapitulation* during development was originally, and too simply, interpreted as if an embryo passed through sequential stages which mimicked the *mature* form of its main ancestral groups. Although this view was later modified to include only structural features during *embryonic life* of the ancestors, emphasis is now placed on the essential similarity of the *morphogenetic mechanisms* common to all chordates. Accordingly, the latter closely resemble each other in the early stages of development, and intergroup differences only emerge gradually as development proceeds.

FERTILIZATION



Fertilization includes those mechanisms whereby a sperm approaches, becomes attached to, and then penetrates the surface of an ovum, and the early series of changes which follow. Briefly, the egg surface becomes modified to prevent further entry of sperms, the oöplasmic segregation of factors in the egg cortex which are important in subsequent processes of differentiation may be modified to a varying degree, and final completion of the meiotic cycle of the ovum occurs. There takes place the second of the two meiotic divisions with the expulsion of one set of chromatids into the second *polar cell.* The first division had halved the number of chromosomes, each chromosome, however, consisted of two chromatids. The male and female nuclear derivatives (pronuclei) swell, approach each other and then coalesce (*karyogamy*) to form a single *segmentation nucleus.* Thus, the diploid number of chromosomes is restored, the chromosomal sex of the zygote established, and a series of mitotic divisions which constitute *cleavage* are initiated.

Much evidence from comparative and experimental embryology (usually from non-mammalian forms) has accumulated concerning the forms of symmetry exhibited by ova, the mechanism of sperm attachment and entry, the site of sperm entry and its influence on the distribution of formative substances in the

FORMATION OF EXTRA-EMBRYONIC MEMBRANES

SUPERFICIAL IMPLANTATION
e.g. PIG

INTERSTITIAL IMPLANTATION
e.g. MAN

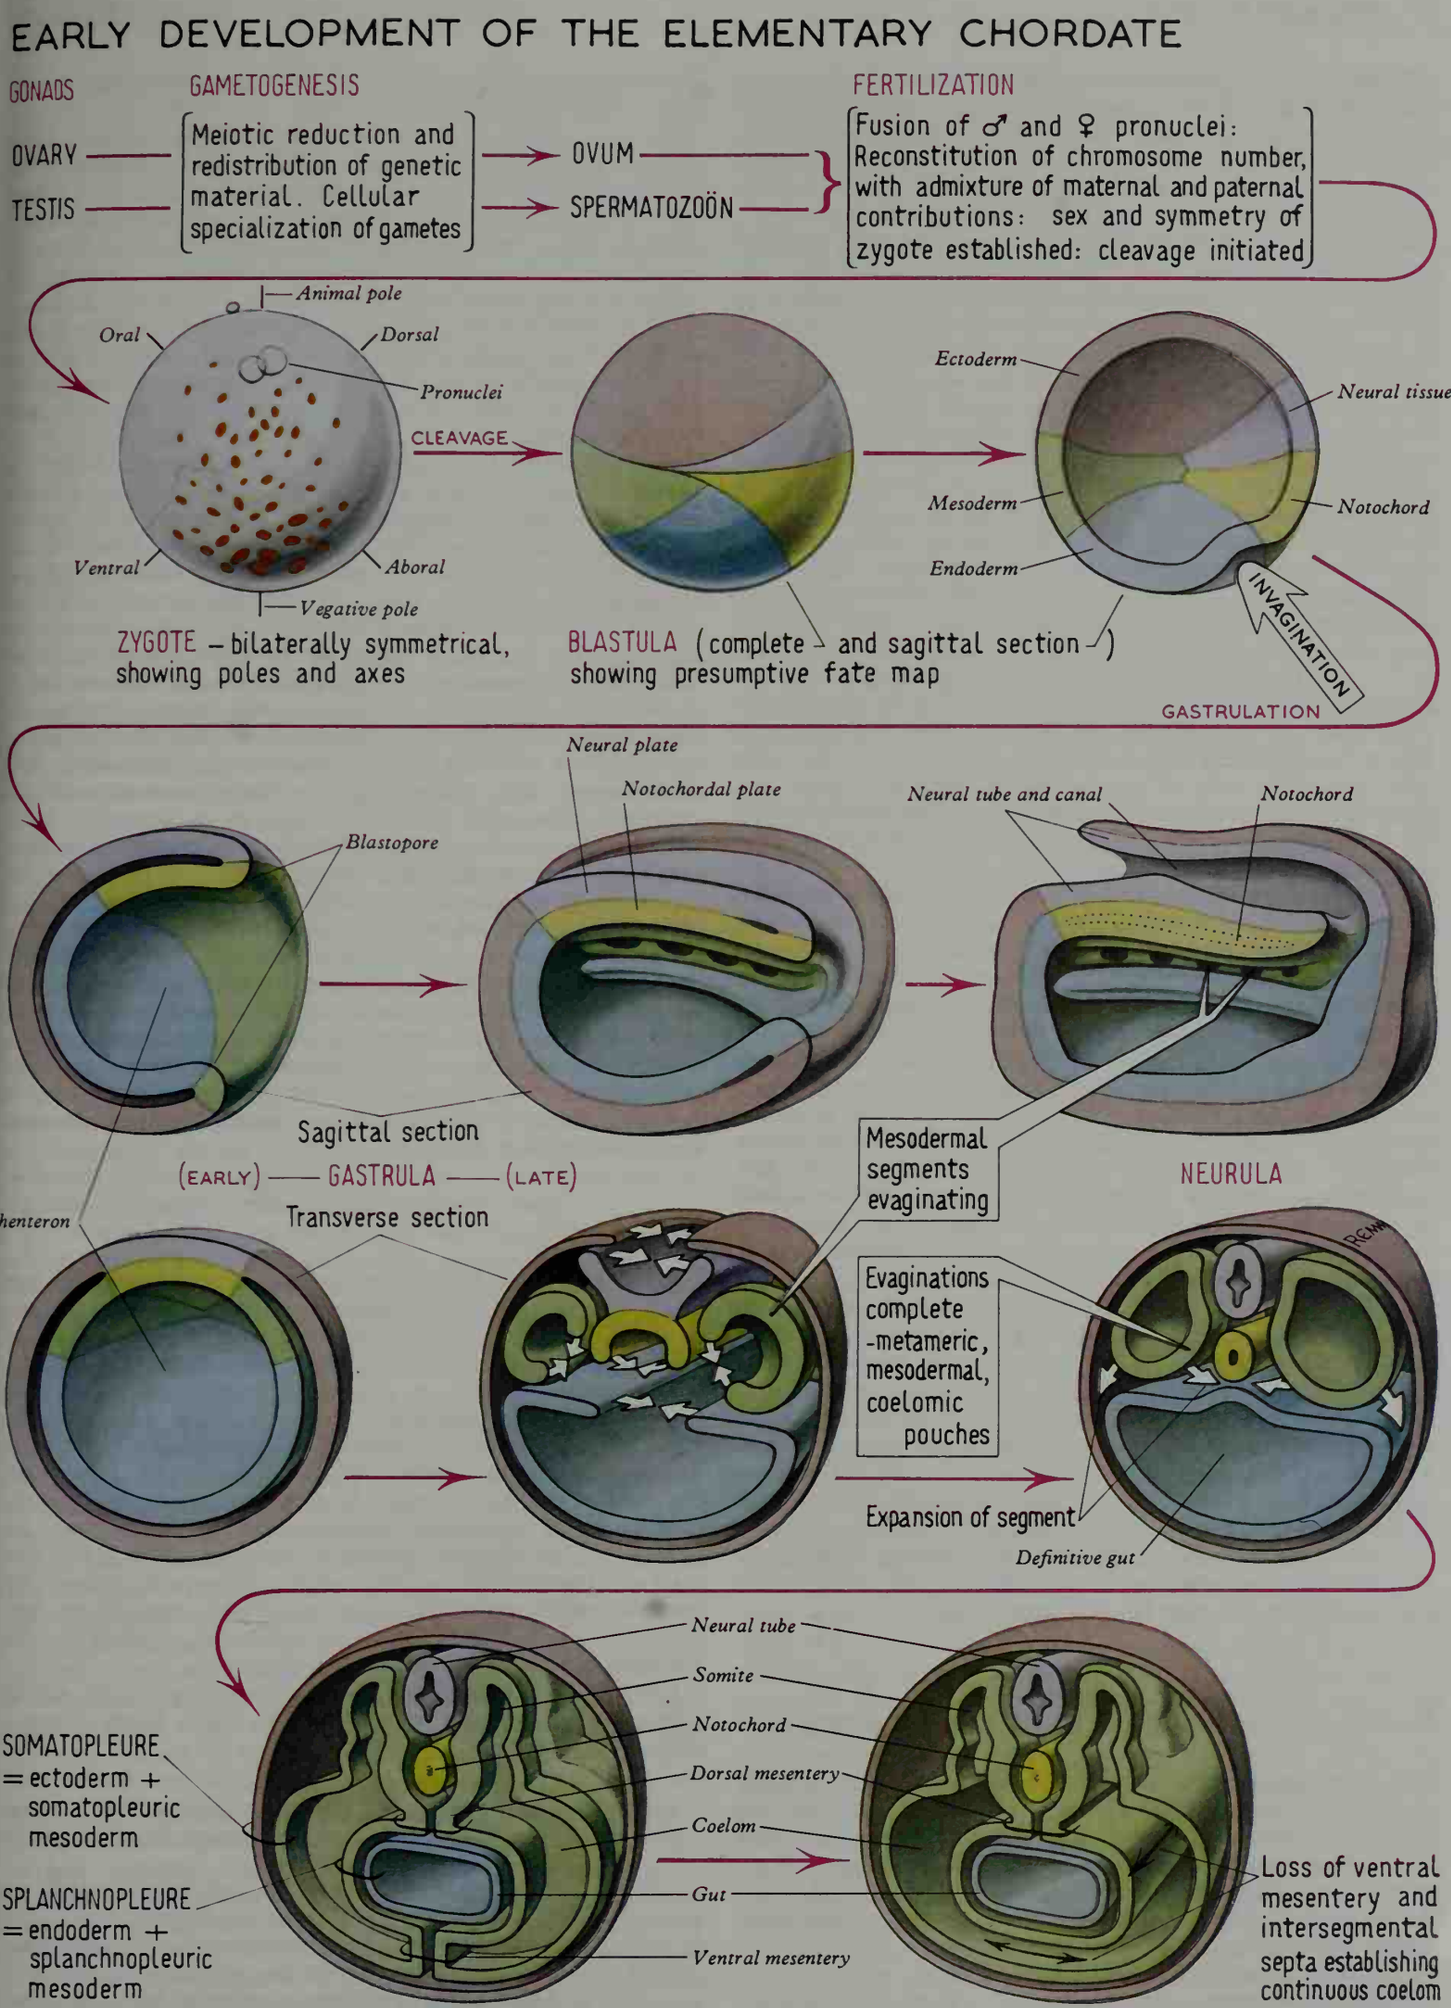
2.2 A generalized series of diagrams to allow comparison of the mode of formation of extraembryonic membranes in a megalecithal egg-laying amniote (e.g. chick) with that of a eutherian mammal exhibiting superficial implantation and a large allantois (e.g. pig), and a eutherian mammal showing interstitial implantation and a diminutive allantois (man). Note in each case the vascularization of the yolk sac, and the manner in which the expanded allantois (chick, pig) or its homologue in man, the body stalk mesoderm continuing from the small allantoic diverticulum, bear allantoic blood vessels which vascularize the overlying chorion. The latter is applied either to the shell, or to the uterine decidua.

egg cortex, and the relative fixity, or lability, of such substances. For some of the prominent earlier contributors to this important area of biology *see*, for example, Needham (1942); Waddington (1956, 1962); Brachet (1960, 1965); and Raven (1958, 1961, 1963, 1966). A comprehensive recent review lies outside the scope of the present volume, and only a few salient points can be mentioned. All ova are *polarized* with an axis extending between the largely cytoplasmic *animal pole*, near which the nucleus lies, and the more heavily yolked *vegetative pole*. Whilst ova of some species possess a fairly simple *radial symmetry* around this axis with experimentally demonstrable *gradients* of *developmental potential* extending between the poles, all others exhibit, in addition, further localizations of materials which confer a *bilateral symmetry* on the ovum. The time of appearance, degree and reversibility of this bilateral symmetry varies greatly between animal groups. Again, in occasional types of ova, the site of sperm entry is restricted by the egg coats to a small area on the surface, whereas, in the majority of others, entry may occur at any point. Further, in some, the bilateral symmetry is largely reorganized in relation to the point of sperm entry, whereas in others, it is little affected. There is little evidence that sperms are specifically attracted towards ova by any form of chemotropism, but in mammals it is often held that approach towards the egg surface, which at this time is surrounded by granulosa cells of the corona radiata and the zona pellucida (p. 93), is facilitated by hyaluronidase produced by the acrosome of the sperm. However, the degree of development of an acrosome and its concentration of hyaluronidase vary considerably—both are poorly developed in man. In some instances the egg cortex and its coats have been shown to contain proteins (*fertilizins*) which can activate and agglutinate sperms, whilst the sperms contain *antifertilizins* which, when extracted, can agglutinate ova; penetration is assumed to involve an interaction of the antigen-antibody type between the two. Finally, in some cases the deeper part of the acrosome has been shown to extrude an *acrosomal filament* which, when it contacts the egg surface, becomes engulfed by a *fertilization cone* of cytoplasm which protrudes from the surface of the egg. The degree to which these postulated mechanisms, symmetries and rearrangements apply to human ova and their fertilization remains uncertain.

CLEAVAGE

When compared with the majority of somatic cells (excepting large neurons and certain other large cells), recently fertilized ova are unusual in possessing but a single diploid nucleus within a large volume of cytoplasm. The mitotic divisions of cleavage are, however, not accompanied by any substantial synthesis of cytoplasm, and so the repeated replication and division of nuclear material, together with the partitioning of the existing cytoplasm, soon causes a return to the more usual *nucleo-cytoplasm ratio*. The resulting cells are called *blastomeres*, but their individual potentiality for further development varies considerably between animal groups; accordingly, a variety of terms have been used to describe cleavage 'types', which can only receive brief mention here.

Types of Cleavage (2.1)



Cleavage of miolecithal eggs is known as *complete* and *equal* since the whole zygote segments and the resulting blastomeres are approximately equal in size. In contrast, medialecithal eggs, whilst having a complete form of cleavage, it is *unequal* with large yolk-laden blastomeres at the vegetative pole which grade into small yolk-free ones at the animal pole. In heavily yolked eggs the yolk mass does not segment and divisions are restricted to the cytoplasmic accumulation at the animal pole. Such purely descriptive terms have been supplemented by others designed to summarize the *developmental potential* of the various regions of the zygote and the blastomeres derived from them. As has been intimated, experimental analysis of the *causal mechanisms* of early development has indicated that all zygotes exhibit some degree of segregation of cytoplasmic factors which, in their interactions with different blastomere nuclei, are of primary importance in the subsequent emergence of different cell varieties. However, the degree, precision, and lability of this segregation varies greatly between animal groups. In some invertebrate ova it is highly ordered, and in such *'mosaic eggs'* cleavage often follows a fairly precise geometrical pattern (e.g. spirally cleaving forms), and is called *determinate*. The fate of each blastomere is relatively fixed, and removal of blastomeres results in the development of a partial embryo. In contrast, in so-called *'regulative eggs'* with *indeterminate cleavage* the segregation, although present, is much more diffuse and flexible. In such forms, a blastomere when separated from its fellows often proceeds to develop into a complete, although small, embryo. However, these descriptive terms unfortunately imply a distinction which is in reality only one of degree. Many intermediate types exist and even the most mosaic ova show a small regulative capacity, and conversely, the most regulative eggs are by no means equipotential systems, and only those regions which include presumptive chorda-mesoderm (*vide infra*) will continue to the formation of a complete embryo when separated from the remainder.

Cleavage in Chordata (2.1)

Cleavage of the miolecithal eggs of elementary chordates soon leads to the formation of a spherical *blastula*, i.e. a ball of cells with a central cavity or *blastocoel*, and the animal pole blastomeres are slightly smaller than those at the vegetative pole. The cleavage product of mesolecithal eggs is also a spherical blastula, but reflecting the large gradation in blastomere size from animal to vegetative pole, the blastocoel is eccentric and sited nearer the former. Cleavage in heavily yolked eggs results in a circular *blastodisc* at the animal pole, which is several blastomeres thick and separated from the underlying yolk by a subgerminal cavity containing products of yolk degradation. The blastocoel is probably represented by a small cleft which soon develops between the superficial and deeper parts of the blastodisc (i.e. it is not homologous with the subgerminal cavity). Finally, cleavage of the miolecithal eggs of mammals leads first to a solid ball of blastomeres, the *morula*, soon to be transformed into a hollow *blastocyst* with an eccentric cavity. The latter is surrounded on most aspects by a thin wall of cells (the early *trophoblast*), but at one point a localized group of cells, the *inner cell mass*, projects into the cavity. The mammalian blastocyst is to be carefully distinguished from the spherical blastula of the more elementary chordates. In the latter, the *whole blastula* undergoes a complex series of foldings, cell migrations and other *morphogenetic movements* and *interactions*, collectively termed *gastrulation*, and is then progressively transformed through early and late *gastrula*, then *neurula* stages, into the embryo. In contrast, only the *central cells* of the avian or reptilian blastodisc are engaged in these transformations. The peripheral blastomeres gradually grow to enclose the yolk, becoming arranged in several layers with an intervening cavity, and by complicated processes of differential growth, cellular changes and vascularization (**2.2**), form the various *extraembryonic membranes* (yolk sac, amnion, chorion and allantois) described more fully elsewhere. Similarly, in the early mammalian blastocyst, only a few *formative cells* in the centre of the *inner cell mass* are directly concerned in the future formation of the embryonic body. The remaining cells of the inner mass and the general walls of the blastocyst are destined to form the same general extraembryonic membranes already foreshadowed in their heavily yolked ancestors. The precocious segregation of blastomeres as extraembryonic structures in mammals contrasts with their later development in reptiles and birds, and the detailed fate of the various membranes and their role in *placentation* shows wide variation between the different mammalian orders (Mossman 1937; Amoroso 1952).

GASTRULATION

Gastrulation in simple forms (**2.3**) entails the conversion of a roughly spherical, hollow, single-walled *blastula* into a more elongated, double-walled *gastrula* containing a cavity, the *archenteron*, for the reception and assimilation of food, and with oral and blastoporic openings at opposite ends. In such forms, this is achieved by the infolding of one half of the blastula into the other, the orifice formed by the invaginating material being the

2.3 Principal stages in the early development of an elementary chordate. The tabbing and illustrations proceed from left to right in a series of rows from above downwards. Note the poles and axes of the zygote, the presumptive fate map of the blastula, and the progression of gastrulation, neurulation, and coelom formation. Consult text for further details.

blastopore, and the point where the first invaginated cells contact the inner aspect of the opposite hemisphere eventually breaks down to form an *oral orifice*. The addition of a third, intermediate, mesodermal layer in the wall is usual in most groups of animals, and its origin is varied; in particular the fate of the walls of the primitive archenteron in the lower chordates is rather more complex (**2**.3). In these, the blastopore is conventionally regarded as presenting a dorsal, a ventral, and a pair of lateral *lips*. The material invaginated through the *dorsal lip* forms a midline strip in the roof of the archenteron which stretches from the blastopore to the margin of the future oral orifice; it underlies the external cellular wall and eventually folds off dorsally to form the *axial notochord*. Laterally placed strips, which flank the future notochord eventually form a series of paired outpouchings—the *metameric coelomic pouches*. The ventrolateral walls of the archenteron grow across ventral to the pouches and notochord to re-form a gut tube. The external wall of the gastrula dorsal to the mesodermal pouches and notochord, thickens and eventually folds in to form the primitive nervous system, whilst the remainder of the external wall forms the epidermis and its derivatives. In many forms the lateral lips of the blastopore gradually approach each other and fuse to form a *primitive streak* as they continue to bud off generations of mesodermal cells into the walls of the elongating gastrula. The dorsal lip continues to contribute notochordal cells and, with the fusion of the lateral lips, it rounds off and thus temporarily connects the archenteron with the caudal end of the developing nervous system (i.e. forming a transient *neurenteric canal*). In a similar way the ventral lip closes around a primitive cloaca, continuous with the gut tube and later with the urogenital ducts.

Accordingly, during gastrulation, originally widely separated cell masses in the walls of the blastula come into close secondary apposition, as the *presumptive organ rudiments* and tissue layers assume their definitive positions. *Presumptive fate maps* of the various regions of blastular walls have been produced by staining small regions of them differentially with vital dyes, and following the stained regions during subsequent development. Much work has also been directed towards an understanding of the mechanics of gastrulation itself and, as we shall see, the profound morphogenetic significance of the secondary association between formerly separated groups of blastomeres (**2**.4, 5, p. 81). Gastrulation, although necessarily modified in the blastodisc of heavily yolked eggs, and within the inner cell masses of mammalian blastocysts, remains an essentially similar process. Ectodermal and endodermal layers become defined, and within the former, a linear proliferative zone of uncommitted cells, the *primitive streak* persists and produces generations of mesodermal cells which pass between the two layers. Near the headward end of the streak a zone corresponding to the dorsal blastopore lip forms a notochordal process, which invaginates and breaks through to form a neurenteric canal, while caudal to the streak a cloacal membrane forms (cf. the transformation of the human bilaminar embryonic disc (pp. 110–114). The basic structural correspondence in these stages throughout the *Chordata* and in forms as diverse as *Amphioxus* and mankind is assumed to imply similar fundamental *morphogenetic mechanisms*—where experimental analysis has proved feasible, this view has been confirmed.

Some General Aspects of Development

The development of a large complex organism from a single diploid cell, the zygote, entails an increase in mass and cell number of many billions of times, and the emergence of a bewildering variety of cell types, each with a characteristic constitution, shape, specific activities, and variously welded into the distinctive tissue masses, sheets, tubes, liquids and so forth, which cooperate in the functioning of the whole.

The *developmental biology* of such an organism, while endlessly complicated in detail, and with as yet only the most rudimentary proposals concerning the control systems involved, can nevertheless, in principle, be reduced to a limited number of basic processes, namely: temporo-spatial variations in *growth, pattern formation, morphogenetic movement, differentiation*, together with *degeneration* and *death* of the cells and their aggregates (*see* for example pp. 79, 153).

The *description, definition* and *causal analysis* of these basic processes, and the degree to which they are independent or interdependent, still hold the centre of attention of modern developmental biologists, although many of the fundamental questions were first formulated, and some of the most dramatic experimental observations made, many years ago (*vide infra*). In the intervening years, as fresh experimental data have accumulated, the questions have often been rephrased, the definitions and terms used have been constantly revised and modified, and there has been a gradual change of emphasis concerning the conceptual frameworks currently in fashion (Locke 1966; Moscona and Monroy, to 1974).

Thus, in addition to attempting to describe and define the various forms, combinations, and differential rates of *positive growth* exhibited by organisms, there has been a more recent upsurge of interest in simultaneous *cell necrosis* and removal, and the factors which may control the regional differences in balance between these processes. Similarly, the detailed analysis of the *specific intracellular events* exhibited by cells undergoing *differentiation* has been paralleled by numerous hypotheses concerning the *spatial patterning* of differentiation. Concepts such as *oöplasmic segregation* of *morphogenetic factors*, *'organizer' phenomena*, *competence* of tissues, *induction*, *determination*, *morphogenetic gradients* and *developmental field phenomena*, and more latterly, ideas concerning *intercellular communication and positional information* available to cells in an aggregate, have emerged. In contrast, other authors have placed much greater emphasis on the probable morphogenetic significance of variations in the *cell cycle* (p. 23) with the establishment of *specific cell lineages* and the emergence of *cell clones* (*vide infra*). Finally, much interest has recently been aroused by the possible morphogenetic implications of the mathematical formulation of *catastrophe theory*. An immense scientific literature has accumulated concerning these fundamental fields of biological study, which of necessity can only be touched upon in a volume such as this, and the interested reader should consult any of the readily available reviews, monographs or original papers devoted exclusively to these topics.

GROWTH

Growth is a term widely used in everyday conversation and applied to both living and inanimate objects; it may, of course, within biology be applied to entire communities, individuals, or parts of an organism such as a whole body segment, an organ, tissue, group of cells or even subcellular features such as mitochondria, cell membrane and so on. This variety in the application of the term is paralleled by the number of definitions for it—evidence that none is wholly satisfactory. They range from the over-simplified 'increase in mass and size', to lengthy, complex, and sometimes incomprehensible descriptions. In general, during ontogeny, growth implies an increase in size and mass which results from synthesis of protoplasm and extracellular materials which are specific tissue components. Accordingly, any increases which follow the mere imbibition of fluid or the ingestion of food do not constitute true growth.

Growth of a tissue is classically considered to be either multiplicative, auxetic, accretionary or, quite often, a combination of these.

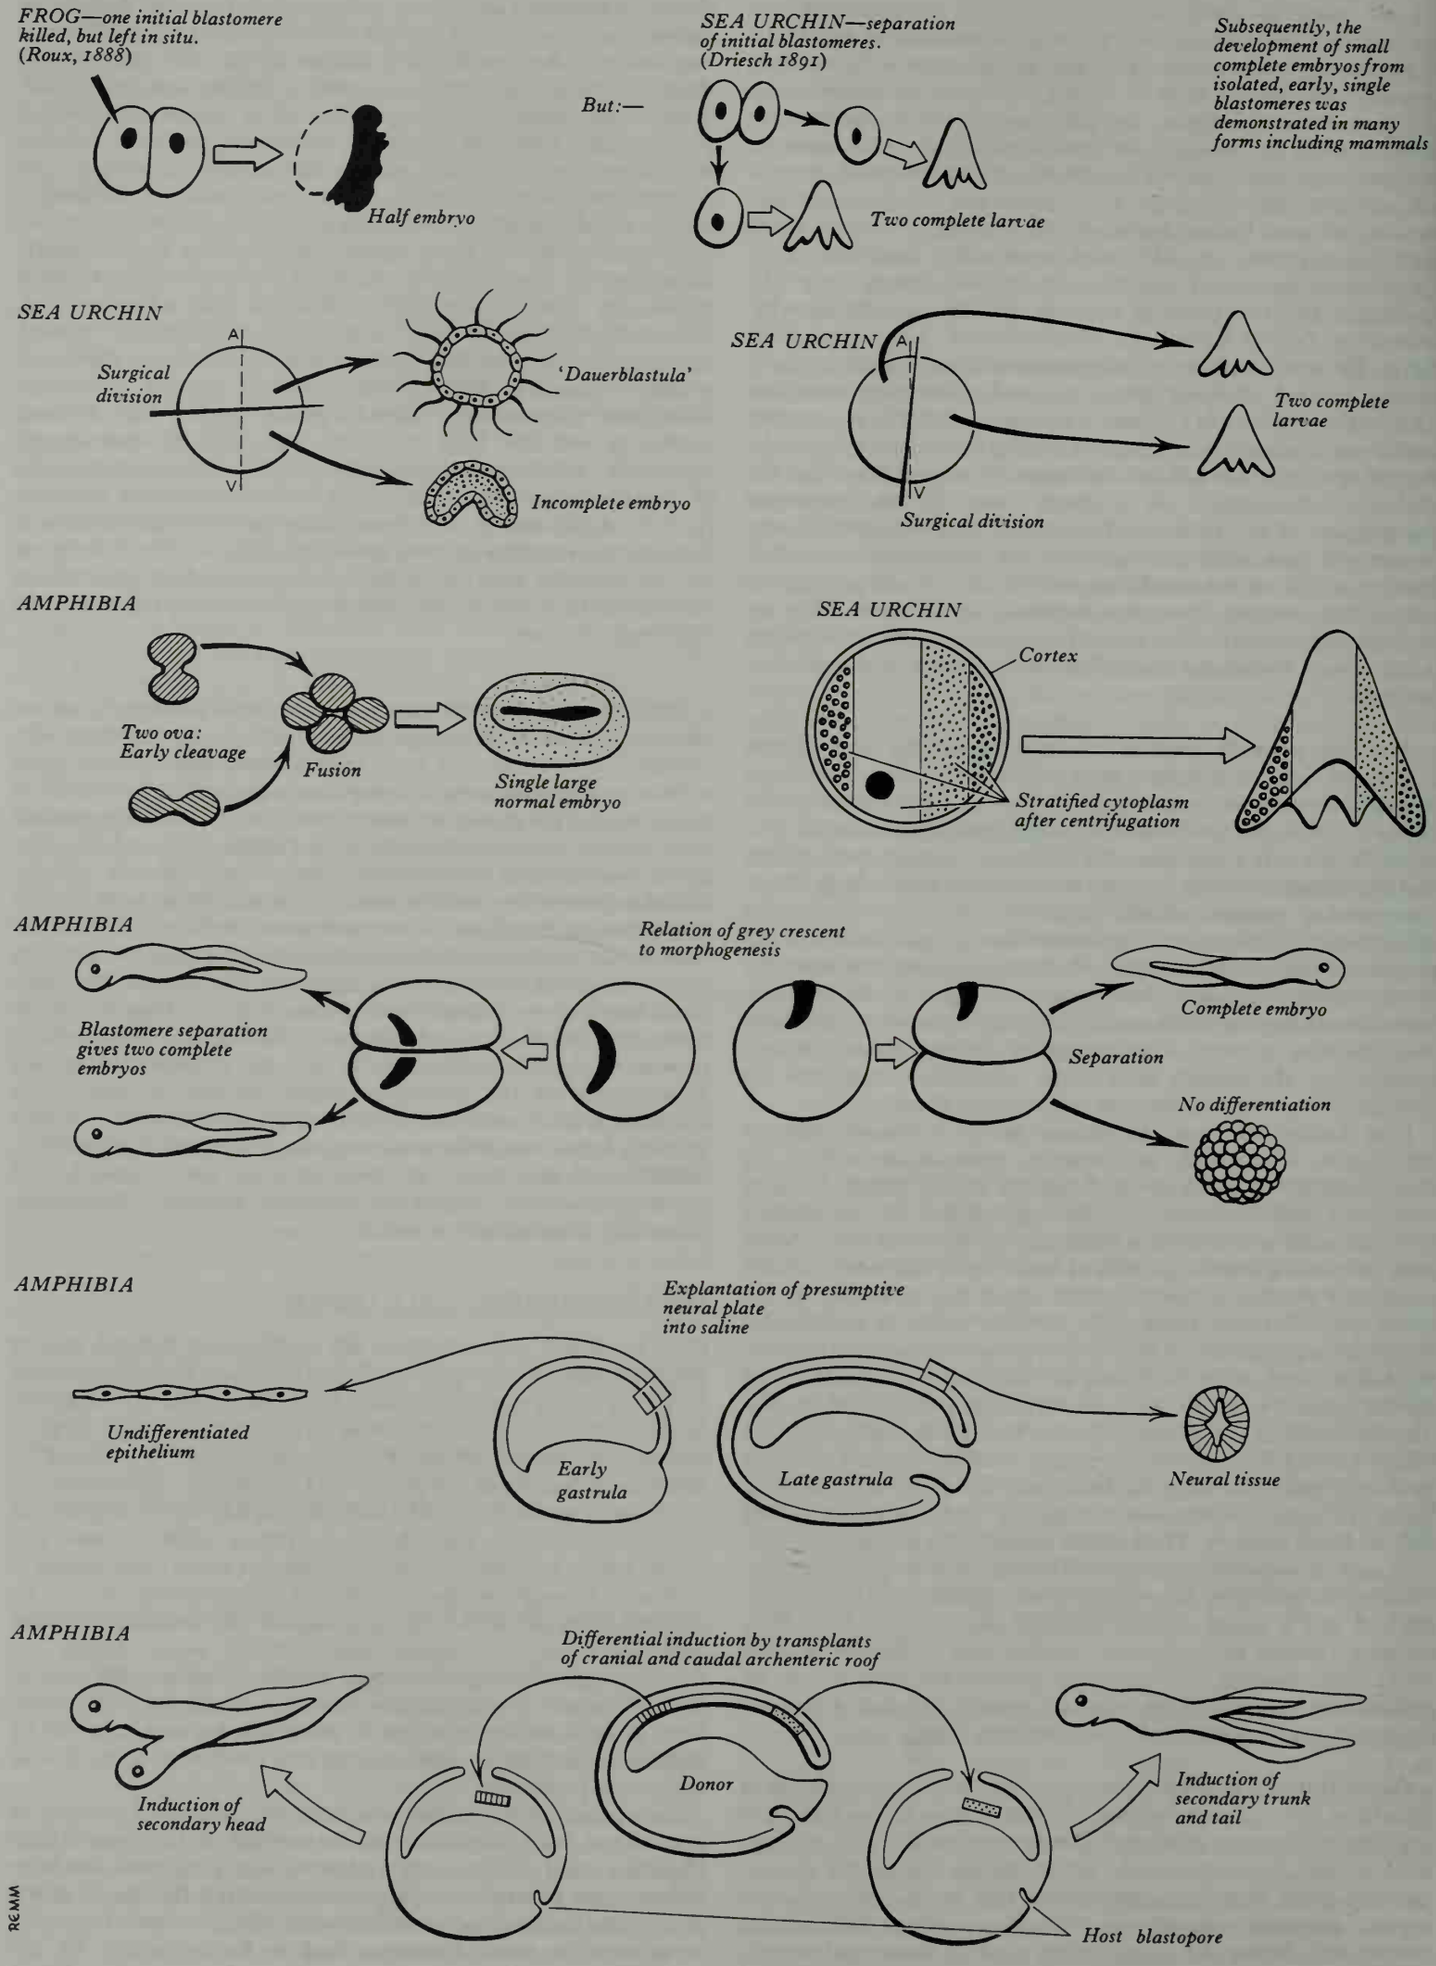
Multiplicative growth, as the name suggests, involves an increase in the number of cells (or nuclei and associated cytoplasm in syncytia) by a succession of mitotic divisions, and all mammalian tissues exhibit this form of growth at some stage. Its persistence, however, varies greatly between tissues with increasing differentiation and maturity. In some, multiplicative growth continues throughout life with continual replacement of senescent or dead cells, as in the epidermis, intestinal epithelium and the myeloid precursors of circulating erythrocytes. At the other extreme, cell division during embryonic life may lead to the full complement of a particular cell, e.g. oöcytes and neurons, and thereafter multiplicative growth ceases.

Much work has thus been directed at establishing the ranges of mitotic rates in many tissues throughout development into maturity and senescence, and towards an analysis of any cyclic (e.g. diurnal) variation in rate, and the extreme differences in potential for further growth during regeneration exhibited by different tissues. Despite the adequacy of such quantitative investigations in tissues of different age, sex and type, and the recognition of many general factors which influence such growth, e.g. genetic, nutritional (p. 135), endocrine, thermal, photic, mechanical, etc., little is known of the intimate processes which initiate, maintain, modify, and terminate, complex three-dimensional arrays of mitoses. In certain tissues (e.g. the epidermis and the growing nervous system) specific growth-promoting factors have been demonstrated (Levi Montalcini 1967). Recently, substances of widespread occurrence in many tissues termed *chalones* have received increasing attention (Bullough *et al.* 1967). They have been defined as internal secretions produced by a tissue which, by inhibition, control the mitotic activity of the cells of that tissue. It is considered that the chalone concentration in a tissue may be an important determinant of the balance which exists between mitotic rate, progressive cell differentiation and the assumption of a full functional role on the one hand, and the rate of cell ageing and progression towards senescence and death on the other. They are perhaps intermediaries between the general growth-influencing factors listed above and the differential activities of the genome (p. 85).

Auxetic growth implies an increase in the size of the individual cells in a tissue. It is particularly characteristic of certain invertebrate tissues such as the salivary glands of the *Diptera*, but is also well shown by some mammalian tissues. For example, there is a vast post-natal increase of both surface area and cytoplasmic volume in many neurons and glial cells (p. 821); the growing striated muscle fibre (p. 513), the oöcyte, the myelinating Schwann cells, and the smooth muscle cells of the pregnant uterus furnish further obvious examples. The majority of other tissues, however, show some auxetic growth but of much more limited degree, while in contrast, in some regions, continued multiplicative growth is accompanied by a *reduction* in cell volume (e.g. the granule cells of the cerebellar cortex, and the formation of small lymphocytes in lymphoid tissue).

It is widely held that the general *nucleocytoplasmic ratio* to which most of the body cells roughly approximate reflects the fixed quantity of DNA in their diploid nuclei which, in turn, imposes a rate limitation on the replacement of cytoplasmic proteins (each of which has a characteristic turnover rate). Thus, with continuing auxetic growth of a cell, its cytoplasmic volume eventually reaches a point beyond which the structural genes could not effectively replace the protein which is undergoing continual degradation. In most cases, growth ceases at this point, or nuclear replication with cell division occurs. The cases of auxetic growth cited above, however, often proceed far beyond the usual ratio of cytoplasmic volume to nuclear material and in these, various methods of providing auxiliary nuclear support have emerged. The large dipteran salivary gland cells develop 'giant' *polytene chromosomes* containing some multiple of the diploid DNA content. The striated muscle fibre and other 'giant' cells such as megakaryocytes are, of course, *multinucleate syncytia*. Finally, the enlarging oöcyte and neuron (possessing but a single haploid and a single diploid nucleus, respectively) have their surfaces clothed by numerous *satellite cells* (follicular or glial cells). Such satellite cells probably provide auxiliary metabolic and nuclear support for the enlarged central cell, that is, the two are functionally interlocked as a cytophysiological unit.

Accretionary growth denotes an increase in the amount of structural intercellular material between tissue, cells—bone and cartilage are the most commonly cited examples. Further, perhaps less obvious, examples are the other fibrous connective tissues, tendons, joint capsules, aponeuroses and fasciae (p. 522), the cornea, growing mesenchyme with its abundant intercellular matrix, and during the development of renal tissue and smooth muscle where the appearance of substantial basal laminae contributes significantly to the growing mass.



In practice, of course, these 'types' of growth as defined above are often welded together in various patterns, with differential growth rates and directions in different parts of the system; furthermore, they overlap with and merge into, the phases of cell differentiation, full functional activity, ageing and senescence. These *differential growth patterns* with either *random*, or *preferentially polarized* directions of mitotic division, together with alterations in cell size, shape, and surface consistency, are central features of embryonic development and are responsible for the moulding of tissues into specific shapes whether they be solid masses, hollow balls, tubes, sheets and so forth. Equally important in some regions, however, is a process of tissue regression, with degeneration, cell death and tissue removal. Where multiplicative (and sometimes accretionary) growth continues throughout the thickness of a tissue mass, it grows as a whole, expanding from within, and its growth is termed *interstitial*. Experimental markers placed within such a tissue during growth are later found to have become increasingly separated—excellent examples are embryonic limb bud ectoderm (p. 153) and the interior of young masses of hyaline cartilage (p. 251). Alternatively, in *appositional growth* new generations of cells and intercellular material are added to the *surface* of the tissue by the repeated division of the cells of a *cambial layer* which surrounds the tissue, for example periosteum and perichondrium (pp. 252, 260, 420).

Differential growth rates, as has been intimated, are an essential feature of many aspects of embryonic development. For example, if in an area of loose mesenchymatous tissue, a locus with a high proliferative rate appears, surrounded by 'shells' of tissue with a progressively lower rate, a mass of tightly packed cells which grades into the surrounding tissue is formed, i.e. a so-called *mesenchymal condensation*. Two adjacent loci in subepithelial mesenchyme with an intervening quiescent zone lead to neighbouring elevations of the epithelium, with an intermediate furrow (cf. the development of the facial processes, p. 146). In many situations, mesenchymal condensations appear and their *shape* foreshadows that of the structure, bone, cartilage or muscle mass, into which they subsequently differentiate. Many other examples of differential growth will be encountered as the development of the individual organ systems is considered. Particularly clear-cut examples are seen in descent of the gonads (p. 217), formation of the cauda equina (p. 161), neck elongation, septation of the heart (p. 184), and in the emergence of asymmetric arterial, venous and lymphatic systems from initially bilaterally symmetrical patterns.

MORPHOGENETIC CELL DEATH

Cell death and tissue removal are as much an integral part of embryogenesis as the positive forms of tissue growth discussed briefly in the foregoing chapters. As we have seen, it is currently held that mechanisms of *tissue homeostasis* exist, possibly operated by the local concentrations of tissue-specific chalones, whereby a balance is achieved between cell division, differentiation, functioning and senescence. Death of cells has been recognized as occurring as early as the blastocyst stage in rabbits (Daniel and Olson 1966), and has been demonstrated at many other stages of ontogeny throughout the vertebrates (Glucksmann 1951). An obvious example is the retrogression of the amphibian tail at metamorphosis, but similar degenerations occur during the development of the axial nervous system (Hughes 1968) and in association with the mammalian primitive streak. At a later stage, bone growth and remodelling in particular are accompanied by surface deposition in some regions and erosion and removal in others (*see* p. 266).

Particularly well studied have been the integrated patterns of growth and death of cells during the shaping of the tetrapod limb (Saunders and Fallon 1966). Massive zones of what has been dramatically termed *cataclysmic necrosis* sweep the length of the developing limb as its contours develop. The process is especially prominent in some localities, and it finally occurs in the interdigital clefts as the digital outlines become crystallized. Neighbouring mesenchymal cells become intensely phagocytic

2.4 A selection of the classical manoeuvres, which were milestones in the development of experimental embryology as a science. Consult text.

and engulf the dying cells and any resulting cellular débris. It should be emphasized that the *normal prospective fate* of such a cell mass is to degenerate and die, and since, in modern terminology, it has become fashionable to regard ontogeny as the unfolding of a *developmental programme*, ultimately encoded in the genome, such cells are described as succumbing to *programmed cell death*. Recently, numerous experiments have been devised in attempts to analyse the precise roles of such necrotic zones in normogenesis, and to elucidate what factors affect the enactment and timing of the so-called '*death clock*'. The *posterior necrotic zone* of the developing chick wing bud has, because of its predictable localization, timing, and susceptibility to microsurgical experiments, become a favourite object for intensive study (Saunders and Gasseling 1968), and its relationship to the establishment of *polarity* in the wing bud is becoming firmly recognized.

DIFFERENTIATION

The appearance of many highly distinctive cell types which become blended in various ways to form the functioning tissues, and the control mechanisms involved, has been for centuries, and remains today, one of the central problems in biology.

The differences between fully differentiated cells in terms of their size, shape, ultrastructural appearance, chemical constitution and functioning (e.g. mature muscle, nerve and glandular cells) are plain, no intermediaries exist, and there is no known experimental situation in which one form changes into another. As we shall see, however, the cells of early chordate embryos may, under suitable conditions, *ultimately* form any one of many different cell types, i.e. they are widely held by many developmental biologists to be *pluripotent*, and as development proceeds, there occurs a step by step reduction in their potential for forming a variety of cells, and finally, the fate of most cells is limited to one type of fully differentiated cell only. Even in the mature body, however, some cells retain some degree of flexibility and can still transform into a number of types—this is seen most powerfully in the ability to regenerate a whole body segment, e.g. limb or tail, shown by certain amphibia.

It may be mentioned here, however, and outlined further below (p. 83) that some groups of cell biologists contest the view just given of the early blastomeres as undifferentiated, totipotent or pluripotent cells with *immediate* access to a wide range of possible phenotypic fates, and advance instead hypotheses of much more strictly compartmentalized cell lineages during development.

Preformation and Epigenesis

For centuries, a controversy raged concerning the form taken by the differentiation which occurs during embryogenesis, whether there was a *preformation* in the early embryo, or whether *epigenesis* took place. The former view held that all the structures of the mature body, although so minute as to be invisible, were present in the zygote and simply enlarged and were thus revealed in subsequent development. The epigeneticists, however, held that the various organ primordia appearing during development were essentially new formations. In a modern context both views, somewhat modified, have their place. In one sense, *the total information content* of both the cytoplasm and the nuclear genetic apparatus of a zygote is a 'preformation' which through a series of complex interactions directs the 'epigenesis' of new structures in subsequent development.

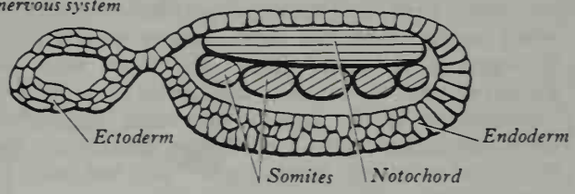
The classical studies of *descriptive embryology* in which times of appearance, shape and size of the various embryonic layers and organ systems at different stages of development were meticulously described in serial histological sections, and similar *comparative studies* of different species, although providing an invaluable framework, could make no contribution to an *understanding* of differentiation. An analytical approach was necessary (**2**.4, 5), and the foundations of 'developmental mechanics' or an *experimental embryology*, which sought to understand the *causal interactions* of development, were laid by Wilhelm Roux late in the nineteenth century. His experiments on frog development were paralleled by other observations of fundamental importance by Hans Driesch on the early sea urchin embryo. Then, passing into the present century, contributions of outstanding penetrance were made by such investigators as Hans Spemann, Ross G. Harrison, Sven Horstadius, J. Holtfreter, and many others. Only the most cursory mention of this field of biology can be contemplated, and those with wider interests should consult the original writings of these pioneers and, as an introduction to the equally important researches of modern development biologists, specific monographs (e.g. Spemann 1938; Willier *et al.* 1955; Hamburger 1960; Balinsky 1970; and the numerous text references up to p. 83).

Experimental Embryology

The final blow to rigid preformationist concepts was delivered when Hans Driesch showed that if the first two blastomeres of a sea urchin egg were separated, each could develop into a complete, although small, embryo (**2**.4). Thus, any idea of strict compartmentalism in the fertilized ovum had to be abandoned, since in normal development each of the blastomeres would have formed half the embryo, but when separated, each could *regulate* sufficiently to form a whole. On this basis Driesch supposed (mistakenly) that there existed *no segregation whatever* in the egg cytoplasm, and that it constituted a *'harmonious equipotential system'* in all directions. Since subsequent differentiation occurred, he regarded this as evidence to support a revival of the Aristotelian *entelechy*, holding that such a phenomenon could not be explained by the laws of physics and chemistry, and that a vital or spiritual 'internal perfecting principle' was present in all living forms.

However, as we have seen elsewhere (p. 76) much subsequent work showed that all ova and zygotes show some degree of *segregation of formative materials* in their cytoplasm, but its *degree* and *lability* varies between species. Ironically, had Driesch's separation been made in an equatorial plane rather than, as was the case, a meridional one, only partial embryos would have resulted!

The experimental methods employed by the earlier investigators (**2**.4, 5) included the preparation of *'presumptive fate maps'* of the blastula or blastodisc, *ablation* of regions of the blastula, *autotransplantation* of cell masses from one place to another in the same embryo, *explantation* of such masses or combinations of these into salt solutions and nutrient media, and finally, the powerful methods of *heteroplastic* and *xenoplastic grafting*, between different species. In the latter, the tissues of both the graft and the host are so distinctive that their relative contributions and interactions in any complex development that occurs after transplantation, can be followed.



The production of maps (**2**.3) showing the *presumptive fate* in normal development of different regions of the blastula or blastodisc, by the application of spots of vital dyes and following their subsequent history, was a necessary prerequisite of experimentation using microsurgical methods.

Self and Dependent Differentiation

From the earlier autotransplantation experiments, and later reinforced by explantation of blastula fragments into salt solutions (**2**.4), the first concepts of two distinct tissue states emerged, i.e. those that exhibited *self-differentiation* and the remainder in which *dependent differentiation* was the rule. In the former, as the name suggests, a fragment when transplanted to an apparently 'indifferent' region of the blastula, or, more critically, into salt solutions, proceeded to develop into the tissues it would have formed, if undisturbed. Regions with dependent differentiation, however, if transplanted early, failed to continue development and only did so if combined with some neighbouring mass of cells. If such a region, which at an early stage showed dependent differentiation only, was not transplanted until a later stage, it was often found to have become self-differentiating. Furthermore by combining such an early region with different regions of the embryo, development would often proceed, but the final tissue produced was changed (e.g. muscle rather than kidney).

From such work, therefore, it was realized that the *prospective significance* or *normal fate* of the various regions of the blastula did not reflect the *prospective potency* of these regions (i.e. the *various*

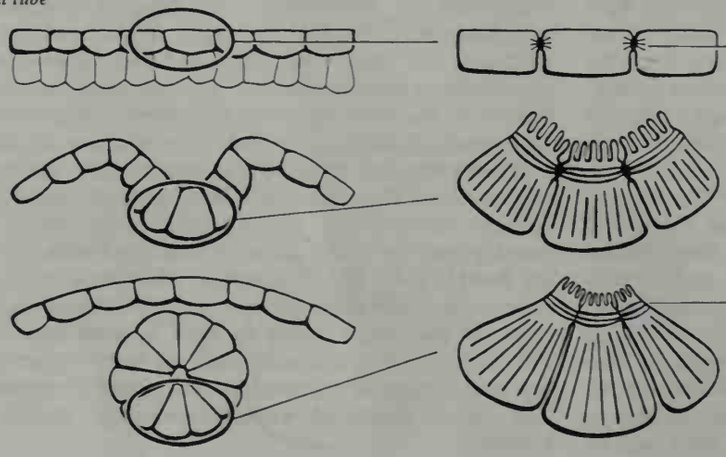
Activated anucleate eggs

1st generation nuclear donor



2nd generation donor

Presumptive fate maps of sequential stages in the development of chick wing bud. Note proximo-distal emergence of mesodermal patterning. A widely studied system: progressive determination demonstrated by culture or chorio-allantoic grafts of whole buds or fragments; Epithelio-mesenchymatous interaction demonstrated by removal, reversal or transplantation of apical ridge. Patterns of cell mitosis, differentiation and cell death have been extensively studied (see text).

An example of morphogenesis: formation and closure of amphibian neural tube

Cells undergo marked changes in shape. Possible ultrastructural correlates are: (a) points of high cohesiveness (desmosomes) in the apical contact zone, (b) circumferential microfilaments encircling the narrowing cell necks; (c) parallel arrays of microtubules aligned in the direction of elongation.

REMM

2.5 A further selection of classical experimental embryological procedures. Consult text.

fates possible under different experimental conditions). Further, it was found that from the earliest moments, certain restricted regions only exhibited *self-differentiation*, that is to say *determination* of their fate had occurred. The remaining regions with dependent differentiation, originally pluripotent suffered a stepwise restriction in their possible fates, i.e. an increasing fixity of determination occurred as development proceeded.

There followed a period in which the features of dependent differentiation were more clearly defined. Classical experiments showing the dependency of the development of the lens vesicle (later transforming into the crystalline lens of the eye), on the approach and close apposition of an evagination from the primitive nervous system (the optic vesicle), were performed, with many variations. These showed that, in the absence of an optic vesicle, no lens formation occurred, that many different regions of 'indifferent' ectoderm, if exposed to the influence of the vesicle could form lens tissue, and similarly, if the same ectoderm was used to replace that covering the hindbrain, it would develop into a membranous labyrinth. In this manner, the concept of *embryonic induction* developed. This held that for a restricted period of time a particular region of pluripotent tissue was *competent* to react to an inductive influence exerted by an adjacent tissue with different characteristics.

Primary Organization

Experiments by Hans Spemann involving the ablation, or the auto- or hetero-transplantation of the future dorsal lip of the blastopore region, further clarified the process. In the absence of a dorsal lip, continued development of an organized nature ceased. When, however, such a region was transplanted to the flank of another gastrula a dramatic series of changes ensued. The graft proceeded to proliferate, invaginate and develop into a notochord, surrounding skeletal structures and adjacent muscle masses, showing that extremely early determination had occurred, and it followed its normal course of self-differentiation. In addition, the surrounding host tissues displayed an equally dramatic series of responses to the inductive influences of the graft. The superjacent ectoderm developed into a remarkably complete nervous system, with recognizable subdivisions of brain and spinal cord, laterally placed host mesoderm formed musculature and kidney tissues, whilst on occasions, a subjacent gut tube was induced. Host and graft tissues often continued to interlock in the development of what was virtually a complete second embryo, attached to the abdomen of the host. Because of the early determination and self-differentiating nature of the tissues of the dorsal blastopore region, and their profound inductive influence on surrounding tissues which lead to the development of an embryonic axis and adjacent tissues, it was called the *primary organizer region*. Then followed a series of experiments which demonstrated regional differences in the inductive capacity of the tissues sequentially invaginated through the dorsal lip (**2**.4); thus, so-called head, trunk and tail 'organizer' regions were recognized. Subsequently, however, a wide variety of substances, including some inorganic compounds which do not exist in developing embryos, were shown to have inductive effects, and similar effects sometimes followed the microsurgical killing of a few blastomeres, or the introduction into the blastocoel of powdered glass. Interestingly, extracts of adult tissues produced various responses, either a *mesodermalizing* effect or a *regional neuralizing* effect (with the formation of predominantly forebrain, hindbrain or spinal structures)—*see* Toivonen and Nieuwkoop (1967). Thereafter, many subordinate inductive systems were shown to operate in coordinated sequences throughout chordate development. In some cases competent tissue was separated from its relevant inductor tissue by a 'millipore' filter which prevented the passage of cells (**2**.5); inductive effects still occurred, presumably because of the passage of chemical messengers between the two. (It should be mentioned, in this context, that since the advent of the scanning electron microscope, the full effectiveness of such filters has been subjected to a critical reappraisal.) Since the turn of the century much effort and ingenuity have been expended in attempts to isolate and identify specific intercellular chemical inducers, but despite many claims, none have been substantiated in the embryogenesis of metazoa (Grobstein 1967).

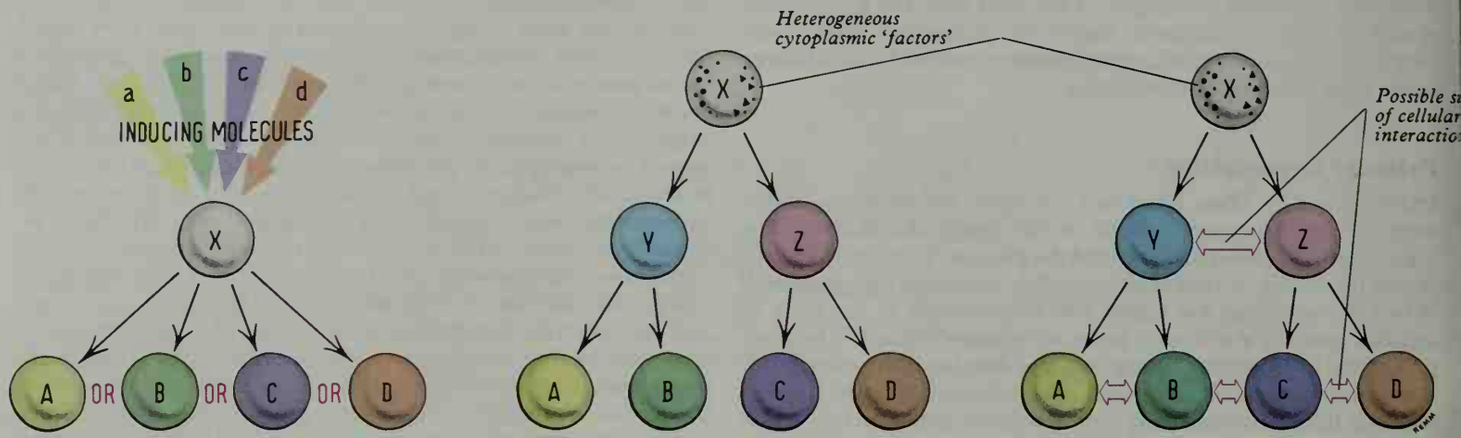
In contrast, considerable detail has now accumulated (Beckwith and Zipser 1970; Woods 1973) concerning the differential activation and repression of the genome in micro-organisms associated with the *induction of enzyme synthesis* (*vide infra*) and also concerning the two-stage inductive events which transform an uncommitted lymphoid stem cell to, firstly a committed cell (p. 59), and secondly to express this committal by the production of specific antibody (Feldman and Globerson 1974). In the latter case, the second stage inducer, the antigen, is, of course, often a chemically well-defined molecule. Whilst such studies are of great intrinsic interest, and may well have parallels with events in embryogenesis, direct extrapolation is at present premature, and it is perhaps unfortunate that the term induction has been applied to all these situations.

In recent years there has occurred a great change of emphasis when developmental biologists consider inductive phenomena. The dramatic responses demonstrated by Spemann following blastopore transplantation, coupled with his all-embracing term 'primary organizer', led for many years to the following view of early embryogenesis. Namely, that the majority of the early blastomeres were *undifferentiated*, *totipotent* cells, with highly labile control mechanisms, and with *numerous* alternative developmental paths *immediately* available to them. A *master organizer* region or regions, was assumed to produce complex organizer or inducer molecules of *high information content* which passed to, and *directed*, the subsequent developmental path of the reactive cells. Naturally, great interest focused on the possibility of isolating and characterizing physico-chemically these *instructive molecules*. Gradually, however, as data have accumulated concerning other possible modes of interaction of cell aggregates (*vide infra*), the use of the term organizer has fallen into disuse, and the search for complex instructive molecules has slackened. It may well be that the inductive phenomena which undoubtedly occur during embryogenesis are mediated by slight variations in ubiquitous molecules of relatively simple chemical constitution (e.g. metabolites) of low, or absent, intrinsic information content, and that the developmental path followed is largely determined by the currently available metabolic options provided by the *cytoplasm* and *genome* of the reacting cells.

MODERN VIEWS OF DIFFERENTIATION

Differentiation has often been defined as the emergence of *irreversible*, *inheritable* differences between somatic cells, in contrast to the many *reversible* changes shown by cells in response to changed local environments, termed *modulations*. However, the apparent irreversibility seems to be a feature which is only especially prominent in cells of vertebrates in the relatively few experimental situations so far studied (and in this sense any such claim must remain empirical). Further, many marked changes in the cells of plants and higher invertebrates closely resemble processes of differentiation, but are in fact reversible (*see* p. 72). Perhaps the terms differentiation and modulation imply a rigid distinction between two states exhibited by cells, when in fact a range of states, with varying degrees of reversibility, may exist.

It has been held (Sager 1965) that from the earliest times the simplest, non-nuclear (*prokaryote*) units of life consisted of '. . . a stablized tripartite system: nucleic acids for replication, a photosynthetic or chemosynthetic system for energy conversion, and protein enzymes to catalyse the two processes'. To these essential ingredients common to all living forms, were later added the enzyme systems which accompanied a dependency on environmental oxygen, and then greater variety of cellular form paralleled the appearance of *eukaryote cells* with a well defined chromosome-bearing nucleus. It is in the *interactions* between these different phases of one cooperative system, the cell, that clues to the nature of differentiation are currently sought (Bell *et al.* 1965; De Reuck and Knight 1967; Bullough 1967; Toivonen and Nieuwkoop 1967; Grobstein 1967; Wolstenholme and Knight 1970; Harris 1970; Ashworth 1973; and subsequent text references).

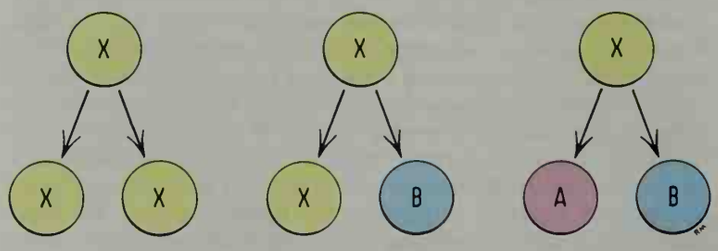


As we have seen elsewhere (pp. 21–27), proteins are of fundamental significance in the construction and operation of all prokaryote and eukaryote cells. In great variety they are essential

constituents of the cytoplasmic matrix, nucleoplasm, cytomembranes including the plasma membrane and walls of the membrane-bound organelles and, with nucleic acids, as the nucleoproteins of the genetic apparatus. Perhaps most significantly in this context, they form the basis of the innumerable enzyme arrays which catalyse all the steps in the structural and energetic transformations which constitute 'life'.

Thus, it has been stated quite simply that when cells with the same genome synthesize different proteins, differentiation has occurred (Jacob and Monod 1961, 1963). This widely held view implies, therefore, that an understanding of the processes of differentiation lies not in the details of the protein synthetic pathways as such, but rather, in the various control systems to which these are subjected. The latter are currently believed to involve varieties of chemical messengers which operate within and between cells.

proliferative cell cycles with amplification of cell numbers, the progeny having precisely the same synthetic capacity as the parent cell (**2.6B**); and *quantal cell cycles* which, at some point, make available for synthetic activities, regions of the genome in the subsequent cells which were *not available* in the mother cell. Such a view securely links the essential steps in differentiation to particular phases of a *critical series* of quantal mitoses, perhaps interspersed by proliferative cycles, and at each quantal cycle that parent cell is maximally *bipotential*. Thus, the division may be *symmetrical* giving derived cells with identical synthetic capacities, or *asymmetrical* in which their capacities differ (**2.6B**). In one particular type of asymmetrical division, one of the progeny retains the synthetic capacity of the parent cell (**2.6B**), that is, it persists as a *stem cell* (p. 27). A quantal cell division, therefore, is a decision point at which the progeny enter one of two new paths of differentiation. A series of such divisions would



THEORIES OF MITOSIS AND PROGRESSIVE DIFFERENTIATION

2.6A Theories of mitosis and progressive differentiation. The tabbing is further explained in the accompanying text.

The foregoing definition of differentiation, however, does not specify which gene products may be regarded as indices that differentiation has occurred, and disregards the phases of the cell cycle. On such a view, early 'pluripotent' embryonic cells have a *wide repertoire* of possible responses, any one of which would *immediately* follow a local change in the operative control system, during any phase of the particular cell cycle occurring at the time. Thereafter, the early, labile control systems would become progressively stablized in subsequent generations as the cells differentiate (**2.6A**).

TYPES OF MITOTIC DIVISION

2.6B Varieties of mitotic cell division: these include a symmetric proliferative mitosis, and two types of asymmetric quantal mitosis. Consult text for discussion.

Other groups of cell biologists, in contrast, propose an alternative set of hypotheses (Holtzer *et al.* 1972, 1975; Reinert and Holtzer 1975, and **2.6A**). These authors class materials synthesized by cells as either '*essential molecules*', i.e. those synthesized by most cells and required for their viability, or '*luxury molecules*' which are 'those cell-unique molecules responsible for the state of differentiation of the cell that either synthesizes them or has inherited them'. Secondly, cell mitotic cycles are regarded as of two fundamentally different types—clearly lead to diversification of cell types, each ultimate *clonal type* being the product of a precise and strictly compartmentalized *cell lineage*. This hypothesis, presented here in the barest outline, rejects the conventional view of the pluripotentiality of early blastomeres, holding that all cells are optimally differentiated for the stage of development they have reached, and further, relegates the inductive capacities of exogenous molecules to a relatively minor role (Holtzer *et al.* 1972, 1975; Reinert and Holtzer 1975). Such views are, however, not wholly in accord with those proposed by other groups in relation to the spatial patterning of differentiation (*vide infra*). The contrasting views concerning cell diversification, and the varieties of mitotic division are summarized in illustrations **2.6A** and **B**.

The Control of Gene Action

The general structure and role of nucleic acids in the form of nuclear and extranuclear deoxyribonucleic acids (DNAs), and various ribonucleic acids (RNAs), in relation to protein synthesis has been discussed elsewhere (p. 25). Mention was also made of the concept of the *operon* which emerged from elegant investigations on micro-organisms (Jacob and Monod 1961, 1963). Essentially, an operon is a functional grouping of DNA loci including several *structural genes*, an *operator segment* (*o*), a *promotor region* (*p*), and a *regulator gene* (*i*). Each structural gene carries the information necessary for the specification of a particular polypeptide (which forms part of either a structural or an enzymatic protein). In the case of the *lac operon* of *Escherichia coli*—the first to be thoroughly analysed by the study of the activities of mutant forms (Beckwith and Zipser 1970; Ashworth 1973)—the linear sequence of DNA loci has been demonstrated to be: *i p o z y a* (*z*, *y* and *a* denoting structural genes which encode for the synthesis of *β*-galactosidase, a permease, and a transacetylase respectively). The prefix *lac* indicates that lactose is the physiologically important substrate for *β*-galactosidase. Subsequently, further examples of more complex operons have been analysed, with many features in common with the lac

operon, but with alternative controlling mechanisms. A comparison of these studies is now leading to rapid advances in our knowledge of the main variations in gene activity in *prokaryotes*.

In general the activity of the structural genes is dependent upon the state of their associated *operator*; they are active only when it is 'free' and they become inactive when it is 'blocked' by combination with a specific chemical group. The neighbouring *regulator gene* produces a *repressor protein* which, depending on local conditions, may exist in an active form capable of binding with the operator, or in an inactive form when it cannot do so. In this manner the activity or otherwise of a particular group of structural genes is dependent upon the production of a *first order* chemical messenger or repressor protein. In turn, specific *second order* messengers (*effectors*) determine the state of the repressor molecules. Some repressors can only block the operator when combined with effectors termed *co-repressor* molecules. In some instances it has been shown that low molecular weight end products of certain *biosynthetic pathways* act as co-repressors, thereby providing a negative feedback system controlling the synthesis of enzymes essential to the biosynthetic path. Thus, heightened activity in the biosynthetic path leads ultimately to gene *repression*, whereas diminished activity leads to *derepression* of the relevant genes.

Other effectors, such as *enzyme inducers* act in a converse way—by combining with the repressor protein they so modify its structure that it is unable to combine with the operator, and consequently the related structural genes become active. The *promotor region*, which lies adjacent to the operator, is now known to be the site where binding of DNA-dependent RNA polymerases (*transcriptases*) occurs, when the operator is not blocked by repressor protein. These determine the *loci* for the *initiation of transcription*, and further, variations in a number of factors entering into the constitution of the transcriptases (e.g. the σ-factor) result in *modulation of the rate* of transcription.

Thus, through the balanced activities of *negative* (repressor/operator) and *positive* (transcriptase/promotor) controls, a great flexibility of gene action may be achieved varying from *on/off switches* to delicate *adjustments of transcription rates*.

Certain gene loci have also been considered to control the *mitotic* behaviour of cells; on this view, when the loci are active multiplicative growth persists, and when inactive, the cells are channelled into avenues of differentiation and ageing. The *tissue-specific chalones* mentioned previously have been proposed as co-repressors of such mitosis-initiating genes (Bullough 1967). The activities of the tissue chalones may be modified by the concentration of general circulating hormones and thus as intermediaries between the endocrine system and the state of the genome in the tissue cells. (In certain invertebrates a further class of substances called *pheromones* even pass between different individual members of a community, and affect the reactions of their tissues and also their behaviour patterns.)

However, as indicated previously, some cell biologists would not regard the foregoing as an adequate view of the role of mitosis in cell differentiation. Firstly, many would prefer to consider the delicate on-going quantitative controls of protein synthesis as more the province of the cell physiologist, and regard true differentiation to occur only at certain definite phases of *quantal cell cycles* (p. 25). As stated, in the latter, regions of the genome of derived cells become available for synthetic activities, which were *not available* in the parent cell. In this regard, mention must be made here of the elegant researches on the structure, distribution and possible roles of varieties of the basic proteins called *histones* (*see* reviews by Zubay 1968; Cook 1973; Wasseman 1973; Borun 1975). Five principal classes of histone are present in eukaryote cells, and these form strong, stable complexes with each other; and with DNA, thereby being important structural and functional components of the chromosomes (*see* the discussion on the *nucleosome*—p. 25, and 1.22). It has been proposed that in combination with certain 'operator-like' regions of the chromosomes the histones provide a powerful *non-specific repression* of these regions and their associated structural genes. Such regions, it is thought, become *unblocked* by the cooperation of *non-histone components* only at specific times during chromosome replication in quantal cell cycles. It is possible that such non-histone components, or their precursors, form the basis of the so-called *morphogenetic substances* which many workers have indirectly demonstrated to be differentially distributed in the cortex of the oöcyte, thereafter being unequally partitioned in the various blastomeres at cleavage and further, they may form the substrate for cell-cell interactions in later development. Experimental analysis of the components that may interact with the histone complexes is still in its infancy. Particular interest has recently been centred upon the structure and metabolism of certain *'acidic' non-histone chromosomal proteins* (Borun and Stein 1972; Stein and Borun 1972; Gerver and Humphrey 1973; Borun 1975) which may be responsible for the production of specific RNA transcripts and, accordingly, be closely related to aspects of the control of cellular differentiation. (Over 400 varieties of such proteins have recently been demonstrated in mammalian cells.)

Some authors have stressed that the genome of *prokaryotic cells* is permanently *unblocked* but can be repressed or derepressed (Tsanev and Sendov 1971; Tsanev 1975), while in metazoan *eukaryotic cells* the genome is initially *blocked* and during embryogenesis *sequential deblocking* different gene combinations occurs. The *functional state* of the fully differentiated cell is thereafter determined by repression and derepression 'within the limits of the deblocked regions of the genome'. Computer simulation of model systems of metazoan development indicates that the final stages of cellular differentiation can be reached only through 'a chain of events in which both processes of repression-derepression (realized by embryonic induction) and of blocking-deblocking (realized by the mitotic cycle) are successively involved'.

It should be noted that many of the control systems described above seem to be mediated by that ubiquitous regulator molecule cyclic adenosine monophosphate (3′5′cAMP) which therefore also appears to have a central role in cellular differentiation.

An abbreviated account such as the foregoing can do little justice to the numerous, elegant, and rapidly expanding researches in these fields. Nevertheless, enough has perhaps been said to emphasize that the earlier evidences stemmed largely from work with micro-organisms, and although considerable advances are now being made (Lewin 1976), the positive identification of the specific roles of intracellular and intercellular chemical messengers in advanced metazoan tissues is still awaited. However, as a working hypothesis it is considered that the patterns of growth, differentiation and functional expression in metazoa result from the varied activation and repression, coupled with sequential deblocking, of gene groups which stem from an interlocked hierarchy of chemical messengers—repressors, co-repressors, inducers, transcriptases, blocking/deblocking proteins, tissue chalones, and circulating hormones (and in some communities pheromones), which act in coordinated sequences in space and time, as integral parts of cell cycles. Many modifications of this scheme will undoubtedly prove necessary. Furthermore, the informational role of extrachromosomal nucleic acids and other self-replicating cytoplasmic substances (or *plasmagenes*) which may be of great importance in normal development have as yet been little investigated in the higher metazoa.

CONCEPTS RELATING TO PATTERN FORMATION

The events outlined in the previous sections dealt largely with hypotheses concerning the *intracellular* mechanisms controlling cell differentiation, neglecting two other fundamental aspects of development, namely *pattern formation* and *morphogenesis*. The latter, acting in concert with cell differentiation, are the means by which the total genetic information available to the zygote is ultimately expressed in the mature functioning phenotype.

Pattern formation concerns the processes whereby the individual members of a mass of cells, initially *apparently* homogeneous, undergo a number of different avenues of differentiation, which are precisely related to each other in an orderly manner in space and time. It is the mechanisms by which such temporo-spatial differences are initiated and maintained that currently engage the attention of many developmental biologists. The 'patterns' embraced by the term, of course, not only apply to

regions of *regular* geometrical order such as the retina, crystalline lens, cerebellar cortex, etc., but all aspects of metazoan development including ordered but *asymmetric* structures such as the tetrapod limb, mammalian liver, etc. Thus, in the case of the tetrapod limb, for example, the intimate *intracellular* events leading to the emergence of chondroblasts, myoblasts, osteoblasts and so forth, will be identical in right and left sided limbs, fore-limbs and hind-limbs, and their counterparts in different species; nevertheless, the *patterned arrangement* of these elemental processes differ in each case.

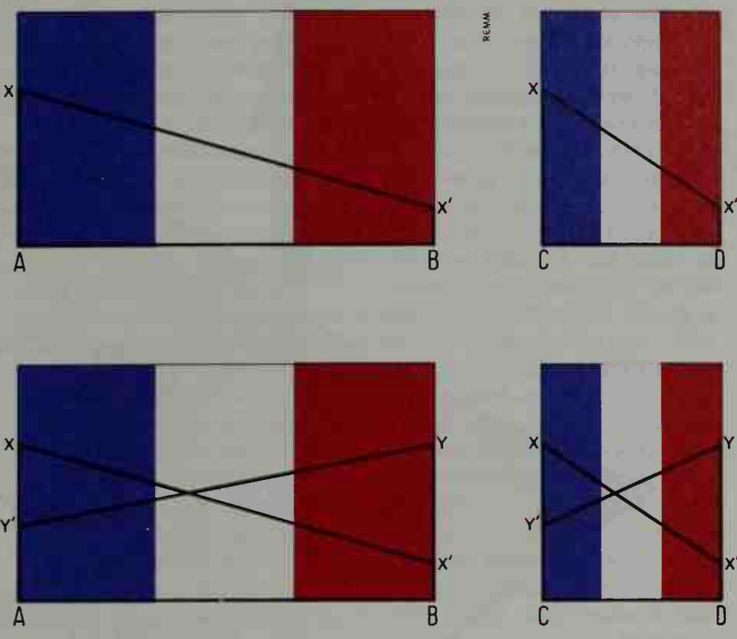
Morphogenesis, or the assumption of form by the whole, or part, of a developing embryo is often for convenience treated as a separate field of study, involving differential rates of growth or degeneration of groups of cells, but particularly in early embryogenesis the relative *morphogenetic movements* of cells or cell aggregates. The movements involved in gastrulation (p. 76) or the wide dispersal of neural crest cells (p. 112) are particularly dramatic examples. Thus, the study involves an analysis of the *mechanisms* and *forces* responsible for cell movement, migration, changes in shape of individual cells and particularly the differential adhesiveness of their surfaces (*see* pp. 7, 92). However, despite the conveniences for research groups, these various elements in development are necessarily *interdependent*. Whether it is differential growth balanced against areas of degeneration, morphogenetic movements and migration, or cellular differentiation under consideration, it is necessary first to *specify* within a group of cells *which particular ones* shall divide, degenerate, migrate or differentiate, and this is the province of *pattern formation*. As an example, when a group of cells migrates to a distant location in normal development, mechanisms clearly exist to *locate* the group about to migrate, in relation to the remainder of the embryo. After an initial period of growth, the selected group enters initial stages of differentiation, which will lead to the development of those organelles, surface specializations and changes of cell shape, responsible for the mechanics of migration; further, these events must follow in correct *sequence* and *orientation*. Following migration, the group is now in a new cellular environment, and further periods of growth and differentiation follow, with crucial interactions between the migrated group and the cells forming its new environment, often affecting the particular avenues of differentiation followed by *both*.

It should be noted that pattern formation is an essential ingredient not only of normal embryogenesis but of processes of *regeneration*, good examples being the regeneration of new heads and tails in transected flatworms, new apical and basal regions in transected *Hydra*, or the replacement of a whole severed limb, or an appropriate part thereof, in adult *Amphibia*. In general, regeneration follows one of two main types; *morphallaxis* in which the whole reforms by rearrangement and differentiation of the existing tissues without further growth, or by *epimorphosis* in which there is new growth of blastemal tissue which subsequently matures into the full regenerate. Whatever control mechanisms are proposed for pattern formation in the embryo, they must be sufficiently flexible to also account for morphallaxis and epimorphosis.

It should be emphasized that the approach to the problems of pattern, form and differentiation contrasts sharply between different groups of workers. Some (Holtzer *et al.* 1975; Lederberg 1967) take the view that finer and finer probing of the genome and the detailed control of protein synthesis, leading to a reasonably complete understanding of the *intracellular* molecular events of cytodifferentiation would, in its turn, with little addition, provide an adequate explanation of changes in form and pattern. Others (Wolpert 1969, 1971), however, whilst conceding the importance of the molecular aspects of cytodifferentiation, hold that the laws and principles of control of pattern and form must initially be sought at the *cellular* and *intercellular* level, and that they will prove to be 'as general, universal, elegant and simple, as those that now apply to molecular genetics'. (For an extensive and critical account of pattern formation consult Wolpert, 1977.)

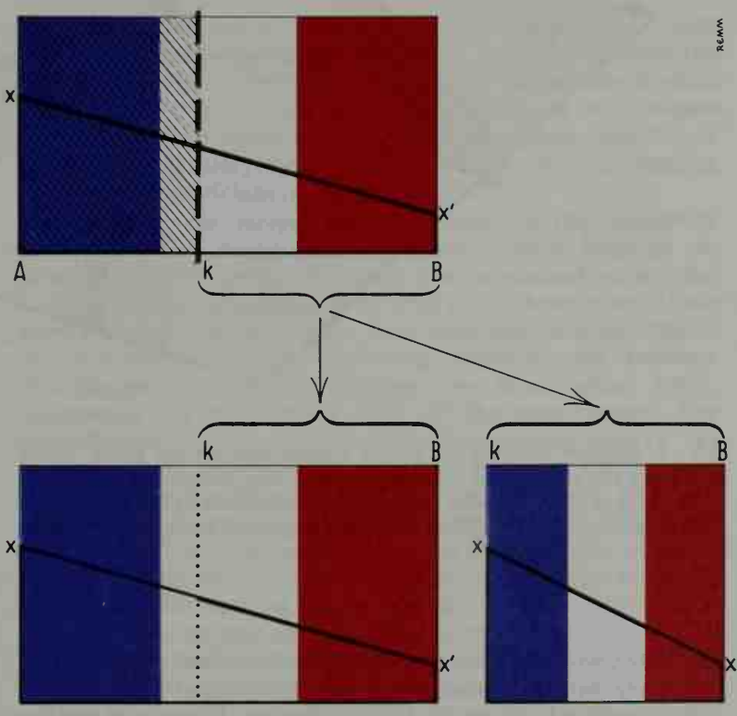
Since the closing decades of the last century, a series of concepts concerning pattern formation have slowly emerged, but with the passage of time these have frequently been rephrased and redefined, often resulting in some differences of definition and terminologic confusion between authors. These concepts were mentioned earlier (p. 81) and include ideas of polarity, axes, gradients and fields, and suggestions concerning the coordinates necessary for their specification.

In the physical sciences, the idea of a system possessing two regions of opposite tendencies or qualities, the *poles*, which can be considered to be joined by a linear *axis* is commonplace, for example in magnetism and electrostatics. At each point in space along and around the axis and poles, a force exists having a specific intensity and direction, i.e. a *vectorial force field* is present in three-dimensional space, and a *linear axial gradient* exists between the poles. Similar terms were adopted by developmental biologists, but whilst some authors (Wolpert 1971) stressed the analogy with the physical sciences, others (Waddington 1970) considered that, except for particular purposes, such approaches were grossly over-simplified. Descriptions of systems exhibiting forms of polarity, axes and gradients, abound throughout biology. Classical examples include the study of regeneration following the transection of *platyhelminths* or *Hydra* at different levels. The details will not be followed here, but in general the presence of an axial gradient concerning the form and frequency of successful regeneration was demonstrated, together with gradients of metabolic activity and susceptibility to toxic materials. Further, the *apical region* (head in flatworms and hypostome in *Hydra*) regenerated first and subsequently inhibited the formation of additional apical structures, and appeared to coordinate the regeneration of succeeding parts (a phenomenon termed *apical dominance*). Similar poles, axes and gradients have been described in many *oöcytes*, for example the animal-vegetative, oral-aboral and dorso-ventral axes (*see* p. 74 and **2**.3). The term axis has, however, been used in rather different ways in different situations. Thus, the animal-vegetative axis of oöcytes is often an obvious structural and cytophysiological feature, reflected by the eccentricity of the nucleus and the differential distribution of yolk platelets, other organelles, pigment granules, metabolic levels, etc. Further, in some forms which have been thoroughly analysed (Gustafson and Wolpert 1963, 1967), e.g. the sea urchin, there exists an experimentally demonstrable 'morphogenetic gradient' along this axis, although it is as yet uncertain what are the relevant 'morphogenetic factors' which are distributed along the axis, although tentative suggestions have been made (*see* p. 85), and of course the mechanisms controlling their distribution are completely unknown. However, it is clear that the animal-vegetative axis is determined early and once formed is extremely stable; in contrast, the dorso-ventral axis is determined much later, is more difficult to demonstrate and is more labile. Similar concepts of polarity and axes have often been applied, for example, to the developing tetrapod limb, and here again, the proximo-distal, cranio-caudal and dorso-ventral 'axes' are determined at different times and vary in their lability.



Such concepts are central to many of the hypotheses relating to pattern formation and may be considered in association with the two forms of development mentioned earlier (p. 76) termed *mosaic* and *regulative*. In a mosaic system, removal of a part results in a specific defect in the final embryo, whereas removal of part of a regulative system is followed by a total proportionate reorganization of the remaining portion, with the formation of a small but complete embryo. Further, division of a regulative system often results in duplication, with two small complete embryos. Similar considerations also apply not only to whole zygotes, but also to presumptive organ rudiments. Although no animal groups are wholly mosaic or regulative, some such as the annelids and molluscs show a high degree of mosaicism, whereas the sea urchin and chordates are typically regulative.

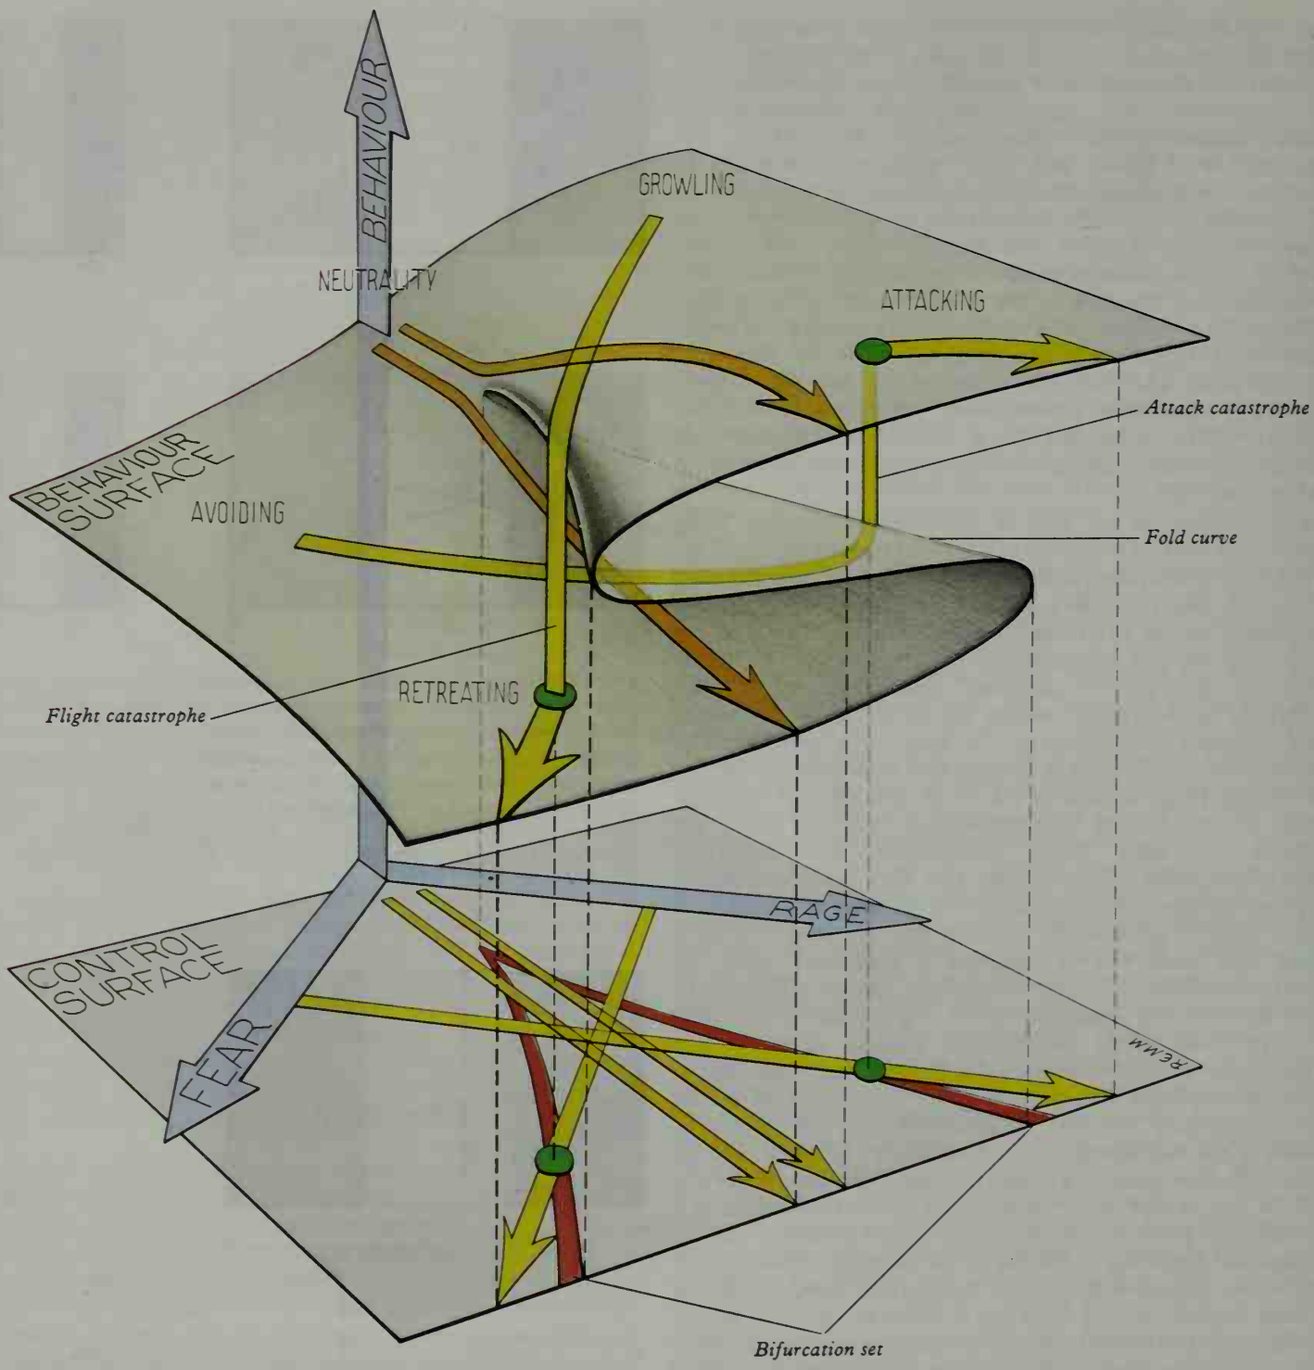
During oögenesis, and perhaps modified to some degree at fertilization, it has been demonstrated (Raven 1958, 1963, 1966; Davidson 1969) that morphogenetically important substances are localized (oöplasmic segregation) in the cortical zone in geometric patterns related to the principal axes of the oöcyte. It is assumed that the distribution gradients of such substances are differentially parcelled between the blastomeres during cleavage. In *mosaic systems* it is thought that the cytoplasmic parcelling which results from their highly ordered and specifically orientated forms of cleavage, is almost wholly responsible for directing subsequent pattern formation, morphogenesis, and cytodiffentiation, as a



series of independent localized events, with relatively little intercellular communication. In contrast, it has been proposed that whilst the blastomeres of regulative eggs also necessarily differ qualitatively and quantitatively, the phenomenon of *regulation* exhibits *global features* wherein the mass of cells reorganizes *as a whole*, and there must exist avenues of *intercellular communication* of crucial significance in development. Such ideas led to the early formulation of the concept of the *morphogenetic field* (Huxley and DeBeer 1934; Child 1941) defined as 'a region throughout which some agency is at work in a co-ordinated way, resulting in the establishment of an equilibrium within the area of the field'. Subsequent years saw the rather sporadic (and occasionally inappropriate) use of the term embryonic field, and then for a period its use was largely abandoned by many developmental anatomists. Only recently has the phrase been subjected to a critical reappraisal and restatement, and as a result, two provocative but contrasting views have emerged.

The first concerns the idea of *positional information* being available to individual members of a mass of cells by virtue of the presence of *reference points* at its borders, the whole constituting a *morphogenetic field*. Essential to the idea is that *gradients* of activity (information) extend from the reference points throughout the cell mass by *cell–cell communication*: accordingly, the unique position of each cell is specified, and subsequently each differentiates appropriately, within the limits of the metabolic options provided at the time by the state of its genome. The picturesque model adopted to present this hypothesis is the so-called 'French Flag Problem' (**2**.7 A, B). In this, a line of cells with channels of intercellular communication between them, are considered to have three possibilities for molecular differentiation—blue, white or red, and they form a correctly proportioned French Flag whatever the number of cells in the line, and even if parts of the original line are removed. It is assumed that each cell is assigned a positional value by appropriate signals with respect to reference sources at the ends of the line. Reference to illustration **2**.7 A, B will make it clear how such a proposal could successfully explain proportionate differentiation, not only with lines of different lengths, but also to include epimorphosis and morphallaxis. A number of model systems proposing possible mechanisms for the mode of operation of the signalling system have been examined. Briefly these include, most simply, a source of a metabolic product at one end of the line, a sink at the other, with the establishment of a linear diffusion gradient between them. More complex models have proposed signalling gradients of two or more substances, or the reversible operation of multiple sources and sinks depending upon local conditions (the so-called homeostatic model), whilst others have invoked active transport mechanisms, or the presence of paths of selective permeability. A most interesting alternative mechanism has been suggested (Goodwin and Cohen 1969; Cooke and Goodwin 1971) that a reference point may be provided by a *pacemaker cell* which emits two wave-like periodic propagations of biochemical activity which are transmitted from cell to cell throughout the morphogenetic field. Positional information would then be signalled by the *phase angle difference* between the arrival of the two waveforms at the cell in question. Recently, in a detailed analysis of amphibian gastrulation it was suggested that *two* such pacemaker regions were present, one at the animal pole and the other at the grey crescent. Their mutual positions change during gastrulation providing a dynamic *two-dimensional grid* of positional information in the mesodermal mantle, thereby specifying its subsequent pattern of cytodifferentiation.

Despite the fact that all the foregoing signalling mechanisms are relatively simple in principle, it has been stressed that such systems, when coupled with variations in the 'rules for interpretation of the signals' on the part of the genome of the reacting cells, could result in the production of highly complex, even asymmetric patterns. Nevertheless, although universality has been claimed for the theory throughout biology (Wolpert 1971, 1977), currently there is no direct evidence for the precise nature of the boundary zones (reference points or pacemaker cells), the detailed mechanisms of intercellular signalling, and the manner of cellular interpretation of the signals. As yet, therefore,



2.7A Diagram illustrating one hypothesis concerning positional information in relation to pattern formation, by reference to the so-called 'French Flag' problem. A–B and C–D indicate long and short rows of cells respectively. X, X′ and Y, Y′ the concentrations of morphogenetically active substances. Above: (X–X′) shows the gradient of a single substance; below: (X–X′ and Y–Y′) the gradients of two substances. In each case a similar triple differentiation occurs. See text for discussion. (Modified from, and kindly provided by Professor L. Wolpert 1971, 1977.)

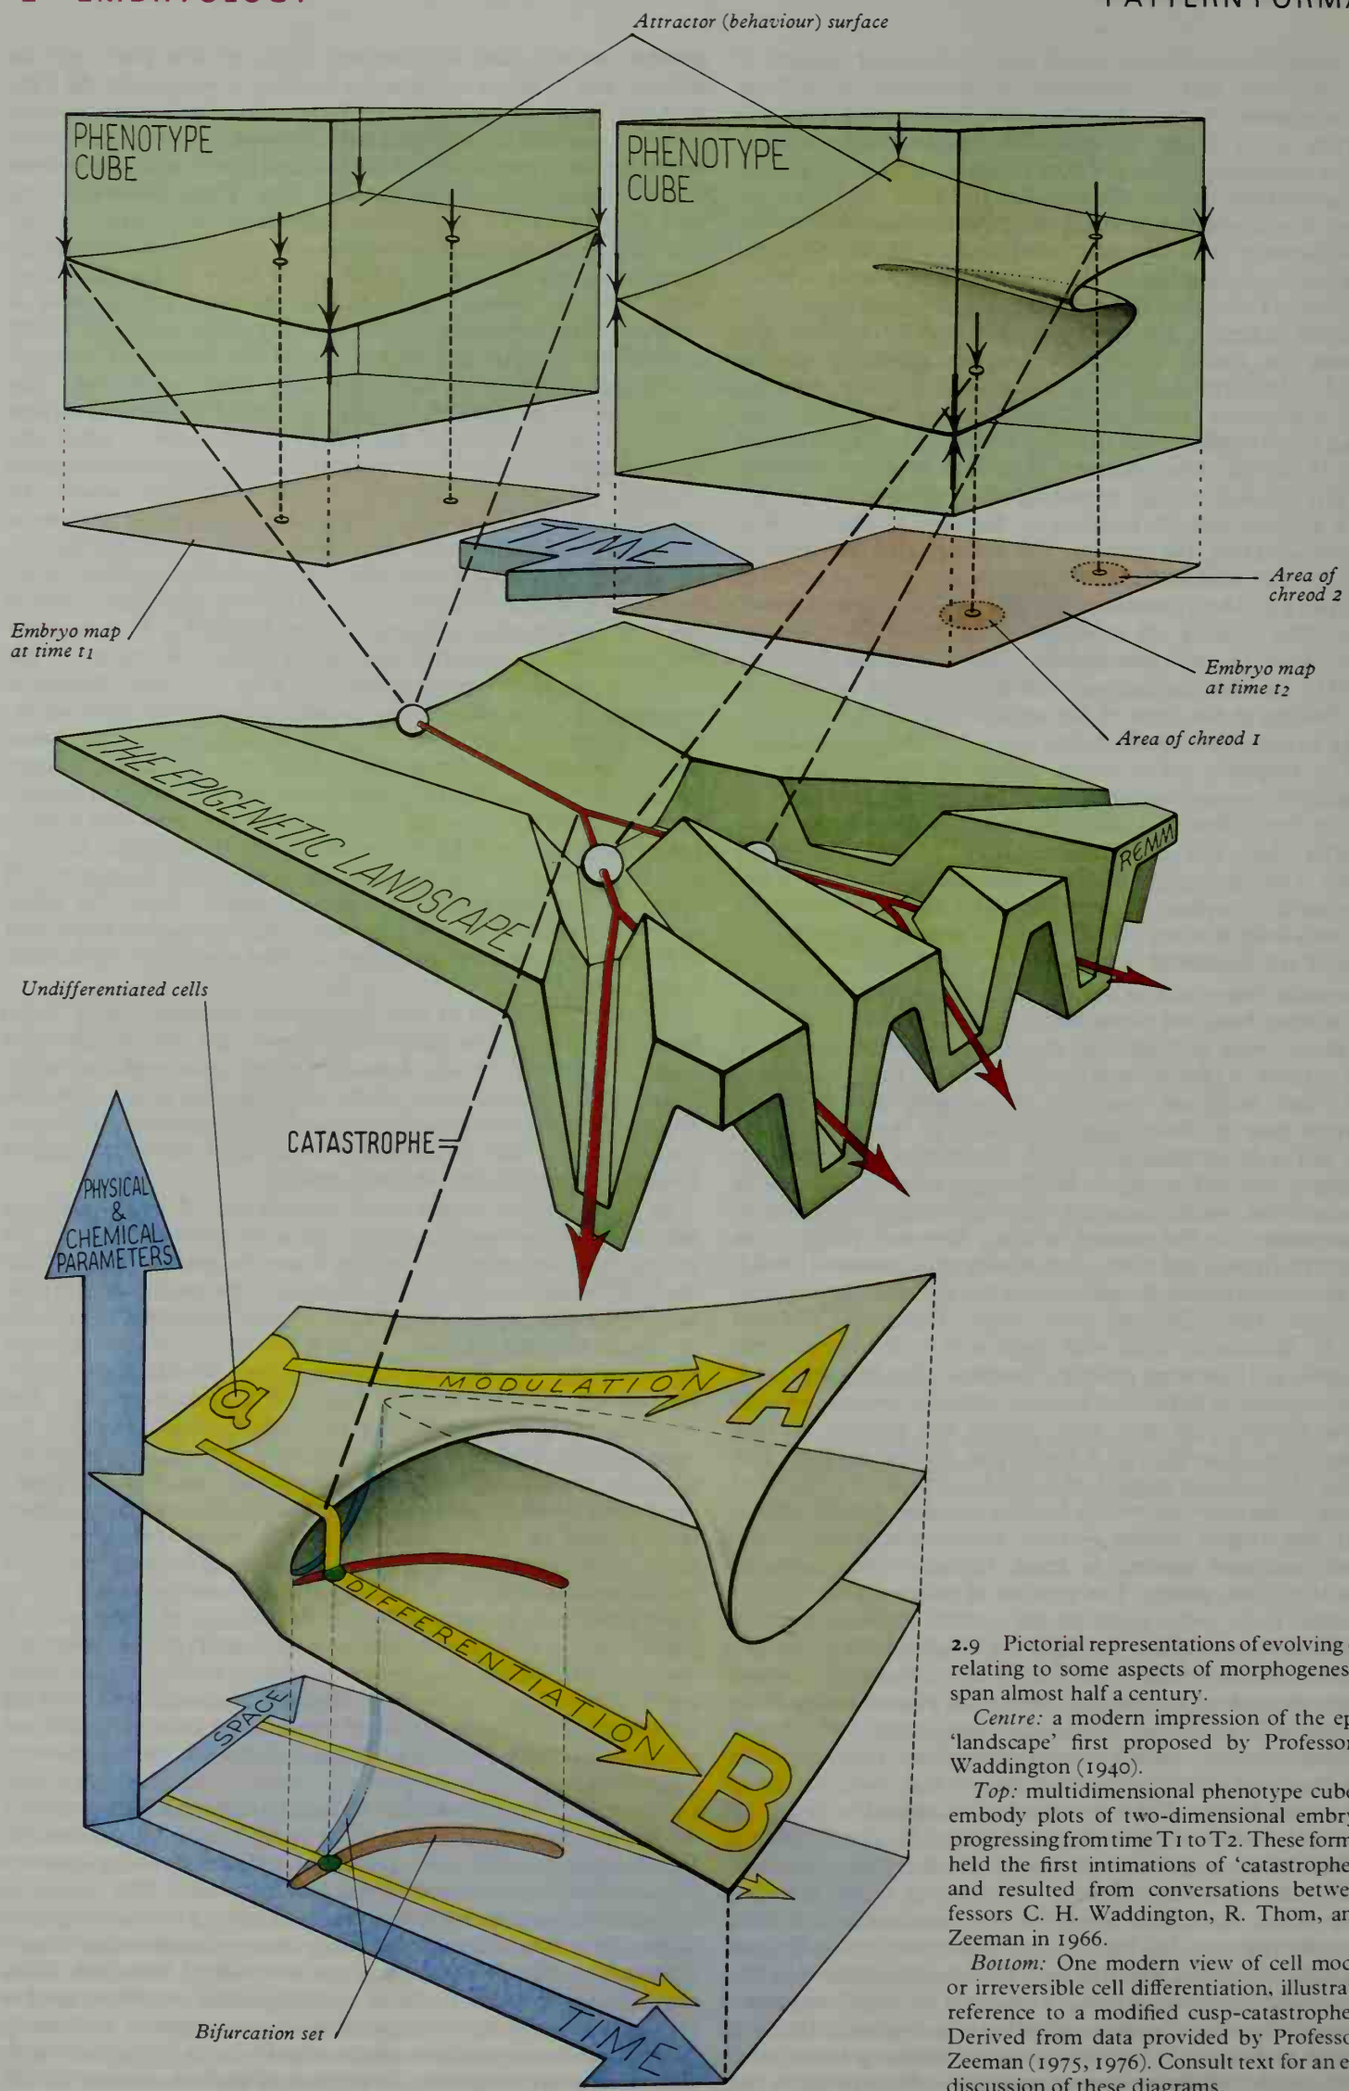
2.7B Diagram using the 'French Flag' analogy to illustrate application of the hypothesis of positional information advanced to explain regeneration, after ablation (cross-hatch), of part of an array of cells, either by morphallaxis, or by epimorphosis.

the hypothesis of a coordinate system which specifies positional information, whilst providing a powerful stimulus for new thought and experiment, must for the present remain the province of tentative theoretical biology.

During the period of emergence of theories of positional information in relation to morphogenetic fields, there has also occurred the convergence of ideas from two other sources. The

2.8 A diagram showing the use of a three-dimensional graph which embodies the single pleat of an elementary cusp-catastrophe model. In this, changes in the possible aggressive or submissive behavioural states resulting from the interactions of varying degrees of fear and rage in dogs have been illustrated. Consult adjoining text for a more detailed description, and explanation of the terms used. Redrawn, and slightly modified, by kind permission from the author, Professor E. C. Zeeman, and the *Scientific American*.

first constituted a critical reappraisal of the definition of the term 'morphogenetic field' and associated terminology by the eminent developmental biologist, C. H. Waddington. The second was the evolution of a new set of descriptive and explanatory mathematical models which have been grouped under the dramatic name of *catastrophe theory*.



During the attempts to redefine the term 'field' as applied to embryology, it was stressed that much confusion had arisen because of the original combination of the ideas of organization and induction (Waddington 1966), and reinforced by the use of terms such as 'organization centre' and 'organizer substance'. Thus it was originally supposed, as indicated above, that such a centre, during an act of embryonic induction, produced organizer substances which transmitted the instructions necessary for the subsequent complex organization of a neighbouring mass of competent cells. In order to avoid this confusion it was proposed (Waddington and Needham 1936; Waddington 1966) that the term *evocation* should be used for 'induction that does not *transmit* organization'. *Individuation* was suggested as the name for organization of a mass of cells *per se*, whether it was preceded by an inductive *triggering mechanism* or not. In this sense it was proposed that a morphogenetic field was only appropriately named when applied to an *individuation field* and it was indicated that some authors had used the term too loosely, denoting merely the *locality* of a normal presumptive organ rudiment. It was also considered that to view a morphogenetic field as the manifestation of the presence of gradients of one, or at most a few, simple diffusable substances, was almost certainly a naïve over-simplification. Emphasis was placed on the fact that when attempts are made to describe a system in developmental biology, cognizance must be given not only to the three dimensions of *space*, but also to the essential dimension of *time*, to embrace the dynamic progressive changes involved. Further, at successive intervals it would be necessary in such a *multidimensional function*

space to establish coordinates which allow a vectorial analysis of the *concentrations* and *directionality of interaction* of a large number of relevant chemical families. The mathematical concepts appropriate to a study of multidimensional space-surface transitions constitute *topology*. Those facets of topology which are of wide application in both the physical and biological sciences, including developmental biology, constitute *catastrophe theory* which has recently been invented, developed mathematically, and provocatively propounded by the distinguished French mathematician René Thom (1972, 1975). Hitherto, the great domains of the physical sciences, for example, the laws of motion and gravitation, the theory of electromagnetism, and the general theory of relativity, dealt with systems exhibiting gradual, smooth, continuous transitions which could be adequately described by the differential calculus invented by Newton and Leibniz. However, it has become clear that in many systems, both in physics and biology including the behavioural sciences, despite a gradual smooth increase or decrease of one or more parameters affecting the system, the response of the system although initially smooth and continuous, a point is reached when there occurs a sudden, dramatic, completely contrasting form of response. The science of topology is involved because the *resultant forces* in multidimensional space systems are best described by smooth, continuously curved *surfaces of equilibrium*. Abrupt changes in the form of the surface indicate the points at which the equilibrium breaks down, and at which equally abrupt changes in response occur—such points of discontinuity are mathematically termed *catastrophes*. They are not amenable to analysis by the differential calculus, and it is to embrace such phenomena that the new mathematical theory has been developed. The rigorous proof of the mathematical validity of the theory is highly complex (Thom 1972, 1975) and cannot concern us here, but a brief allusion to the manner of presentation of *results* of the proof are illustrated (**2**.8, 9).

Catastrophe theory has, at the time of writing, had its greatest impact on other branches of mathematics; applications in physics include shock-wave propagation, non-linear oscillations and the detailed analysis of caustics and fluid flow. It has been suggested, however, that in future years its potentially most powerful applications may lie in biology in relation to the behavioural sciences and in developmental studies. Illustration **2**.8 is redrawn from a paper devoted largely to behavioural science, because its construction and implications are relatively easy to understand. Space constraints in the present volume, however, preclude an adequate description and discussion of even this elemental model, and the interested reader should consult the original sources cited (Thom 1972, 1975; Zeeman 1975, 1976; Thom and Zeeman 1975). The illustration deals with aggressive behaviour in dogs and includes the following principal features. The assumption is made that aggressive behaviour is the resultant of two *measureable conflicting* factors, fear and rage, which are plotted as axes diverging from an origin on a horizontal *control surface*. The behaviour of the dog is plotted on a third, vertical axis, the most aggressive behaviour—growling leading to overt attack—being assigned the largest values, whilst submissive behaviour—avoidance reactions leading to frank retreat—being assigned progressively lower values. The total set of points on the vertical axis, plotted from every point on the control surface, together form the *behaviour surface*. It might be imagined that only *one* resultant behaviour would be predicted from each combination of fear and rage leading to a simple downward slope passing from attack, through growling, neutrality, avoidance and finally retreat. Over much of the behaviour surface there is, indeed, only one resultant behaviour point, but where rage and fear have roughly equal values there are *two* highly probable forms of behaviour, i.e. attack *or* retreat, but neutrality is the *least* probable form of behaviour. Application of catastrophe theory explains this *bimodality* in behaviour pattern. Expanding from a point vertically above the origin along the distant margin and then including the right and left regions, the behaviour surface forms a single continuous slope which is high to the right and low to the left. Centrally, however, starting at a *point of singularity*, and expanding forwards, a continuous double fold or *pleat* is formed. The upper and lower layers denote *two* alternative behaviours each with a *high probability* corresponding to a *single* point on the control surface (the intermediate layer of the pleat can be disregarded in terms of response because it represents the *least probable* form of behaviour). The actual behaviour pattern followed can only be predicted from a knowledge of the particular *starting point* in the behaviour surface and then tracing its route as the relevant parameters change with time. Thus, an enraged but only slightly fearful dog shows aggressive behaviour: as fear increases, behaviour changes only slowly (gentle slope) remaining aggressive, but the point on the upper layer of the behaviour surface moves centrally. Eventually the edge of the pleat is reached, and the behaviour plot *suddenly* drops vertically to the lower sheet denoting a complete contrast in behaviour which is now meek, submissive and ultimately leads to retreat. The projection of the edges of the pleat back on to the control surface comprises a cusp-shaped pair of divergent curved lines, the *bifurcation set*, and the whole system predicting sudden changes in response is therefore termed a *cusp-catastrophe model*. In summary, this model predicts a single behaviour pattern for most parameter combinations, but *bimodality exists within the bifurcation set*. The points at which jumps from the upper to the lower sheet occur, do not correspond with those points at which the converse direction of jumps occurs (*hysteresis*). It is also clear that starting at a point of neutrality, slight differences in the temporal change of parameters may lead to widely divergent responses (passing either on to the upper sheet or the lower sheet, the divergence occurring at the point of singularity). The forces which operate homeostatically within any particular system tending to maintain the behaviour point (or trajectory) in contact with either the upper or the lower sheet of the behaviour surface are collectively termed the *attractor* for that particular surface. The attractor effect is most powerful in unimodal regions which approach the horizontal and are of gentle slope. Its effect diminishes in the region of bimodality and increasing slope, and of course vanishes at the margin of the pleat where it is replaced by a new attractor.

When a maximum of four parameters are considered, Thom has shown mathematically that these can be satisfactorily described by one of seven *elementary catastrophe* models of which the cusp catastrophe is one of the simplest and, as yet, of widest application. The analysis of models embodying larger numbers of parameters and their possible applications, are currently engaging leading mathematicians in many centres.

In view of the recent wide acceptance of the conceptual relevance of catastrophe theory in such diverse fields as the physical and behavioural sciences, it is of the greatest interest that the first formal scientific paper devoted to the theory should have been preceded, by some years, by a brief statement in relation to *developmental biology* following conversations between Waddington, Thom and Zeeman (*see* Waddington 1966). Illustration **2**.9 summarizes some of the main points. For simplification, the developing three-dimensional embryo has been reduced to a pair of two-dimensional embryo maps (compare with the *control surfaces* described above) and these represent increasing developmental compexity at two successive points in time T1 and T2. From each point on the embryo maps, vectorial plots of the activities of relevant chemical groupings are made within multidimensional spaces termed *phenotype cubes*. These plots generate appropriate 'behaviour surfaces' the form of each indicating the homeostatic equilibria present. It will be noted that the almost horizontal featureless behaviour surface at T1, which embodies a single, powerful, effective, *attractor*, has during development by time T2 been subdivided into two different attractor surfaces, separated by a breakdown in homeostatic equilibrium and indicated by the pleat of an *elementary cusp catastrophe*. The term *chreod* (derived from Greek roots meaning 'it is necessary or fated' and 'a path') was introduced by Waddington to refer to equilibrium surfaces showing attractor phenomena in multidimensional space systems. The region of strong effective attractor action was termed by Thom the 'support of the chreod', and the surrounding zone where its effectiveness diminishes, and catastrophes occur was named 'the cone of the chreod'. Accordingly 'fields' in embryogenesis were portrayed as subregions in a multidimensional space-time system, each being chreodic in character with its particular attractor system, and with progressive development, divergence of chreods occurs by the

interposition of catastrophe zones. In the central part of illustration **2.9** each attractor surface has been plotted down to a simplified contour impression of the picturesque concept of an *'epigenetic landscape'* which had been advanced by Waddington a quarter of a century earlier (Waddington 1940). This comprises a system of valleys, initially single but diverging into branch valleys with the passage of time. Each valley and its sloping walls constitutes a chreod. The homeostatic power of its attractor mechanisms is simulated by the steepness of the valley walls, and it is this feature that confers on a developmental field, or chreod, its regulative capacity (p. 81). The points of divergence of valleys are the points at which the homeostatic attraction breaks down with the occurrence of catastrophes. Such a system may be thought of as analogous to the emergence of, for example, a series of separate organ primordia during early development. The lowest part of illustration **2.9** displays a modified cusp-catastrophe model which applies catastrophe theory to two possible modes of change which may ensue when a group of 'undifferentiated' cells (*a*) are subjected to an array of physical and chemical parameters which change temporally and spatially. It will be noted that *modulation* of the cells to condition (*A*) is represented as a reversible process (remaining confined to the upper leaflet of the behaviour surface). In sharp contrast, *differentiation* of the cells to condition (*B*) can be considered as involving a sudden 'catastrophic' change (occurring, perhaps, when particular parameter combinations are present at the time of the *critical mitoses* discussed previously on p. 84). It should also be appreciated that in the model illustrated, the pleat in the behaviour surface is *incomplete*: i.e. there is no return path from *B* to *A* (which would involve a pleat edge). Thus it is assumed that, in this case, such a change (or dedifferentiation) back to condition *a* cannot occur.

It is hoped that the greatly abbreviated accounts given in the foregoing paragraphs relating to pattern formation and the concepts of positional information and catastrophe theory, will be sufficient to convey the general conceptual framework employed by modern developmental biologists. It must be stressed, however, that whilst they have provided powerful stimuli for reappraisal of many outstanding problems, precise laboratory verification and clarification is still awaited. Thus, whilst the *phenomenon* of embryonic induction is widely accepted as adequately demonstrated, its *mechanism* is still unknown. Similar, perhaps identical, questions are posed, but remain unanswered, by the *intercellular signalling* mechanisms implicit in the theory of positional information. In like manner, *mathematical models* based upon catastrophe theory have been constructed for the cardiac cycle, nerve impulse propagation, cell differentiation (**2.9**) and for amphibian gastrulation (Zeeman 1975, 1976), but as yet experimental validation is lacking (and indeed, occasional authors view with scepticism the over-enthusiastic acceptance and application of the theory in the presence of incomplete data—*see* Croll, 1976).

Nuclear Changes During Differentiation

Two main lines of investigation have attempted to demonstrate changes in the nuclei of tissues which have undergone differentiation—firstly, experiments using nuclear transplantation techniques, and, secondly, an examination of the phenomenon of chromosome 'puffing' shown by some species. Many kinds of transplantation experiment have been carried out (King and Briggs 1965; Gurdon 1967, 1968) but in principle, the nucleus is removed from an activated egg and replaced by one removed from a particular site in, for example, an early blastula, early or late gastrula, or more highly differentiated post-gastrulation tissue, and then any subsequent development which proceeds is analysed. In practice more reliable quantitative results can be achieved by the *serial transplantation* of donor nuclei before proceeding to a developmental analysis (**2.5**). Although the results show considerable variation, in general, the transplantation of early nuclei is often followed by the formation of a complete embryo, whereas nuclei from the later stages are sometimes only able to support the development of incomplete embryos or cell masses of a restricted tissue type. However, in contrast, it has been shown that nuclei from quite advanced tissues such as amphibian neural plate cells, and ciliated gut epithelial cells of the tadpole can still support the formation of complete embryos, although the proportion of successful experiments is reduced, whilst nuclei from fully adult tissues fail to do so (Gurdon 1967, 1968). Whilst such results may reflect some stable changes occurring in nuclei as differentiation proceeds, much more work will be necessary before clear-cut interpretations are possible.

Direct visualization of differences between the chromosomes of various tissues, and at various times, has been provided by examination of the giant polytene chromosomes of the *Diptera* and the 'lampbrush' chromosomes of the newt. At certain points along their length such chromosomes exhibit hazy thickenings of their outlines (*'puffs'* or *Balbiani rings*). It is widely held that throughout inactive regions of chromosomes, the DNA threads are closely coiled and supercoiled, but at sites of activity the threads become unwound and spread laterally from the axis of the chromosome and form the basis of the puffs. Each puff may include a number of active operons at which transcription and synthesis of messenger RNA is occurring. In short, although many details of the process of puff formation remain to be elucidated, the puff pattern of all the functional nuclei of a particular cell type in a tissue are identical, but it differs significantly from the patterns in other tissues. The patterns also change as development proceeds; for example, there is a regularly repeating sequence of changes accompanying the 'moult' and 'intermoult' stages in the life of larvae. The latter system is particularly interesting since moulting is a response to a hormone, *ecdysone*, which has been isolated, and which affects the activity of the genome—details of the process are under intense analysis.

It is important to emphasize the fundamental question posed by such investigations, namely—during the growth, patterning and differentiation of complete multicellular organisms, is the *essential sequence* of instructive molecules in the genome of the different emergent cell types *altered* for example, by deletion of segments? Alternatively, is the overall sequence *preserved* and the *expression* of its various segments *modified* appropriately? The consensus supports the latter, with the reservation that the *degree of reversibility of expression control* varies widely with site and species.

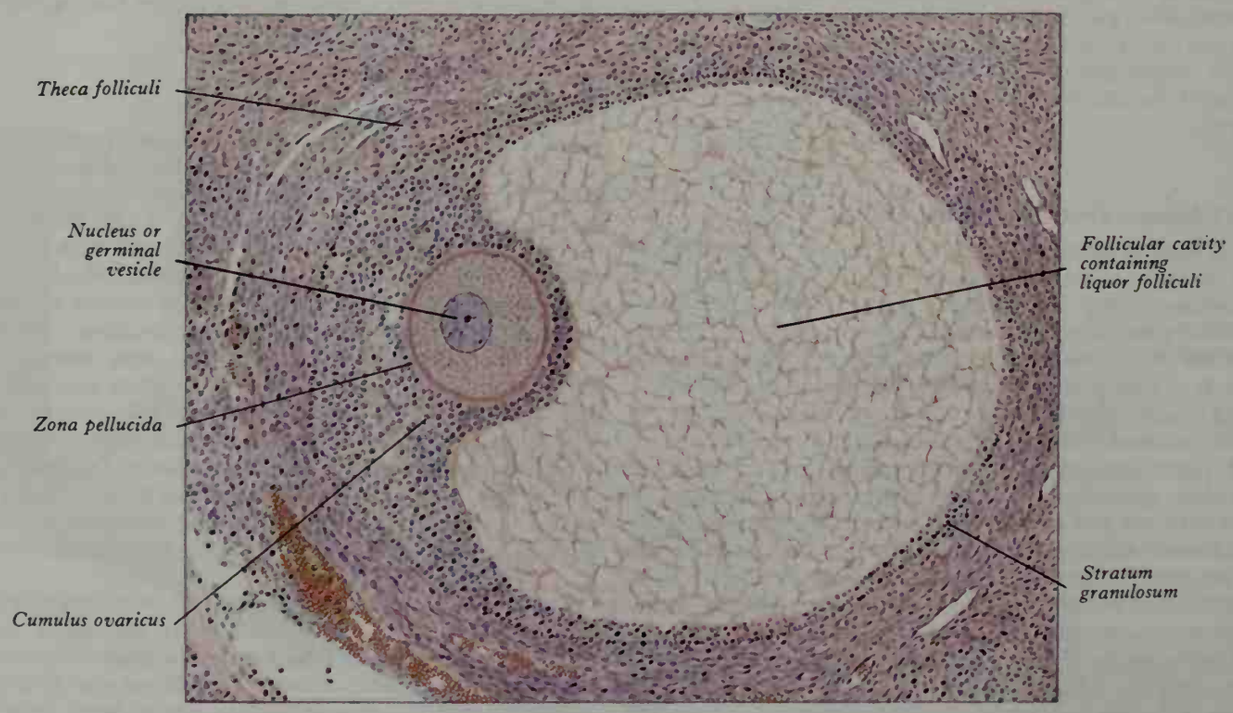
Occasional examples of alteration of genomic sequences have been quoted, for example, the early segregation of gonocyte and somatic cell nuclei in *Dipterans*, with the apparent deletion of sex-determining loci in the latter; another case involves the *amplification* of repetitive gene sequences during oögenesis at the other extreme; it has proved possible, by careful tissue culture techniques, to grow a complete carrot plant from a single isolated parenchymal cell from a mature carrot.

Surface Interaction Between Cells

Further properties of developing cells which reflect some aspect of their state of differentiation, and have important implications in morphogenesis, concern the selective interactions between their surfaces when in contact. Such surface modifications are closely related to the formation of the cellular sheets, hollow balls, tubes, invaginations, solid masses and so on which characterize embryonic life. Following earlier tissue culture studies, (Weiss 1941, 1961; Abercrombie 1961; Abercrombie and Heaysman 1954, 1970) two important principles were enunciated. Many experiments showed that some cells when explanted on to a matrix with an heterogeneous, polarized substructure, often migrated along preferential paths determined by its architecture. This led to the concept of *contact guidance* of cells—particularly well shown in the preferred regeneration of nerve fibres along the surfaces of Schwann cells, or, during ontogeny, the growth of later generations of nerve fibres along the surfaces of the earlier pioneer fibres.

In contrast, when similar cells which were migrating freely in tissue culture, approached each other and made contact, all movement and often cell division in the plane of contact ceased, and this phenomenon of *contact inhibition* was proposed as an important morphogenetic factor. For a brief review of the mechanisms of cell movement *see* p. 35, and for more recent reviews on morphogenetic movements consult Trinkaus (1969);

Abercrombie and Heaysman (1970); Ingram (1969); Garrod (1973).



Since that time many experiments involving the *disaggregation* of tissue cells have been made (Townes and Holtfreter 1965). For example, if the cells of a neurula, or those of a developing kidney are disassociated to form random cell suspensions, they often subsequently reaggregate and similar cells reassociate so that a recognizable neurula, or a fragment of kidney tissue is reformed. Again, if cell suspensions from developing liver and kidney are intimately mixed, similar cells gradually reassociate and organize into kidney and liver tissue. In this manner, using different cell combinations, the potential of different cell types for mutual recognition, reorganization into tissues, sheet formation, invagination and so forth, have been analysed. An adequate interpretation of the phenomena would, of course, necessitate an intimate understanding of the physico-chemical properties and control systems of cell surfaces. Until such become available, the investigators in this active field of research are pursuing the quantitative variations in the *specific adhesiveness* between cells, and are proposing various models for further examination, such as the possession of specific *stereochemical surface configurations* which can only interlock with a complementary surface. For reviews consult Curtis (1967, 1970); Steinberg (1970); Karfunkel (1971); Baker and Schroeder (1967); Schroeder (1970); *see* also p. 7.

In the subsequent sections a brief account of human development is given and, as such, is necessarily and solely *descriptive embryology*. When reading such an account of the emergence of organ primordia and their sequential shape changes, the reader should be constantly aware of the many continuing fields of *experimental analysis* in other forms, which are daily adding to our comprehension of the *causal processes* of the almost incredible and beautiful phenomenon of development.

HUMAN DEVELOPMENT

The Female Gamete: The Ovum

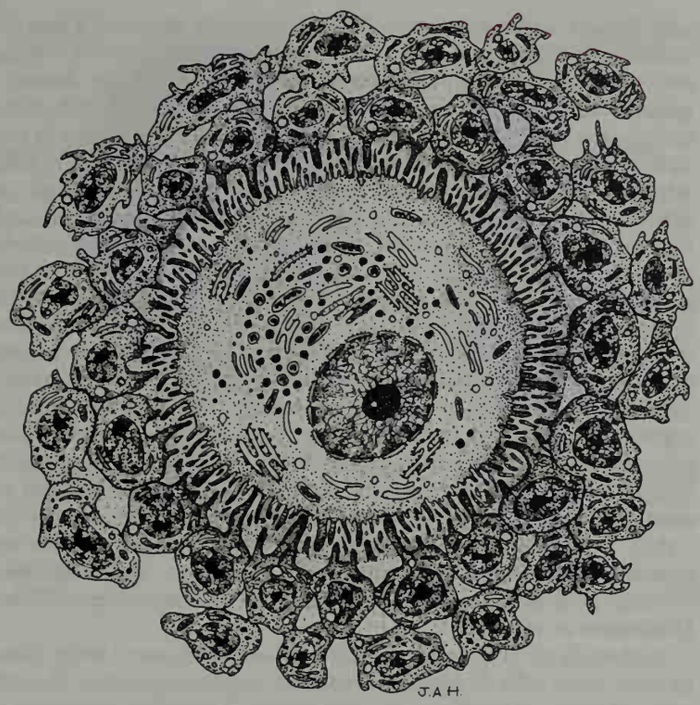
The precise origin of the primordial germ cells, from which both ova (Shettles 1960; Austin 1961), and spermatozoa are derived, remains uncertain (p. 216); but those which reach the genital ridge in the female, the *oögonia*, proliferate and differentiate into *primary oöcytes*. The number of germ cells reaches a maximum estimated at about 6,000,000 in each ovary by the fifth month of intra-uterine development (Baker 1963, 1966). Subsequently, before birth, a widespread degeneration occurs, many oögonia disappearing, leaving a complement of about 2,000,000 primary oöcytes to last throughout reproductive life (Block 1953). However, the majority of these become atretic before puberty, at which time only some 40,000 oöcytes persist in each ovary (Pinkerton *et al.* 1961). A mere 400 or so of these will be shed at ovulation with the potential of fertilization during the reproductive years of the average woman. (Each primary oöcyte passes through a series of changes, becoming a *secondary oöcyte* just before ovulation, and mature *ovum* at, or just after, fertilization. The term 'ovum' is nevertheless used with a confusing vagueness for all three stages, a practice which is best avoided.) Immediately after formation, and still before birth has occurred, primary oöcytes enter the initial stages of prophase of the *first meiotic (reduction) division* in the process of *maturation*, which is not completed until shortly before ovulation. This reduction in the genetic apparatus of the cell is, of course, a central feature of maturation (p. 94). A primary oöcyte is distinguishable from other cells in the ovary by its large size, being about 35 μm in diameter, and by the fat granules in its cytoplasm. Its nucleus is relatively large, vesicular and usually eccentric, with a nucleolus also comparatively large. The Golgi apparatus is well developed and consists of parallel cisternae and numerous small vesicles; the latter also appear throughout the cytoplasm. Juxtanuclear annulate lamellae occur and there is a similar distribution of mitochondria, which are spherical or slightly elongated. At first the endoplasmic reticulum is vesicular and displays few ribosomes. As the oöcyte grows all these organelles increase in number, and usually in size, and they disperse from the juxtanuclear zone throughout the cytoplasm. Granular endoplasmic reticulum and free ribosomes, though not prominent, also increase. Lipid granules begin to appear, the granules corresponding to the yolk platelets of earlier vertebrates, though

2.10 Ovarian follicle from a woman aged 28 years. Haematoxylin and eosin. Magnification × *c.* 90.

they are smaller and less frequent in primates. By the time the secondary or antral stage of follicular growth is reached the oöcyte has completed its increase in size. Usually each ovarian follicle contains one, but two or even more may be present. In some strains of certain animals polyovular follicles may be more frequent. The oöcyte is surrounded by a single layer of cubical cells, and at this stage electron microscopy shows that the relationship is one of close apposition, the adjacent plasma membranes being smooth and separated by 12·5–14·0 nm.

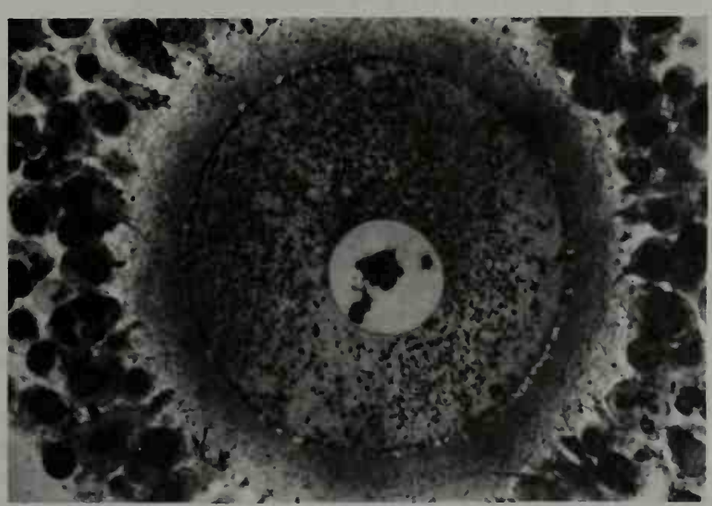
THE OVARIAN FOLLICLE

During the next stage of maturation considerable growth of the primary oöcyte and enlargement of the follicle occurs. By accumulation of cytoplasm and particularly of lipids, the oöcyte reaches a diameter of 117–142 μm—a volume increase of about a thousand times. This is fully achieved before follicular enlargement is completed. The follicular cells first multiply and form several layers; at, or even before, this stage electron microscopy reveals the accumulation of interrupted masses of amorphous material between the cells and the oöcyte. These soon fuse into a complete membrane around the oöcyte, seen with light microscopy as a PAS-positive, thick, and radially striated envelope, the *zona pellucida* (z. striata). The zona contains considerable amounts of carbohydrate and neutral glycoprotein as a structural component (Braden 1955). Variable amounts of sialic acid residues also occur and may contribute to its elasticity (Soupart and Noyes 1964; Soupart and Cleive 1965). Electron microscopy shows it to possess an intricate filamentous structure at the time of ovulation. The origin of the zonal membrane, whether from the oöcyte, follicular cells, or both, is still undecided (Hope 1965); an outer layer, consisting of acid mucopolysaccharide has, however, been attributed to the follicular cells (Wartenberg and Stegner 1960–1). Coincident with the development of the zona, the surface of the primary oöcyte presents numerous microvilli which project into the zona: less frequent processes from the follicular cells pass through the zona pellucida to make contact with the plasma membrane (oölemma) of the oöcyte, without actual cytoplasmic continuity. These intimate relationships may be concerned with transport of materials between the follicular cells and ovum (Shettles 1959, Chiquoine 1959; Sotelo and Porter 1959; Odor 1960).



The zona pellucida is semipermeable and is slowly lysed in alkaline media. It is best developed in placental mammals and persists until the blastocyst stage of development. It is probably the source of fertilizin (Bishop and Tyler 1956) in mammals, and its function in fertilization is discussed below (p. 99).

Dense extracellular granules, *Gall-Exner bodies*, develop between the maturing follicular cells. They are PAS-positive and display a complex ultrastructure. They may be derived from the Golgi apparatus, but are of uncertain significance. They occur in human follicles, but rarely in other mammals.



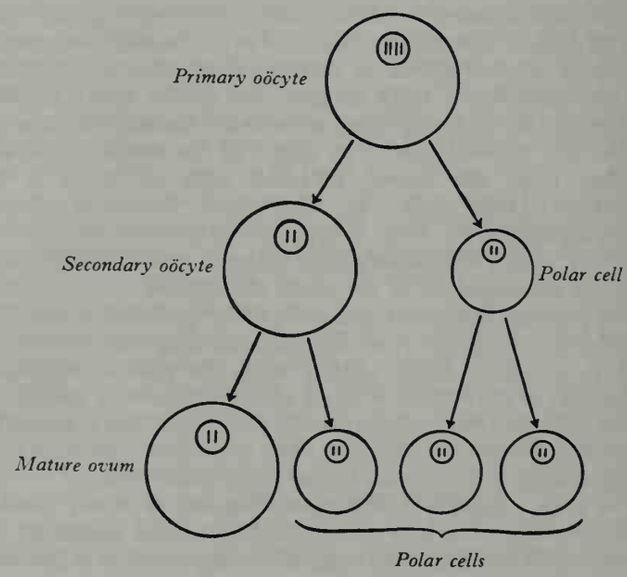
OVULATION

When the follicle has reached a multi-layered form, a fluid-filled antrum appears among its proliferating cells and gradually divides them into an internal stratum, the *cumulus ovaricus* (oöphorus), and an external layer, the *stratum granulosum*; but at one site the two strata maintain continuity (**2**.10). The oöcyte is in the cumulus, the granular stratum forming an envelope around the fluid and gradually thinning out as the latter, the *liquor folliculi*, accumulates. (Antral development has been analysed in detail in the rhesus monkey by Zamboni 1974.) The primary oöcyte retains its microvilli and its complex interrelationship with the follicular cells outside the zona pellucida (**2**.11) until shortly before ovulation, when formation of the first polar cell is initiated. At this point in time the circumvitelline space first begins to appear between the zona and what is now a secondary oöcyte. The processes of the follicular cells are also withdrawn from the zona, which therefore loses the striation evident under light microscopy and becomes more homogeneous. The follicular cells show an increasing abundance of mitochondria, granular endoplasmic reticulum, and free ribosomes, and their Golgi organelles become more prominent, indicating an increasing rate of activity. The stratum granulosum becomes enveloped in a cellular and fibrous sheath derived from the ovarian stroma (**2**.10), termed the *theca folliculi* (p. 1424). By enlargement, and perhaps also some actual translation through the ovarian stoma, the ripening follicle projects from the surface of the ovary and finally ruptures, releasing the 'ovum' (**2**.11), surrounded by the cells of the cumulus, into the peritoneal cavity, from which it rapidly enters the uterine tube for slow transit to the uterus, aided by contractions of the fimbriae of the tube, and of the tube itself, together with ciliary movements of its epithelium (Austin 1963). It should be added here that the secondary oöcyte cannot be strictly regarded as an ovum until after completion of its division into ovum and second polar cell (**3**.12).

The follicular cells adherent to the liberated oöcyte are now termed the *corona radiata*, and they form two or three irregular

2.11A A drawing constructed from electron micrographs of a primary oöcyte surrounded by its zona pellucida, outside which are aggregated follicular cells of the corona radiata. Note extensive invasion of the zona by microvilli of the oöcyte interdigitating with cytoplasmic processes of the follicular cells. Where some of the latter approach the plasma membrane of the oöcyte, desmosomoid junctions are visible. Note the organelle-rich cytoplasm of the oöcyte. (Modified from Anderson and Beams 1960, with kind permission.)

2.11B Human oöcyte photographed in transverse section. Follicular cells surround it, the zona pellucida intervening. Part of the antrum of the follicle is visible above. Epon-embedded, osmic-acid fixed, toluidine blue stained. Magnification × 550. (M. Baca and L. Zamboni, J. Ultrastr, Res., **19**, 1967.)



and loosely arranged layers (2.11). Between them is a matrix containing hyaluronic acid, and in some species there is strong evidence that seminal hyaluronidase brings about the disintegration of the corona which soon occurs. Unless fertilization occurs, the secondary oöcyte is discharged from the uterus in the débris of the next menstrual period; if it is fertilized, the zygote which results is retained and pregnancy begins. (For details of fertilization *see* p. 99.) Usually only one follicle matures fully and ruptures in each menstrual cycle in mankind, but multiple ovulation does occur (p. 138). Hence only a small fraction of the primary oöcytes which persist in the ovaries of the new-born female are destined to survive to ovulation, the remainder degenerating. Atresia occurs before birth, as stated above, and even at birth about half of the surviving oöcytes are abnormal. Several follicles usually develop normally to some extent in each reproductive cycle, but only one commonly completes the process, the others becoming degenerate, being invaded by blood vessels and connective tissue which ultimately replaces them as *atretic follicles* (eventually forming small *corpora albicantia*—p. 1425). An interesting laparoscopic technique for observing normal, and artificially controlled, ovulation and follicular development in primates other than man has been exploited by Dunkelow *et al.* (1973).

Although an oöcyte is exceedingly large compared with other general body cells, it resembles them in general structure, though some of its parts are given specific names. Thus, the cytoplasm is the *yolk* or *oöplasm*, the nucleus is termed the *germinal vesicle*, and the nucleolus the *germinal spot*. The cytoplasm is also often known as the *vitellus*, and hence the plasma membrane of the cell is the *vitelline membrane*. The yolk comprises two major components—(1) cytoplasm such as that of any other cells, termed *formative yolk*, and (2) the *nutritive yolk* or *deutoplasm*, which consists largely of fatty droplets containing lecithin. In mammalian ova the deutoplasm is small in amount and is only sufficient for the initial stages of embryonic development prior to implantation in the uterus. In contrast, as we have seen (p. 74), the eggs of birds contain a supply which nourishes the chick throughout its entire development up to hatching. The distribution of the deutoplasm varies in different animal groups; the abundant deutoplasm of certain ova tends to accumulate in one part of the cell, which is therefore termed *telolecithal*. In human ova the dispersion is rather more uniform or *isolecithal*. The formative yolk contains some of the organelles characteristic of cytoplasm, such as mitochondria, Golgi apparatus and centrosome; centrioles are sometimes visible in the neighbourhood of the nucleus, but they disappear when the female pronucleus is formed after fertilization (p. 100). (For a detailed analysis of the fine structure of the developing human oöcyte *in vitro* consult Zamboni *et al.* 1972.)

MEIOTIC DIVISION OF THE OÖCYTE

The series of changes which produce a fertilizable 'ovum' are known as maturation (Monroy and Tyler 1967), some features of which have already been mentioned above. The primary oöcyte's initial period of growth by accumulation of deutoplasm is followed by two successive cell divisions (2.3), the first being *heterotypical, reduction division,* or *meiosis*, during which the so-called *diploid* or full complement of chromosomes is halved, the second division being *homotypical* and involving no such reduction (p. 29). Unfortunately, both forms of division, intimately linked in the formation of mature ova (and spermatozoa) from their precursors, are, in current practice, grouped together under the term meiosis (which strictly implies a reduction or lessening), a custom which is misleading but probably now ineradicable.

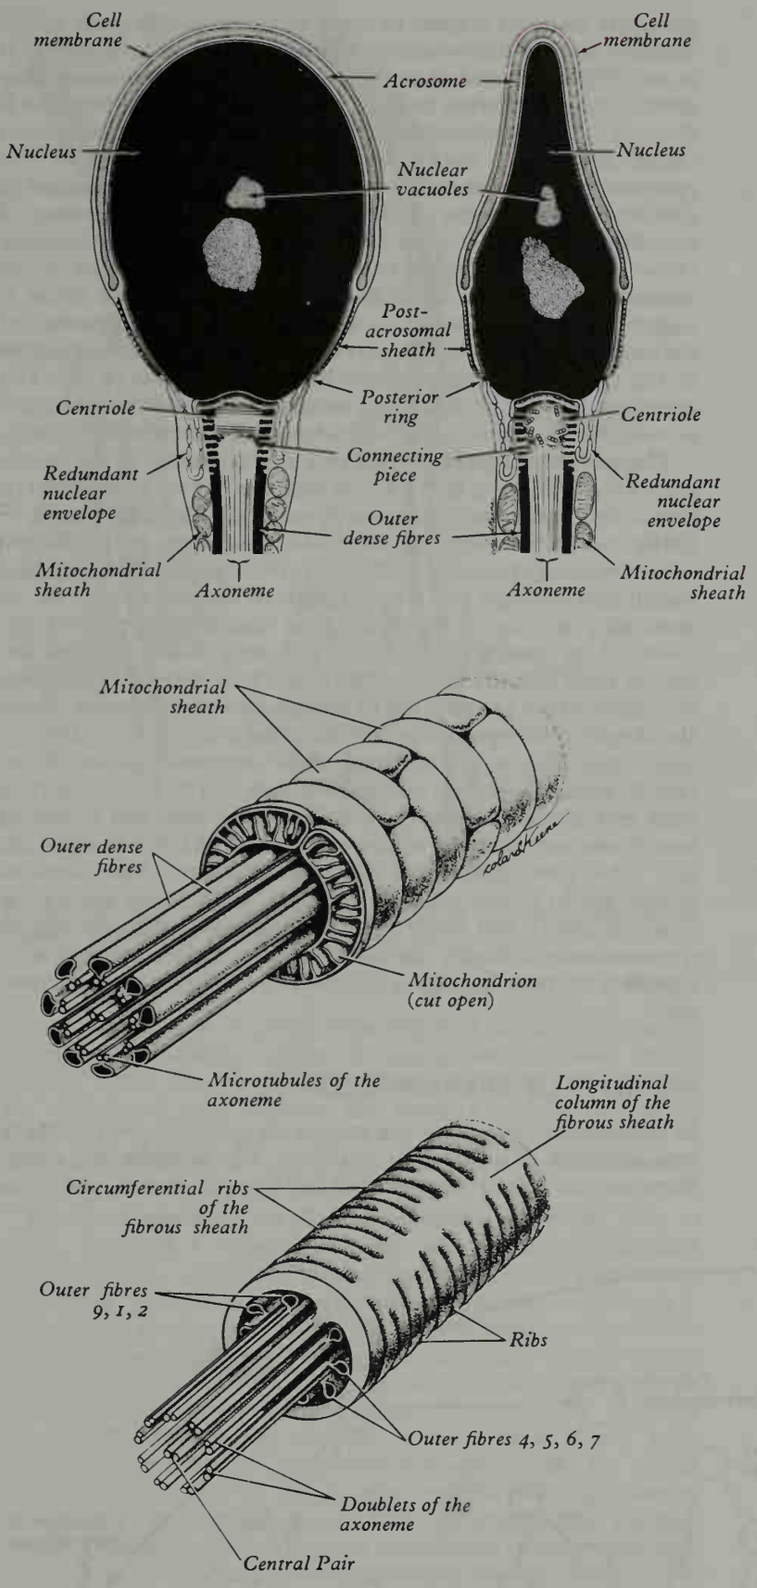
The primary oöcyte, which is already in the prophase of the first meiotic (true reduction) division, contains the diploid number of chromosomes. It should be emphasized that most, if not all, the primary oöcytes have completed the prophase stage of the first meiotic division before the individual's birth (Manotaya and Potter 1963; Ohno and Smith 1964). Instead of proceeding to metaphase, they enter the so-called *dictyotene* stage, a resting state between prophase and metaphase, which is characterized by a reticular arrangement of chromatin and lasts until the first meiotic division is resumed and completed shortly before ovulation. As this division is resumed, the nucleolus disappears, the nuclear membrane disintegrates, the chromosomes appear and become arranged in homologous or *bivalent* pairs at the equator of a spindle radially orientated at one pole of the oöcyte. The chromosomes separate, and one member of each pair passes centripetally into the central region of the cell, while the others move centrifugally, forming a projection at the upper pole of the oöcyte, which becomes separated off as the *first polar cell* or 'body'. Unlike that of the nucleus the division of the cytoplasm is highly *unequal*, the polar cell carrying with its equal chromosomal complement an exiguous share of the cytoplasm. The larger cell resulting from this reduction division is a *secondary oöcyte*, and it is not fully reconstituted before it divides again. Its haploid complement of chromosomes (22 autosomes + an X sex chromosome) is again rearranged around the equator of a spindle at the upper pole of the cell. The nuclear membrane is not reformed before this second maturation division commences. A similar division may occur in the first polar cell, but this is abortive, since all the polar cells degenerate. At the moment of spindle formation the secondary oöcyte is shed from its mature follicle to enter the uterine tube. The division is only completed after fertilization, as had long been suspected (Allen *et al.* 1930; Hamilton 1944, 1949).

2.12 A diagram showing the reduction in number of the chromosomes during the maturation of the ovum. The first division is heterotypical the second homotypical.

If fertilization ensues, the haploid group of chromosomes split longitudinally, so that each of the resultant two cells receives an equal amount of genetic material, although the chromosome content has been halved. The larger cell is the ovum, which retains almost all the cytoplasm, a small amount only of which enters into the formation of the *second polar cell*. The first polar cell may not undergo division in every instance, but as many as three, theoretically the full complement, have been observed in association with fertilized ova within the zona pellucida (Shettles 1955).

The chromosomes of the fertilized ovum now lose their identity and form a reticulum near the centre of the cell and constitute its nucleus, at this stage termed the *female pronucleus*, around which a nuclear membrane reappears. The cytoplasm shrinks a little, so that a distinct circumvitelline space develops, in which the polar cells may be visible. At this stage the mature ovum is characterized by its chromosome content—half the typical number for the somatic cells of the species—and its large size, due to the great accumulation of deutoplasm. Its pronucleus is now ready for union with the male pronucleus, already in the cell, in the last act of fertilization, the formation of a zygote (p. 99). (The above remarks concentrate upon chromosomal and nuclear organization; for the equally essential organization of the *cytoplasm* of the oöcyte prior to fertilization and further development, *see* pp. 74–76.)

The Male Gamete: The Spermatozoön



Gametogenesis in the male exhibits marked similarities and differences in comparison with the development of ova. During the process of maturation there is the same reduction of chromosomes to the haploid number, but in the testis there is a continuous formation of spermatocytes and spermatozoa during the reproductive life of the individual, a difference linked with the enormous number of gametes which must be formed. In each ejaculate there are many times more spermatozoa than there are germ cells in both ovaries at their peak content before birth; whereas the latter is of the order of 10 to 12 million, a single ejaculation may contain 300 million spermatozoa (**2.13**), only one of which may fertilize an ovum. (The nomenclature of male gametes is not yet unified; spermatozoön, spermatoid, sperm and spermium are all used, but official agreement has not yet been satisfactorily established.)

THE MORPHOLOGY OF SPERMATOZOA

A spermatozoön, or sperm (Fawcett 1961, 1975; Piko 1969; Rothschild 1957), is a smaller cell than an ovum, highly specialized to reach the latter and to carry to it its own haploid chromosome complement. Its expanded *caput* or *head* contains little cytoplasm, and is connected by a short constricted section, the *cervix* or *neck*, to the *cauda* or *tail*. The latter is a flagellum of complex structure, usually divided into *middle*, *principal*, and *end parts* or *pieces*. Volumetrically the tail much exceeds the head, which varies greatly in different species (Rothschild 1957; Phillips 1975), being ovoid or piriform in man, somewhat flattened at the tip in lateral profile, with a maximum length of about 4 μm and a maximum diameter of 3 μm. The tail, about 45–50μm in length, displays a greater uniformity from species to species.

The head is a most extreme example of chromatin concentration, consisting essentially of a dense and uniform nucleus, with a distinct bilaminar nuclear membrane and a bilaminar *acrosomal cap* (head cap), the latter covering the anterior two-thirds of the nucleus and partly derived from the Golgi apparatus of the spermatid (p.97). The acrosomal cap is thin in the human spermatozoön, but in other species it is often large and more complex in shape. The acrosome has been shown to contain several enzymes including acid phosphatase and a protease (*acrosomase*), which are probably involved in penetration of the ovum. The nucleus and acrosome are enveloped in a continuous plasma membrane without intervening cytoplasm (Fawcett and Burgos 1956; Anberg 1957). The chromatin is stabilized by disulphide bonds, as if to protect its genetic content during the spermatozoön's journey (Fawcett 1975). So densely packed is the chromatin of the nucleus that it appears homogeneous even under electron microscopy. It has a strong affinity for basic stains, consisting of about 40 per cent (dry weight) deoxyribonucleic acid (Leuchtenberger *et al.* 1953) and a protein rich in arginine (Daoust and Clermont 1955). It is also resistant to physical stress, e.g. ultrasonication (Henle *et al.* 1938), and to mechanical shear (Mann 1949). Defects in condensation of nuclear material may be visible under light microscopy as relatively clear areas or *nuclear vacuoles*. Attempts to discover structural details in the nucleus in a variety of species, by polarization microscopy, X-ray diffraction, and freeze-fracturing techniques, have shown a lamellar structure which cannot yet be equated with chromosomal content. The human Y chromosome has been identified using fluorescence microscopy (Barlow and Vosa 1970; see also p. 34).

Between the head and the middle part or body of the spermatozoön is a slight constriction, the *neck*, about 0.3 μm long. In its central axis, close to a shallow recess in the base of the nucleus, is a well-formed centriole, corresponding to the *proximal* centriole of the spermatid from which the spermatozoön differentiated (p. 96). The axial filament complex (axoneme) is derived from the *distal* centriole, a funnel-shaped *connecting piece*, or *basal body* from which the outer fibrils of the tail extend (*vide infra*). (The *nuclear recess*, or *implantation fossa*, is the region of attachment of the complex filamentary structure of the tail. It is continuous with the postacrosomal part of the nuclear envelope concerned in fusion with the ovum and its nucleus.) A small amount of cytoplasm exists in the neck, covered by a plasma membrane continuous with that of the head and tail.

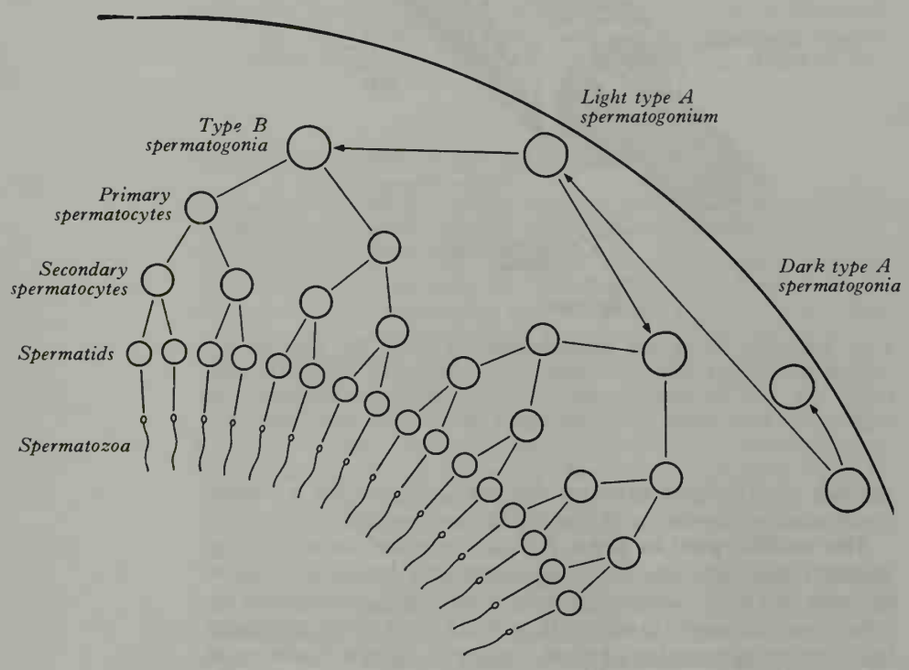
2.13 Diagrams of human spermatozoön, showing the head above, viewed in its major (left) and minor (right) diameters, the middle part below this, and the principal part or tail in the lowest diagram. (By courtesy of D. W. Fawcett, E. S. E. Hafez and C. V. Mosby Company.)

The middle part or piece is a long cylinder, about 1 μm in diameter and 7 μm long. It consists of an *axial bundle of fibrils*, or *axoneme* (the axial 'filament' of light microscopy), surrounded by a *mitochondrial sheath* in which the mitochondria of the spermatid have become arranged in a helical manner (**2.13**), the whole being enveloped by cytoplasm and a plasma membrane, as in the neck. The axoneme consists of a central pair of fibrils within a symmetrical set of nine doublet fibrils, as in a typical cilium (p. 19), and outside this is a second ring of nine coarser fibres, less symmetrical in arrangement and unequal in size. These external

fibres are also less regular in cross-sectional profile (*vide infra*), showing marked interspecific variations in size and regularity. It is no longer believed that they are contractile, although they demonstrate a striation in their surface layer. Their function is obscure. The mitochondrial helix exhibits ten to fourteen turns (Reed and Reed 1948), but like other structures in the spermatozoön. this sheath is subject to considerable variation in abnormal spermatozoa (Fujita *et al.* 1970). The number of mitochondria appears to be excessive in some species including *Homo sapiens*, when related to the energy requirements of the axonema. Their close relation to the external coarse fibres is suggestive, but as noted, these are apparently not contractile. At the caudal end of the middle part of the cell, immediately anterior to the tail, is an electron-dense body, the *annulus* (**2**.13). The mitochondria of the sheath are much compressed, but it is now certain that they retain their individuality (Fawcett and Ito 1965).

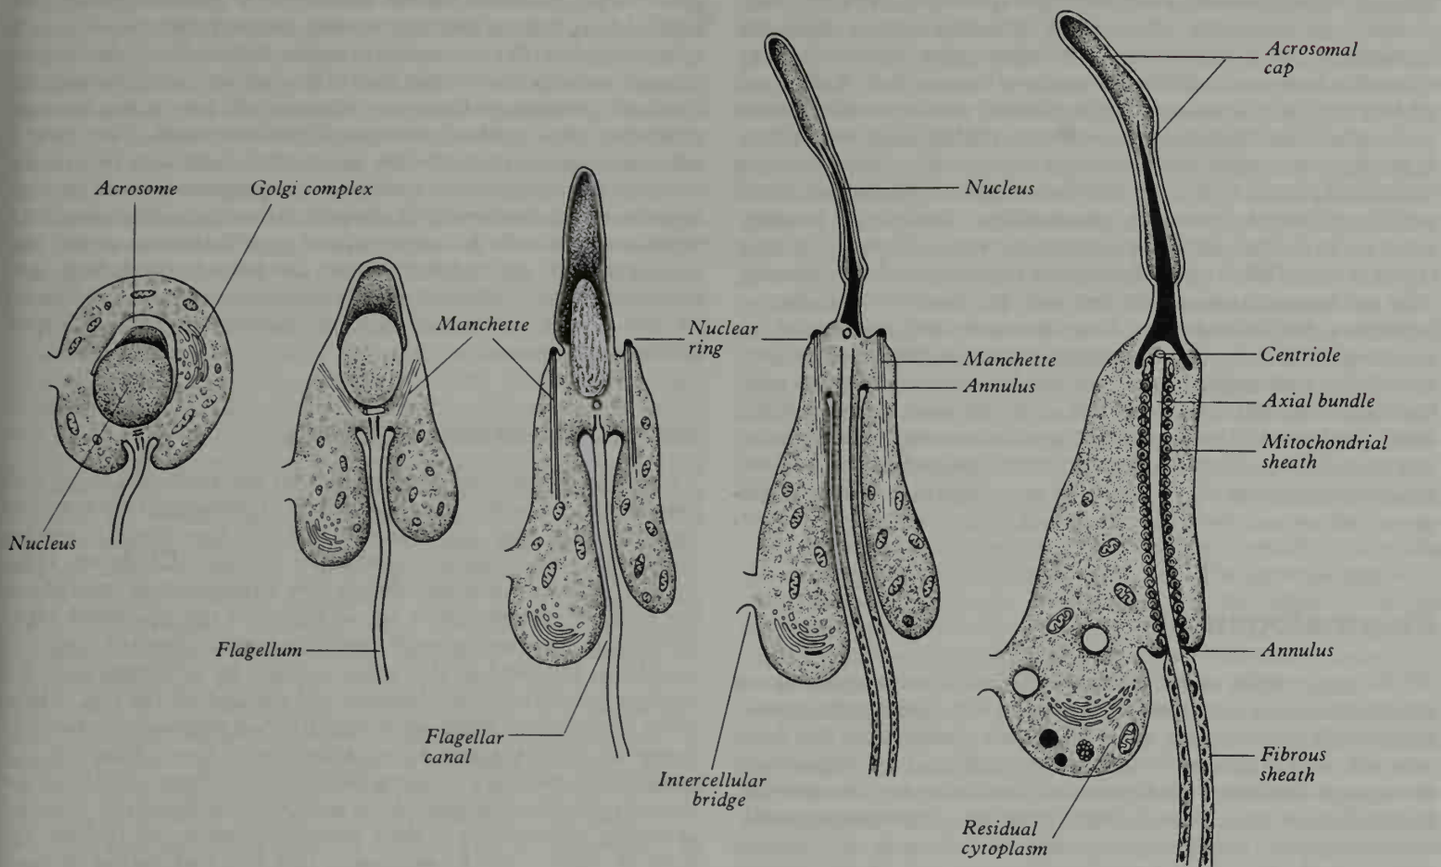
The principal part or tail of a spermatozoön is the motile part of the cell. Being about 40 μm long and 0·5 μm in diameter, it forms the greater part of the spermatozoön. The axial bundle of fibrils and the surrounding array of coarse fibres are continued uninterruptedly from the basal body, through the mitochondrial sheath and through the whole length of the tail except for its terminal 5 to 7 μm, in which the axial bundle alone persists, the coarse fibres ceasing before them. It is only in this terminal *end part* or *piece* that the tail has the typical structure of a flagellum; the coarse fibres are peculiar to mammalian spermatozoa, which also display other specializations. External to the fibres and fibrils, coarse and fine, is a circumferentially orientated dense *fibrous sheath*, whose individual elements branch and re-unite to form a tight reticulum. A small amount of cytoplasm and a plasma membrane complete the major elements in the structure of the tail. The finer details of the structure have been studied intensively in recent years in mammals such as the guinea-pig (Fawcett 1965), and while there is little doubt that the human spermatozoön is highly similar (Pedersen 1969), the following summary of these findings is based on appearances in the guinea-pig.

MOTILITY OF SPERMATOZOA



In cross-section the tail is oval and tapers caudally, and its central area is typical of a flagellum or cilium. The surrounding coarse fibres are obovate or petal-shaped and unequal in size, one being consistently the largest. This is given the number 1 and the rest are numbered from this in a clockwise manner. These fibres are separate into two unequal groups by slender *longitudinal* columns in the fibrous sheath which interrupt its circumferential fibres and extend inwards to meet the coarse fibres numbered 3 and 8. This divides the interior of the tail into *major* and *minor compartments*, containing respectively coarse fibres 4, 5, 6 and 7, and 9, 1 and 2. The plane through the two columns also passes through the central pair of the axial bundle of fibrils and can be used as a reference datum for other structural details of the spermatozoön. For example, the transverse diameter of the head has been considered to lie at right angles to the plane of the columns, but it has now been shown in the guinea-pig that the angle between the two planes is 20–30 degrees less than a right angle (Fawcett 1968). Such details may be instrumental in elucidating the motile activities of the tail. It is now generally accepted that the tail executes undulatory movements in one plane (Bishop 1958) (p. 20), but it has also been suggested that a helical component is superimposed upon this, there being perhaps two separable mechanisms, one involving flat waves travelling along the tail, the other associated with torsional activity (Gray 1958; Bishop 1962; Lindahl and Drevius 1964).

The latter variety of movement has been linked with the unequal size of the coarse fibrils, which are considered to act, like the fine fibrils, as contractile elements, though it has been suggested that the central pair act as axial stiffeners. The asymmetry of the spermatozoan head has also been invoked to explain supposed helical movement. However, it has to be admitted that the full details of the mechanisms of spermatozoal motility have yet to be worked out.



Some further details deserve mention. The dense outer fibres have been shown to exhibit an oblique or helical striation in replicas of dried whole mounts of rodent spermatozoa (Phillips and Olson 1974). The central axoneme (**2**.13) consisting of the usual ciliary pattern of nine double fibrils or 'doublets', has been intensively studied (*see* p. 19, and Fawcett 1975 for recent literature). Each fibril is a microtubule, itself constructed of a regular number of protofibrils. Protein bridges connect adjoining doublets at regular intervals, and radial links extend centrally to the central doublet of the axoneme (**2**.13).

Maturation of spermatozoa (**2**.14, 15) is a complex process which has received much attention in recent years. Spermatozoa show little independent motility while still in the male genital tract, though when removed from the epididymis they may even display circular swimming movements or even directive movements if taken from the cauda epididymis, near the beginning of the ductus deferens (Blandau and Rumery 1964). From the results of artificial insemination of rabbits with spermatozoa from the caput and cauda of the epididymis, it has been postulated that some form of maturation process takes place in this organ, during which the spermatozoön attains its specific pattern of motility (Gaddum 1968). Apart from these incomplete activities, spermatozoa are largely transported through the genital tract by ciliary action, fluid currents set up by localized secretion and absorption, and by muscular contractions. Associated with the maturation of spermatozoa in the genital tract in some mammals, is the extrusion of a small mass of cytoplasm, the *kinoplasmic* droplet or *residual body*, which migrates backwards along the surface of the head and middle part of the spermatozoön before disappearing. It consists of membrane-enclosed cytoplasm containing fine tubules and vesicles (Bloom and Nicander 1961; Guraya 1963). Human spermatozoa have not been shown to undergo any demonstrable structural changes during passage through the epididymis, but there is evidence of an increase in sulphide cross-linking between proteins (Bedford and Calvin 1974). Moreover, restorative surgery after vasectomy indicates that at least part of the human epididymis is essential for motility (Bedford *et al.* 1973).

As soon as they are ejaculated the spermatozoa display their full pattern of motility. The precise factors which trigger off these movements enabling human gametes to travel at a rate of 1·5 to 3 mm per minute, are not yet clear; but the other constituents of semen, derived from the epididymis and testis and from the seminal vesicle and prostate, are generally considered to exert an activating influence on spermatozoan motility. The motility

2.14 A diagram showing the stages in the maturation of the spermatozoön. The division of the primary spermatocyte is heterotypical; the remaining divisions are homotypical. Some observers have described a further division of the spermatids in the human testis—*see* text for further details and compare with illustration **8**.168.

2.15 Differentiation of the spermatid (guinea pig), from left to right. Note nuclear condensation and elongation, appearance of the *manchette* and fibrous sheath, caudal movement of the annulus, and development of the mitochondrial sheath. (Modified after D. W. Fawcett in Bloom and Fawcett's *Manual of Histology*, Saunders. 1975.)

varies greatly in different species, disappearing in minutes in some fish, but usually persisting in mammals for hours and even days when introduced into the female genital tract. Exact figures for its persistence in the human female are uncertain, and are of doubtful value, since it is likely that, as in other mammals, human spermatozoa quickly lose their potency for fertilization, though still motile. They have been recovered in a motile state in human cervical mucus several days after insemination, and will survive in this condition for as long as seven days when implanted into such secretions *in vitro* (Paerloff and Steinberger 1964). These survival periods may, however, be of little significance, in view of the speed with which spermatozoa reach the infundibulum of the uterine tube and the brevity of their fertilizing power. Spermatozoa have been shown to reach their tubal destination in a manner of minutes after ejaculation in some mammals, and experiments on recently excised human uteri and tubes indicated a time of about 70 minutes (Brown 1944). The conclusion must be that factors other than their own motility are responsible for the transport of spermatozoa from their site of deposition in the vaginal fornix to the ovarian end of the uterine tube, and there is considerable evidence that contraction of the uterine and tubal musculature is responsible (Bickers 1960).

It is not usually recognized that a spermatozoön must be adaptable to a wide range of environments in its long journey from the seminiferous tubule to the uterine tube, encountering major changes in the electrolyte and non-electrolyte constituents in the fluids with which it is successively surrounded. Nevertheless, a collectively vast amount of observation and experiment has been recorded in connexion with the effects of the multitude of factors, both physical and chemical, in the natural media involved regarding the behaviour of these cells, and particularly their motility and fertility (Nelson 1967; Mann 1967). For example, the effects of respiratory gas tensions, reaction, various ions, antibodies, vitamins, hormones, inhibitory substances, temperature, different forms of radiation, and other factors have been studied in remarkable detail, for which monographs and original papers must be consulted. The effects of low temperatures in preserving spermatozoa, and perhaps prolonging their vitality, have attracted much research in connexion with artificial insemination, both in stock-breeding and in infertile human marriage. Mammalian semen, including that of human beings (Parkes 1960), can be stored at temperatures of about −70°C for weeks and even months, the motility and fertility of its suspended spermatozoa reappearing when the suspension is unfrozen. However, storage of human semen presents difficulties (Polge 1957).

Seminal plasma, the fluid component of *seminal fluid* or *semen*, contains a remarkable array of substances, including muco-proteins, a dozen or more identified proteolytic enzymes, the bases spermine, glycerylphosphorylcholine and ergothioneine, a group of organic acids called prostaglandins (which have pharmacodynamic actions on the uterus and smooth muscle in general), acids, such as citric, ascorbic, uric, lactic and pyruvic, and the sugars, sorbitol, inositol and fructose. The fructose, added to the fluid by the secretion of the seminal vesicle, is an essential substrate in the anaerobic glycolysis by which spermatozoa survive the low oxygen tensions existing in semen itself and in the female genital tract. Prostaglandins are now believed to play a role, perhaps by modulation of neurotransmitter release, in the contraction/relaxation activity of the non-striated muscle in the testicular capsule and interlobular septa adjacent to the seminiferous tubules (as suggested by von Euler 1936). Consult Ellis and Hargrove (1977) for literature.

CAPACITATION

After ejaculation into the female, the spermatozoa undergo the final step in their maturation, a process known as *capacitation*. It has been shown that spermatozoa are not able to fertilize ova until they have been within the genital tract of the female for a period of time, usually of hours but varying with the species (Austin 1951; Chang 1951; Austin and Watton 1952). The mechanism of capacitation, whereby the spermatozoön is activated to enter and fertilize the ovum is still uncertain. A confusing array of findings with regard to the interactions of the two gametes immediately prior to this event have been described, unfortunately in widely different vertebrates and invertebrates. It is highly probable that hyaluronidase hastens the separation of the corona radiata cells

from the ovum, and thus facilitates the spermatozoön's approach to the zona pellucida. The origin of hyaluronidase from the acrosomal cap is associated with subsequent loss of the cap (Leuchtenberger and Schrader 1950), at least in part (Austin and Bishop 1958). 'Capacitated' spermatozoa observed in the zona pellucida or perivitelline space have invariably lost most of their acrosomal material (Leuchtenberger and Schrader 1950; Pikó and Tyler 1964), and it is clear that capacitation is some process of activation which precedes penetration. Antigenic 'coating' substances on the surface of mammalian spermatozoa, including those of man (Weil 1965), have been recorded and it is possible that an immunological reaction may be involved. Interaction between a *fertilizin*, derived from the ovum or elsewhere in the female genital tract, and a spermatozoan *anti-fertilizin* has been associated with capacitation, but the interrelationship between the various events is still *sub judice*, as the most recent reviews show (Mety and Monroy 1969). Capacitation may be regarded as the terminal event of maturation of the spermatozoön, prior to actual fertilization, for which it is a preparation. For a recent survey of current views *see* Chang and Hunter (1975).

Spermatogenesis

This is the complex series of changes by which spermatogonia are transformed into spermatozoa, similar in some general features—particularly in reduction division—to the evolution of ova from oögonia, but differing in the more profound morphological metamorphosis involved. Spermatogenesis may, for convenience, be divided into three phases. During the first, **spermatocytosis**, spermatogonia proliferate by mitotic division to replace themselves and to produce primary spermatocytes. In the second phase, **meiosis**, two successive maturation divisions, the first a true reduction division, as in the case of the oöcyte, produce *secondary spermatocytes* and then *spermatids*, all with the haploid number of chromosomes. In the third phase, **spermiogenesis** or **spermateliosis**, the spermatids become spermatozoa; it is during this period that the greatest visible transformation of structure occurs.

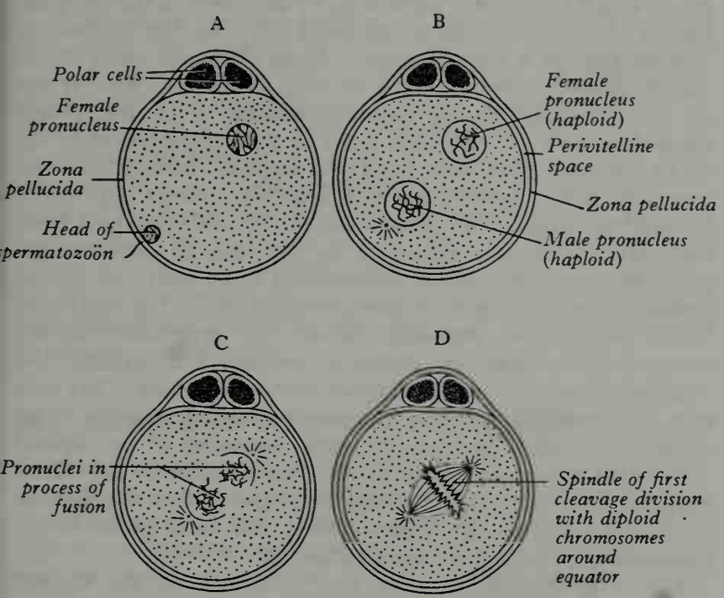
SPERMATOCYTOSIS

During embryonic, fetal, and perhaps also early post-natal life, the *primordial germ cells* (p. 216) in the tubules of the testes divide mitotically to produce spermatogonia (Everett 1963; Minty 1960), from which, at and subsequent to puberty, the development of spermatocytes and spermatozoa commences. It is the cyclic divisions of these cells, the details of which have attracted much attention in recent years, that form the starting place for production of the huge numbers of spermatozoa discharged into the seminal plasma to form the seminal fluid. The series of changes involved do not occur in a synchronous manner in all seminiferous tubules at the same time, though they do in considerable parts of an individual tube, with individual variations in different mammalian species, including mankind. As the cycle of change from spermatogonia to spermatids proceeds at any particular locus in a tubule, a succession of varying cell associations can be observed and measured; the process is termed the *cycle of the seminiferous epithelium* (Clermont and Leblond 1955) (p. 1414).

In man, three types of spermatogonia can be distinguished and are termed the *dark type A*, the *light type A*, and the *type B* (Clermont 1963). Spermatogonia are large rounded cells, the three types showing little difference in size or in their cytoplasm, but the A series, light and dark, are distinguishable by their nucleoli, which are eccentric and attached to the internal aspect of the nuclear membrane. The type B spermatogonia have a more constantly spherical nucleus, in which the nucleolus is central in position. The dark type A is distinguished from the pale type A by its dark nucleoplasm and a large pale-staining nuclear vacuole. This latter type is now considered, largely on morphological grounds, to be the progenitor or stem spermatogonium (Clermont 1963). Such cells, peripherally situated in the tubule, and often in pairs, divide mitotically at the beginning of a seminiferous cycle, some to produce two further dark type A spermatogonia, thus replenishing the complement of stem cells, others into two type B spermatogonia. On theoretical grounds, it is probable that in man a larger series of spermatogonial divisions may occur, so that the ultimate spermatocyte progeny of a stem cell may in fact be more numerous than is here indicated (Clermont 1966). Each type B spermatogonium then divides again mitotically into two *resting primary spermatocytes* or preleptotene spermatocytes. The dark type A cells remain arranged along the basement membrane of the tubule, whereas the pale type A, and type B spermatocytes, and the spermatids derived from them, lie closer to the lumen, into which the free end-product, spermatozoa, will be discharged (**8**.168). These events constitute spermatocytosis, which is now followed by meiosis.

MEIOSIS OF SPERMATOCYTES

The primary spermatocytes soon enter the prophase of the *first maturation (reduction) division*, which is prolonged over several days through the successive stages of leptotene, zygotene, pachytene, diplotene and diakinesis (p. 30) (Clermont 1963, 1966). As the nuclear membrane now disappears in metaphase, the bivalent chromosomes are arranged on the equatorial plate, separating into two groups and moving to opposite poles in anaphase, followed in the usual manner by reformation of the nuclear membranes in telophase and division of the cell. These three phases occur much more rapidly than prophase, and during the whole process there is a considerable increase of nuclear and cytoplasmic material, bringing the primary spermatocyte back to a size comparable with that of the stem spermatogonium. The two *secondary spermatocytes* thus formed contain, of course, the haploid number of chromosomes, this *first* maturation division being the one which is strictly speaking *meiotic*. After a brief interphase each secondary spermatocyte now undergoes a *second maturation division*, which is by mitosis. The two resultant cells are spermatids, and with their formation, the phase of meiosis may be considered to end, being followed by their maturation into spermatozoa (spermiogenesis). Theoretically each primary spermatocyte may be expected to produce four spermatids, but in mankind the yield is less than this, presumably because some spermatocytes degenerate during maturation.



Criticism of the traditional view that spermatids do not divide has been expressed (Roosen-Runge 1952), and corroboration of this has come from electron microscope and other studies (Fawcett *et al.* 1959; Fawcett 1961). Electron microscopy has also shown that the division of the cell body (cytokinesis) in both spermatocytes and spermatids may be delayed, so that fine cytoplasmic bridges may remain interconnecting such cells even beyond the stage of the next nuclear division (Fawcett *et al.* 1959). These bridges, which may remain in the case of spermatids until a late phase in their transformation into spermatozoa, are short, devoid of spindle fibres or other remnants, and are enclosed in annular thickenings of the plasma membrane. They probably permit interchange of organelles, may be involved in synchronization of development, and may contribute to the mechanical stability of the spermatid-Sertoli cell complexes. Such cytoplasmic interconnexion may also help to explain the formation of multinucleated masses when the seminiferous epithelium is injured, as in making teased preparations. Except where connected together by bridges the developing spermatids are very closely associated with Sertoli cells, whose processes are insinuated between them.

During the differentiation of some rodent spermatids a fusiform conglomeration of microtubules, the 'spindle-shaped body' appears between the annulus and fibrous sheath. The same structure has been observed in human spermatids; its functional significance is uncertain but an association with the development of the fibrous sheath has been suggested. (Pedersen 1969; Wartenburg and Holstein 1975).

SPERMIOGENESIS

During *spermiogenesis* (spermateliosis), spermatids go through a complex series of changes to become spermatozoa (**2**.15) and this

metamorphosis has been studied in particular by light microscopy, using preparations stained by the periodic-acid Schiff technique (PAS) (Leblond and Clermont 1952; Clermont 1963). Electron microscopy has confirmed these observations (Fawcett and Burgos 1956). In the newly formed spermatid the Golgi apparatus (idiosome-Golgi complex) is large but otherwise typical, consisting of flattened membrane-enclosed vesicles, usually stacked in a parallel array, together with rounded minute vesicles which are possibly nipped off from the flattened variety, the whole complex being juxtanuclear. A few electron-dense homogeneous *paracrosomal granules*, which are intensely PAS-positive, develop in separate Golgi complex vesicles, and the latter coalesce into a single large *acrosomal vesicle*, the separate granules fusing into a single spherical *acrosomal granule*. This vesicle, with its granule attached to its juxtanuclear wall, becomes adherent to the nuclear membrane over an area which will be anterior or 'leading' in the maturing spermatozoön. The granule flattens, but its central part bulges slightly into a shallow depression in the nucleus, which becomes progressively more ovoid (**2**.15). By successive absorption of further vesicles from the Golgi complex, the material in the acrosomal vesicle increases, and the vesicle expands as a bilaminar cap over the anterior two-thirds of the nucleus. Coincident with these changes, the spermatid elongates and the Golgi complex and associated cytoplasm migrate to the posterior part of the cell, bringing the external wall of the acrosomal vesicle into contact with the plasma membrane at the anterior aspect of the cell. The acrosomal granule now spreads out between the layers of the vesicle until it is uniformly distributed and no longer a localized structure. When the centrioles begin to separate (*vide infra*), microtubules develop forming an inverted conical array, *the manchette*, perinuclear in position, and expanding from the region of the acrosomal cap; its precise significance is not yet explained.

2.16A–D The process of fertilization in a mammalian ovum. Diagrammatic. (After Sobotta.) The female pronucleus and second polar cell shown in A, are only formed after fertilization.

In the early spermatid the nucleus is of relatively low density, containing finely dispersed granules which aggregate into larger and denser masses as development proceeds. These finally agglomerate into a homogeneously dense mass, usually containing one or more regions of low electron-density and variable in size, position and shape—the *head vacuoles* (Fawcett and Burgos 1956). Correlated biochemical and ultrastructural studies indicate a considerable variation in the chromatin content of spermatozoa, this heterogeneity being more marked in mankind than other primates or rodents; it probably indicates a lower fertilizing power (Bedford *et al.* 1973).

The two centrioles are near the posterior aspect of the nucleus from an early stage. One remains unmodified, the other becomes modified into the basal body of the spermatozoön (*see* p. 95). The annulus arises close to the latter (the distal centriole), but its origin from it is doubtful. The axial fibrils begin to develop from the basal body, extending 'caudally' into the cytoplasm of the cell as it becomes progressively more elongated. Only the proximal part of the bundle of fibrils remains surrounded by cytoplasm, to form the definitive middle part of the spermatozoön. In this, the mitochondria of the spermatid assemble to form the helical sheath (Challice 1953). The detailed development of the fibrous sheath of the tail part is unknown. These changes complete what might be called the period of 'organogenesis' of the spermatid, whose further development into a spermatozoön is largely concerned with enlargement of the tail.

During the final maturation of spermatids into individual spermatozoa some of the cytoplasm is detached as a *residual body*. This contains some mitochondria, Golgi membranes and vesicles, RNA particles, lipid granules, but of course no nucleus. Residual bodies are prominent when spermatozoa are being released into their tubule. They are engulfed by Sertoli cells, which accounts for the increase in lipid content of these cells at this period (Lacy 1960).

As already stated, there is a close relation between developing spermatids and Sertoli sustentacular cells. The spermatogonia are external or basal to the Sertoli cells in the tubule, and the spermatocytes which develop from the former are embraced by Sertoli processes; the spermatids are even more deeply embedded in the supportive cells. (For further details *see* p. 1413.) These associations have been regarded as symbiotic, a single sustentacular cell being grouped with several spermatids. The Sertoli cells are phagocytic and absorb not only residual bodies but also degenerating germ cells. They have been attributed a metabolic role and may form, or at least transmit, hormones involved in the maturation of germ cells. Until released into the seminiferous tubule, spermatozoa are very firmly held by the Sertoli cells. Their release is sometimes termed *spermiation* and is followed by rapid translation of the spermatozoa to the epididymis.

Spermatogenesis is an orderly and complex sequence of events, with characteristic time constants and cell associations for each mammalian species. The details of these in the human testis will be discussed with that organ (p. 1411).

Fertilization—Union of the Gametes

It has become customary to speak of an ovum as being fertilized by a spermatozoön, and, in view of the apparent passivity of the former and the extreme specialization of the latter for motility, it is tempting to consider the ovum as being merely stimulated to further development, in which the part played by the sperm nucleus may be consequently overlooked. It is of interest to note that in some of the earliest organisms to propagate by sexual reproduction, such as primitive algae, the gametes are all alike, except presumably in their genetic content, whether chromosomal or cytoplasmic. The profound differences which have nevertheless evolved in the gametes of the great majority of plants and animals—vertebrate and invertebrate—appear to depend on a conflict between adaptation for carriage of nutriment and improvement in motility. The effectiveness of *syngamy*, the bringing together of two gametes to produce a new individual, has been furthered by the development of this marked dimorphism between them. This dimorphism has, in turn, entailed the evolution of equally profound differences between the individuals producing the two kinds of gametes, males and females, in regard to the organs concerned in bringing together these dissimilar gametes and ensuring the development of their fused product, the *zygote*, until able to undertake a separate existence. Strictly speaking, therefore, the expression 'fertilized ovum', insofar as it appears to assign a merely stimulatory role to the spermatozoön, is misleading and hence undesirable. However, it should be noted that almost all the cytoplasm of the zygote is derived from the ovum, and, as indicated elsewhere (pp. 74–76), its organization has a profound morphogenetic significance.

The occurrence of parthenogenesis in a very small fraction of animals, mainly invertebrates, does not invalidate the fact that

fusion of two gametes, from separate parents, is the central feature of reproduction in most animals and plants (Tyler 1967). There is also abundant evidence that the critical element of this fusion is the conjunction in one cell of two haploid complements of the particular species' chromosomes, these being sufficiently identical to entail the development of a viable new unit in the species. Differences involving a number of genes, arising during the phenomena of crossover and segregation of the chromosomal material, or (very rarely) by sporadic mutation, are thus also able to express themselves in individual variation, with all its implications in evolutionary reactions between the species and its environment (p. 72).

Nevertheless, it would be equally misleading to regard the union of the ovum and spermatozoön as little more than restoration of the diploid number of chromosomes, because other events, of equal significance in the further development of the zygote, also occur. The ovum immediately resumes and completes its second maturation division; without fertilization this does not occur, and the ovum begins to degenerate within twenty-four hours (Allen *et al.* 1930; Hamilton 1949). A second polar cell is thus produced, and if the first has divided, as it sometimes does in human beings (Shettles 1955), three may be present in the circumvitelline space. In many mammals, and probably in mankind, what is apparently a small excess of nutritive yolk, or deutoplasm is extruded from the ovum into the same space after fertilization (*deutoplasmolysis*). This event is followed at once by segmentation, which is also dependent upon fertilization for its initiation.

ACTIVATION AND SEX DETERMINATION

The phenomena which ensue upon the entry of the spermatozoön can thus be conveniently divided into those described in the preceding paragraph, which together constitute *activation*, and those concerned in the intermingling of the separate hereditary influences of the two parents, and associated with the fusion of the nuclei of their gametes, a process described as *amphimixis*. The latter really falls within the scope of genetics (*see* p. 101), but a particular aspect—the determination of the sex of the zygote—may be mentioned here, because the actual determination is in a sense effected as soon as a spermatozoön has entered the ovum. In approximately equal numbers, spermatozoa of many animal groups, including mammals, contain either an X or a Y chromosome, whereas mature ova contain only an X chromosome. If both gametes contain an X chromosome the resultant individual is female; but when the spermatozoön contains a Y chromosome, the cells of the new individual will each contain an X and a Y chromosome, which is characteristic of the male. This may not, however, be the only factor involved in the determination of sex (p. 221).

UNION OF THE GAMETES

In mammals, generally only one spermatozoön pierces the vitelline membrane to enter the ovum, although numbers usually penetrate the corona radiata and even the zona pellucida. Enzymes of acrosomal origin cause dispersal of the cells of the corona, thus opening the route to the zona. Though some form of chemotaxis, as exists in the syngamy of plant gametes, has been claimed for some animals, no clear evidence for this has been recorded (Tyler and Bishop 1963). The mechanism of union of the ovum and spermatozoön has been studied extensively in all its stages. The primary reaction between the gametes appears to be of an immunological nature, which would account for the exclusive specificity of fertilization. Landsteiner (1899) and Metchnikoff (1899) first reported the antigenicity of spermatozoa, and a species recognition system, dependent upon an agent in the ovum, a 'fertilizin', was identified surprisingly early (Lillie 1913). The sequence of the reactions of this with spermatozoan antifertilizins (associated with the plasma membrane) have attracted much attention (Metz and Monroy 1967, Bedford 1977). Such antibody-antigen interaction appears not only to be essential to contact between the gametes but also to initiate the subsequent entry of the spermatozoön by the lytic action of enzymes derived from the acrosome (*see* p. 95, and Austin and Bishop 1958; Strivastava *et al.* 1965). This *zona-lysin* enables the spermatozoön to pass through the zona pellucida into the circumvitelline space and to come into direct contact with the oöcyte. Penetration is followed immediately by permeability changes in the zona which effectively block the subsequent entry of other spermatozoa (Austin and Braden 1956). The *zona reaction*, as this phenomenon is called, is however, not a complete block to polyspermy; two or more spermatozoa may pass *simultaneously* through the zona, a not uncommon event in the case of some rodents, seemingly also a possibility in man. The result is one of the types of *triploid* zygotes that may arise. Further, there is evidence of a second line of defence, the *vitelline block*, associated with the plasma membrane of the ovum. Both blocking mechanisms may depend upon discharge of the contents of *cortical granules*—electron-dense particles subjacent to the plasma membrane—into the circumvitelline space (Szollosi and Ris 1961; Szollosi 1967). However, recent evidence derived from *in vitro* fertilization of *human* ova suggests that the zona pellucida is, under these conditions, a complete block to polyspermy (Soupart and Strong 1975). Electron microscope studies suggest that the actual entry of the spermatozoön into the ovum is effected by fusion of their plasma membranes, that of the former being left on the surface of the ovum (Szollosi and Ris 1961; Szollosi 1967). Once within the ovum the head and neck of the spermatozoön become detached from the middle part and tail, which soon disappear, their significance in fertilization, if any, and their ultimate disposal being obscure. For a review of the uncertainties and problems in regard to the mechanisms of fertilization consult Bedford (1975), and for ultrastructural details *see* Austin (1968). The occurrence of auto- and iso-immune anti-spermatozoal antibodies has been exhaustively surveyed by Hekman and Rümke (1976).

The second maturation division of the ovum is now completed, with the extrusion of a second polar cell into the circumvitelline space, which has become opened up by shrinkage of the oöplasm. Failure of extrusion of the second polar cell is another mechanism of formation of a *triploid* zygote. Meanwhile, the head of the spermatozoön swells to become the *male pronucleus*, being at this juncture morphologically indistinguishable from the *female pronucleus* (**2**.16). Both nuclei move to a central position in the ovum and each duplicates its DNA content. Meanwhile, two centrioles appear, probably derived from the anterior centriole of the spermatozoön. The chromosomes become organized from each pronucleus and arranged on the spindle between the centrioles, and since 23 are contributed from each, the typical diploid number for man is now re-established. The degree of fusion of the two pronuclei before the appearance of the chromosomes varies in different species, but usually the chromosome groups remain separate during prophase. They now split longitudinally and the resultant halves segregate as in an ordinary mitosis. The two sets, each consisting of the diploid number of chromosomes with the normal amount of DNA, retreat to opposite poles of the cell, on whose surface a deepening grove develops, as the zygote enters the next phase in its development, *cleavage* or *segmentation* (pp. 76, 103).

The chronological element in the events of the human fertilization are still only inexactly known. A particularly detailed study of the temporal march of events has been contributed in the pig (Hunter 1974).

PARTHENOGENESIS

It is generally agreed that a mature ovum contains within itself all the material potentiality to form a new being. Apart from the *natural parthenogenesis* which occurs in some invertebrates, this potentiality of the ovum to develop further without fertilization can be released experimentally by a variety of mechanical, chemical, and physico-chemical means, such as pricking, exposure to alteration of tonicity and reaction in the surrounding medium, treatment with various kinds of radiation, etc. (Beatty 1957, 1967). Such *artificial parthenogenesis* has been studied in a wide range of invertebrate and vertebrate animals, including mammals. Such offspring rarely survive beyond the embryonic stage, but viable young have occasionally been obtained in the

case of rabbits, for example. The particular interest of these parthenogenetic phenomena in vertebrates is that they illustrate the fact that, apart from its normal necessary chromosomal contribution, the spermatozoön plays little part in embryogenesis. However, there is some evidence that the plane of bilateral symmetry is determined in many animals by the direction and place of entry of the spermatozoön. Nevertheless, both in this determination and the early polarization of the zygote, there must be a considerable flexibility, because the blastomeres resulting from its early segmentation are 'totipotent', in the sense that they may separate to form complete embryos, as in the formation of uniovular twins (but *see* p. 138).

Heredity and Human Genetics

The operation of genetic influences is so basic to reproduction, growth, differentiation, regeneration, and indeed to all life processes, that a brief account of heredity and its mechanisms must be included here. Great progress has been made in recent years, and not least in the medical field. Further details can be sought in the many excellent general and medical texts available. *See*: Clarke (1970); Whitehouse (1973); Thompson and Thompson (1973); Ford (1974); McKusick (1975); Fraser and Mayo (1975); Bodmer and Cavelli-Sforza (1976); Yuris (1977).

Before chromosomes were discovered, Gregor Mendel (1822–84) had postulated, as the basis of his explanation of the phenomena of heredity, the presence of certain factors which have subsequently been termed *genes* (Mendel 1866). The study of heredity has been increasingly intensified following the discovery of chromosomes, investigation of their behaviour during somatic and germinal cell divisions, and detailed mapping of them, coupled with studies of the transmission of inherited characteristics in complex organisms such as the fruit fly *(Drosophila)*.

More precise genetic analysis of fast-breeding and simple organisms, developments in molecular and chemical genetics concerning the identity of the genetic material, and investigation of the modes of transmission of genetic information from the genes in which it is encoded to the proteins fabricated in cell cytoplasm—all these have led to a clearer understanding of the processes of heredity. Consequently it is now established that the units of inheritance foreshadowed by Mendel (1866), and now called genes, do in fact exist, that they are contained by the chromosomes in all somatic cells, that each gene occupies a specific *locus* or position in its chromosome, and that the genes are transmitted from parents to offspring in the chromosomes of the ovum and spermatozoön.

AUTOSOMES AND SEX CHROMOSOMES

Each chromosome carries a number of genes arranged in a *linear series* along its length. The 46 chromosomes in the human species consist of 22 genetically homologous pairs of *autosomes* and one pair of *sex chromosomes*, one member of each pair being paternal and one maternal in origin. Corresponding genes, or *alleles* (allelomorphs), occupy identical loci in each of a chromosomal pair. The alleles occupying a pair of homologous loci may be identical or different, and thus exert the same, or a different, influence on the function (or functions) which the given gene controls. Although the two sex chromosomes are homologous in the female, both being X, there are X and Y chromosomes in the male which differ markedly in size (p. 34), Y being much the smaller. The X chromosome carries a number of genes which are not represented in Y and which, therefore, must be essential to ordinary life processes. The Y chromosome in man seems largely devoid of genes recognizable by their action on *somatic* tissues, but contains genetic factors responsible for the differentiation of the primordial indifferent embryonic *gonad* into a *testis*.

DOMINANT AND RECESSIVE GENES

At the molecular level each *structural gene* is concerned with determination of the amino-acid sequence in a particular polypeptide and therefore with the structure of the enzyme-proteins on which biochemical and morphological features of the cell depend (pp. 23, 85). (*Regulator genes* are those which modify the structural genes, hence the distinction—pp. 23, 25.) At the more general *phenotypic level* major genes control the development of specific characteristics. The two alleles sited at corresponding loci in a pair of homologous chromosomes may, as indicated above, be identical or different. If different, they may be in a *dominant-recessive* relationship with respect to the character which they influence. Thus, the expression of one allele may be *dominant* over the other member of the pair, which is therefore *recessive* in its expression. If in a given population there are just two different alleles at a particular locus—call them *A* and *a* to represent their dominant-recessive relation—different individuals in the population may carry a pair of identical alleles at the locus or a differing pair. In the former situation individuals are said to be *homozygous*, being either *AA* (homozygous dominant) or *aa* (homozygous recessive). In the other case the individual is *heterozygous—Aa*. If the effect of *A* is completely dominant over that of *a*, an *Aa* individual can be indistinguishable as regards the character involved from the *AA* genotype (*vide infra*). More complex situations exist, but the ABO blood group system is convenient to use as an example. Given the presence in a population of the three alleles at the ABO locus for the A, B, and O characters of the red blood cells, individuals can belong, on test, to groups A, B, AB, or O—as *phenotypes* (*vide infra*). Because of the dominant-recessive relationship which exists in this genetic arrangement, an individual of A phenotype may be either of *AA* or *AO* genotype. Similarly, an individual of group B may be genetically *BB* or *BO*. However, AB group individuals must be genetically *AB*, and group O must be *OO*. The allele for O thus acts recessively to those for either A or B group characteristics, while the alleles for the latter two traits act *co-dominantly*.

HEREDITARY CONDITIONS

In certain diseases, which are known to be hereditary, such as Friedreich's ataxia and fibrocystic disease of the pancreas, the autosomal gene concerned operates recessively; hence only those who carry the allele in question in 'double dose' (genotype *aa*) actually suffer from the disease. The frequency of such sufferers, and hence the incidence of this disease, is generally so low (but there are exceptions) that the majority of the population must be homozygous with respect to this particular gene, both alleles being of the 'normal' or 'wild' type, i.e. they specify a gene product which results in 'normality' of the character under consideration. In these circumstances the normal allele is widely distributed in the population and is therefore present in 'double dose' in most people. The abnormal allele is uncommon and is thus very rarely present in double dose. Persons carrying the abnormal alleles in double dose are, in the examples cited, sufferers from serious diseases. However, the frequency of heterozygotes is, as is always the case, greater than that of the abnormal homozygotes suffering from the disease. Since affected individuals rarely marry, the disease appears sporadically in the offspring of healthy parents, both of whom must be heterozygous in this respect, because it is practically only in these circumstances that the two abnormal alleles may come together in one individual's cells, the probability being 1 in 4. Careful inquiry into the family history in such instances generally adduces no evidence of affected forebears. Since the frequency of the gene responsible for Friedreich's ataxia is very low in the general population, a person who is known to carry it is more likely to mate with a person with the same allele if he or she marries a relative than if the spouse is unrelated. Furthermore, the closer the relationship, the greater the risk, which is naturally in ratio to the proportion of genes carried in common—that is, of genes derived from the common ancestor and therefore identical by descent. On this account intermarriage of the first cousins in families in which a recessive gene is responsible for a serious disease *segregates*, i.e. is transmitted, should always be discountenanced, when there is no way of distinguishing unaffected heterozygotes from homozygotes. Both are phenotypically healthy, but the former are genotypically capable of handing on the abnormal gene which their blood-related spouse may also

carry. In some other hereditary diseases possible carriers can be positively identified, and therefore estimates of risk with regard to certain recessive pathological traits can be given precisely, even for close relationships. Other hereditary autosomal diseases, for example neurofibromatosis, are *dominantly* inherited because the abnormal gene acts dominantly over the normal, wild-type, allele. If one of the parents carries the abnormal allele in single dose he or she has a fifty-fifty chance of transmitting it, and with it the dominant affection, to any of his or her children. Yet other hereditary characteristics may be transmitted by genes on the *sex chromosomes*. An important feature of the genetic material of the chromosomes, the DNA (p. 23), is the fact that it can change in response to a variety of environmental influences. These special changes are called *mutations* and produce *mutant genes* which are in fact alleles of the original wild-type forms of the genes. A mutant gene may act dominantly and be the allele responsible for a dominant disease, e.g. neurofibromatosis. Alternatively the mutant gene may be recessive and transmitted silently for a number of generations.

GENETIC LINKAGE

Since each chromosome contains a large number of genes, neighbouring genes, specifically their alleles, in a linear series in the same chromosome will always tend to be inherited together; and the nearer they are in the chromosome the less often will the alleles of these genes be separated from each other and recombine following crossing-over in meiosis (p. 32). The characters associated with such alleles thus tend to appear together in the same individual, and their genes are said to be *linked*. *Linkage* refers specifically to the fact that the gene loci under consideration are on the same chromosome more or less close together. Some hereditary diseases, for example, Huntington's chorea, which is inherited as an autosomal dominant, may not display any recognizable signs or symptoms before marriageable age; this makes it difficult to advise members of affected families as to the desirability or otherwise of procreation. Definite knowledge of any other easily recognized characteristics with which such diseases could be proved to be closely linked, would allow a degree of prediction as to which members of certain affected families carry the gene. Unfortunately, present knowledge of instances of such linkage in human beings is scanty, and much additional data must be collated before such studies can make a significant contribution to genetic counselling in most conditions, although there are exceptions. (*See*, for example, histocompatibility antigens—p. 69.) Nevertheless, new experimental techniques involving *cell fusion* (especially human cells with rodent cells) are now making possible the analysis of human genes and, together with familial studies, are rapidly helping to build up 'maps' of human genes on man's chromosomes, similiar to the maps available for classical genetic organisms like *Drosophila* or the mouse. Further, mention should be made here of the intensive research currently being directed towards linkage analysis in various conditions, such as the juvenile 'rigid' form, or Westphal variant of Huntington's chorea (consult also, for example, Butterfield 1977; Caro 1977; and p. 136).

In mankind still the best demonstration of linkage concerns the X chromosome; while the Y chromosome seems to carry rather little in addition to genetic factors essential to determination of sex, the X chromosome carries genes concerned with other non-sexual characters. The *X-linked* genes, whose alleles determine characteristics said to be *sex-linked*, are concerned with haemophilia, the commoner forms of colour-blindness, a special blood group antigen (the Xg system), and a number of rare diseases of the skin, eyes and nervous system.

Haemophilia, in which clotting of shed blood is greatly slowed or abolished, leading to serious haemorrhage, is operated by a recessive sex-linked gene; it affects only males (with very rare exceptions), but is transmitted by females. The mother of a haemophiliac male must be a heterozygote carrier of the abnormal allele responsible for a deficient clotting factor. As the allele behaves recessively, the XX female, though not affected by the condition, may nevertheless be able to transmit it to her male offspring. However, at times, the mother is *not* a carrier because the abnormal allele has arisen as a *fresh mutation* of the clotting gene on the X chromosome received by the haemophiliac male. In this event subsequent males born in the family will not receive the haemophia allele. The father of a haemophiliac male is usually unaffected, because his X chromosome carries the normal allele for the elaboration of the normal clotting factor, and his Y chromosome does not contain genes concerned with blood clotting. When the mother is a carrier the female offspring will have an equal chance of being homozygous and normal (incapable of transmitting the disease) or heterozygous like their mother; the sons will have equal chances of being normal or haemophiliac. The mating of a normal male with a heterozygous female, and the possible varieties of their offspring may be represented as follows:

$$X^H Y^{\cdot} \times X^H X^h$$
$$X^H X^H \quad X^H X^h \quad X^H Y^{\cdot} \quad X^h Y^{\cdot}$$

On the other hand, when a haemophiliac male ($X^hY^{\cdot}$) mates with a healthy woman who is a homozygote normal in this respect (X^HX^H), their sons will not be affected ($X^HY^{\cdot}$), but their daughters will all be heterozygotes (X^HX^h). The condition therefore skips this generation, but will reappear in half of the sons of these heterozygous females. The only possible combination which could produce a haemophiliac female is one between an affected male and a heterozygous female ($X^hY^{\cdot} \times X^HX^h$).

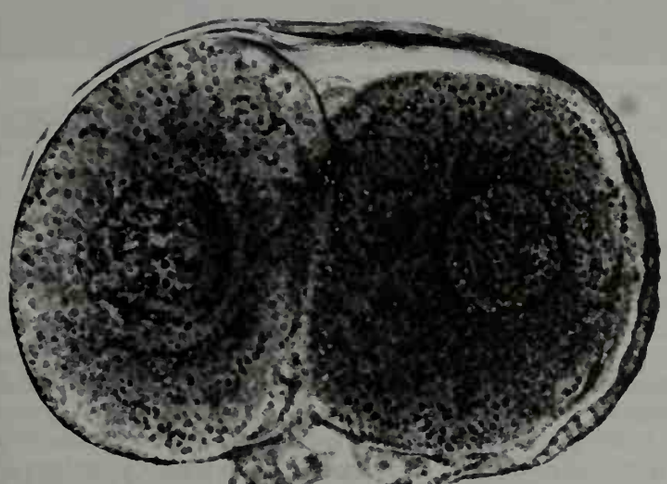
GENOTYPE AND PHENOTYPE

The *genetic constitution* of an organism is termed its *genotype*. Variations in this are due to chromosome segregation and to recombination of the genetic material in changed linear relationships as a result of crossing over during meiosis (p. 32) together with any *mutations* that may have occurred. *Chromosomal mutations* (involving structure or numbers) and *gene mutations* are sudden effects in the genetic material which alter its effects on the cell. Mutations are structural alterations in DNA brought about by a variety of environmental factors, such as ionizing radiation, certain chemical agents (e.g. nitrogen mustards), etc. Such variations in genetic constitution, particularly when including some form of mutation, are frequently harmful in their effects, ranging from non-viability of the initial zygote, embryo, or fetus, through serious to mild, and finally occult forms of abnormality or disease complex. However, it must also be emphasized that it is upon such variants that the forces of *natural selection* operate leading to the diversified forms of resulting from *organic evolution*.

The *expressed* constitution of the organism is its *phenotype*; this results not only from the totality of its genetic constitution, but also from interaction between this and the environment. Nature interacts with nurture, and defects in the latter may impede full expression of the genotype and alter the pattern of the genotype-controlled response. The phenotype may be the same even where the genotype is not, as exemplified by the operation of a dominant allele in homozygotes and heterozygotes. Conversely, in individuals with the same genotype (with respect to a given locus in a chromosome) their phenotypes may be different. This may be partly due to interactions between genes, partly to environmental effects. The influence of the latter can best be observed in comparisons of uniovular twins. Some agents, such as teratogenic drugs, may bring about changes in an organism leading to the production of abnormalities known to be dependent upon genetic influence in other instances. Such an abnormality, usually determined genetically, but artificially induced as a replica in an organism lacking the associated genetic mechanism, is termed a *phenocopy*.

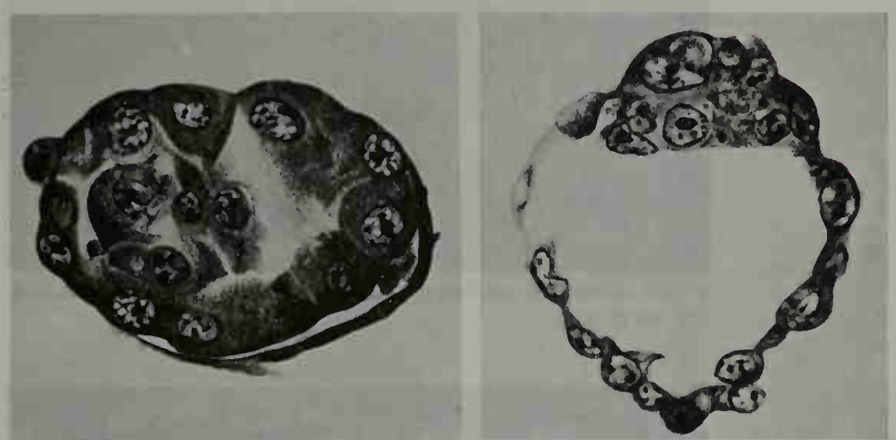
EARLY DEVELOPMENT OF THE HUMAN EMBRYO

CLEAVAGE



As we have seen (p. 76), cleavage is the process whereby a *unicellular* fertilized ovum with an exceptionally large ratio of cytoplasm to nucleus is transformed into a *multicellular* mass of *blastomeres*, each of which approximates to the ratio found in general somatic cells. For example, in the sea urchin, volumetric ratios are 550:1 at the onset of cleavage, reducing to 6:1 in individual blastomeres at its termination (Brachet 1950). Comparative studies show that cleavage is essentially a series of mitotic divisions in which little true growth occurs, but with a dramatic synthesis of nuclear DNA, and cytoplasmic factors important in subsequent development are differentially parcelled in the cytoplasm of the resultant blastomeres (p. 85).

As each generation divides, the nuclear population is, of course, doubled, preceded by replication of chromosomal DNA as in any other mitotic division (p. 29). The precursors for this replication are dispersed in the oöplasm of the zygote which is rich in various RNAs (p. 25); *cytoplasmic* DNA is contained in both mitochondria and yolk platelets, whilst the oöplasm also contains abundant low molecular weight nucleic acid precursors. The relative contributions from these different sources, to the processes of replication, transcription and translation remains uncertain. Similarly, the interesting question of whether cytoplasmic nucleic acids are wholly broken down into unitary molecules before they are incorporated into nuclear DNA, or perhaps are utilized in more substantial segments, sufficiently large to bear coded genetic information, remains unresolved. (For earlier comparative reviews on the synthesis and transformations of nucleic acids during early embryogenesis, consult Brachet and Quertier 1963; Brown 1966; Tyler 1967; Gurdon 1968; Brachet 1969.)

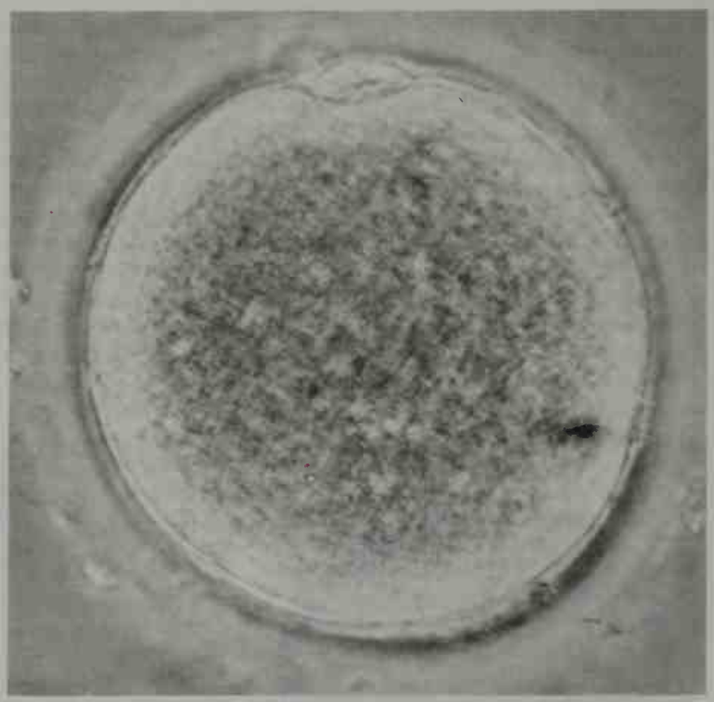


Synthesis of *new* ribosomal RNA is low during cleavage, but protein synthesis continues and this is particularly related to the formation of the microtubular asters of mitotic cell division, the synthesis of increasing quantities of cell membrane, and the formation of DNA polymerases. The foregoing remarks, until recently, applied mainly to observations on non-mammalia and, for technical reasons, mammalian data were less plentiful and lacked the same precision (*see* Jones-Seaton 1950; Dalcq 1954; Austin 1961, 1965, 1968). However, detailed analyses on mammalian oöcytes and during early embryogenesis are now accumulating (Neyfakh 1971; Herbert and Graham 1974; Church and Schultz 1974).

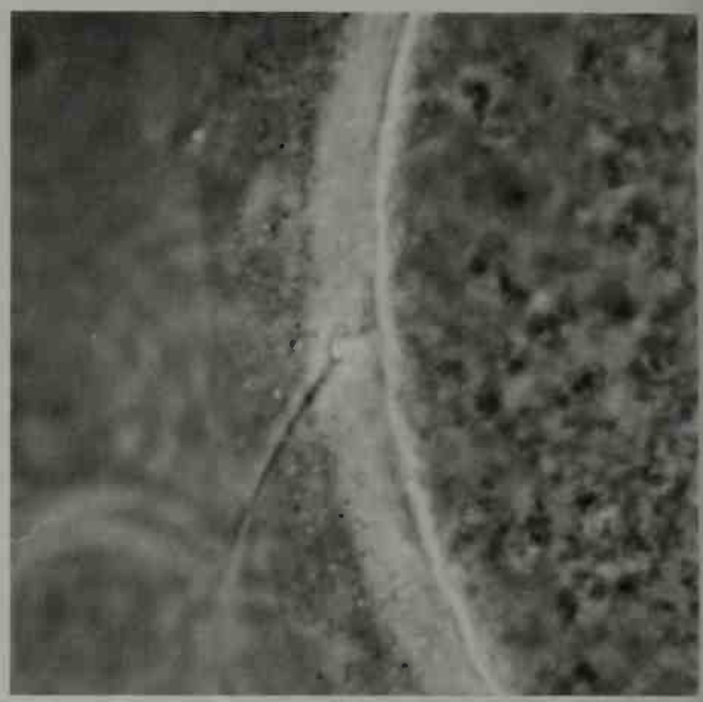
Relatively few specimens of the earliest stages of human development occurring in the normal environment of the female genital tract have been recovered and studied (Hertig *et al.* 1954, 1956)—these include one 2-cell stage, a few, possibly abnormal, up to the 12-cell stage, and one presumed normal 12-cell stage (*vide infra*). Recently a 7-cell stage has been recovered and analysed (Avenado *et al.* 1975).

Successful attempts at the *in vitro* fertilization of mature mammalian ova and their subsequent culture up to the blastocyst stage, have been made since the early 1930s (Lewis and Hartman 1933; Mulnard 1964, 1965). Early development was recorded using time-lapse cinematography, and over the last twenty-five years, similar techniques have been applied to human ova (Shettles 1953, 1955, 1958). Recently, techniques of *in vitro* fertilization of human ova have been greatly improved (Edwards *et al.* 1965, 1969). Preovulatory oöcytes, recovered by laparoscopy in women under the control of gonadotrophins (Steptoe and Edwards 1970), have been repeatedly fertilized and cultured to the 8- and 16-cell stages and beyond (**2.**20). Reintroduction of cultured morulae into the uterine cavities of women with pathological uterine tubes and in whom pregnancy would otherwise be impossible—Steptoe and Edwards (1976), although initially unsuccessful, resulted in the first full-term birth late in 1978. This clinical approach is now being vigorously pursued. However, it should be noted that studies of *in vitro* fertilization in various mammals other than man, stressed that such procedures are followed by an increased incidence of abnormal morphological development in rabbits (Fraser *et al.* 1975) and rats (Toyoda and Chang 1974), and of chromosomal abnormality in mice (Fraser *et al.* 1976; Barnes 1976).

2.17 Early human cleavage. Two-blastomere stage recovered from the uterine tube. A polar cell is seen at each end of the cleavage plane. Magnification × *c.* 700. (A. T. Hertig, J. Rock, E. C. Adams and W. J. Mulligan, *Contr. Embryol.*, **35**, 1954.)



2.18 Section of a 58-cell human blastocyst recovered from the uterine cavity showing the zona pellucida, trophoblast and inner cell mass. Magnification × *c.* 510. (A. T. Hertig, J. Rock, E. C. Adams and W. J. Mulligan, *Contr. Embryol.*, **35**, 1954.)



2.19 Section of a 107-cell human blastocyst recovered from the uterine cavity. The mural and polar trophoblastic cells and the inner cell mass can be distinguished. Magnification × *c.* 550. (A. T. Hertig, J. Rock, E. C. Adams and W. J. Mulligan, *Contr. Embryol.*, **35**, 1954.)

The following account is based upon specimens from these various sources, supplemented where necessary by reference to other primates, especially the macaque monkey (Heuser and Streeter 1941).

Fertilization occurs in the lateral part of the uterine tube, probably within 24 hours of ovulation. After completion of the second maturation division the zygote divides into two blastomeres of approximately equal size (**2.**17). (Human cleavage may be *total*, *equal* and *indeterminate*, *see* p. 76). The human 2-cell stage recorded was recovered from the middle of the uterine tube 60 hours after a fertile mating (**2.**8), the menstrual pattern, however, indicating an age of 36 hours. By repeated division and subdivision of the blastomeres a mulberry-shaped mass of cells, hence termed the *morula*, is formed (**2.**20, 21). Intense activity of their cytoplasm is evidenced by the constant streaming of contained granules, and the individual blastomeres are not motionless, but restlessly alter their positions relative to one another and reorientate themselves within the zona pellucida. The human morula is believed to enter the uterus at

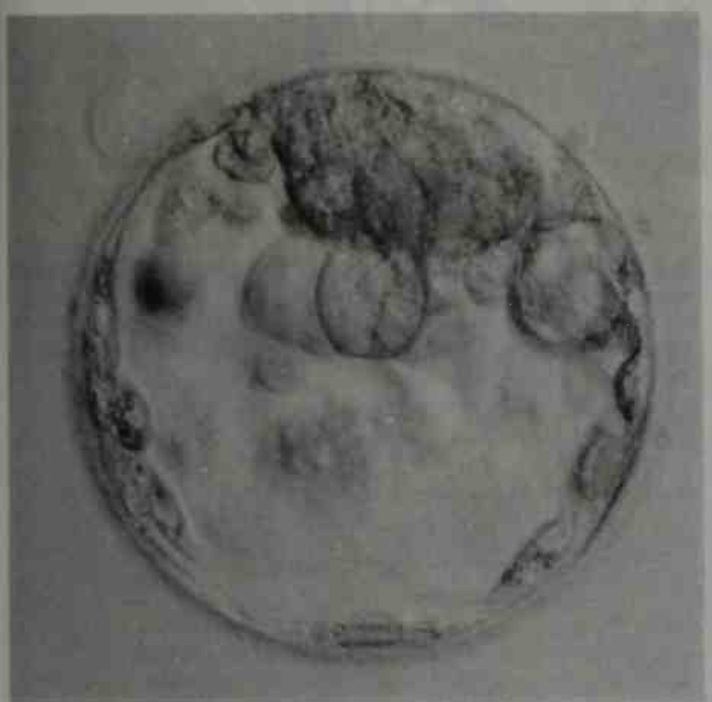
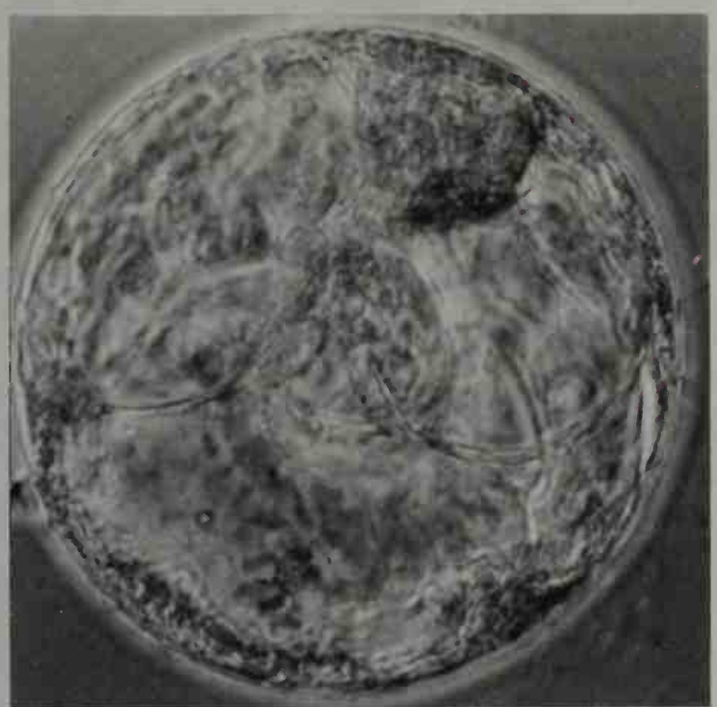
about the 8- to 12-cell stage and about 72 hours after fertilization. The four human morulae of 5–12 blastomeres which are recorded, however (all believed to have been abnormal), were recovered from the uterus on the fourth day after presumed ovulation and fertilization. The 12-cell stage, assumed to be normal, consisted of 11 small peripheral cells which surrounded a larger centrally placed one, indicating that during the earlier cleavage divisions two different groups of cells emerge, and the earliest visible signs of such differentiation has now been claimed even at the 7-blastomere stage (Avenado *et al.* 1975). Of these diverging cell lines one will form the embryo and the other will form the nourishing and protective membranes by which it is surrounded. The former is composed of centrally sited larger cells, few in number, which divide more slowly and retain to a high degree the developmental potential of the fertilized ovum, termed the *formative cells*; the latter consists of smaller and more numerous superficially placed cells, which divide more rapidly as they differentiate into progenitor *trophoblastic cells*. (For a discussion of the possible *causal mechanisms* leading to the emergence of distinctive formative and trophoblastic cell lines in mammalia consult Herbert and Graham 1974.)



If the first two blastomeres are separated, each is potentially capable of continuing development into a complete embryo—it has been claimed that 25–30 per cent of instances of monozygotic twinning in man follow separation at this stage. It has been demonstrated experimentally in the mouse (Tarkowski 1961, 1963; Minty 1962, 1964, 1965) that if one of the first two blastomeres is killed, the remaining one can continue to develop



C After penetration by the spermatozoön, the male and female pronuclei can be seen near the centre of the ovum, whilst two polar cells lie beneath the zona pellucida.

D Human cleavage—4-celled stage.

H A blastocyst which has lost its zona pellucida and started to expand.

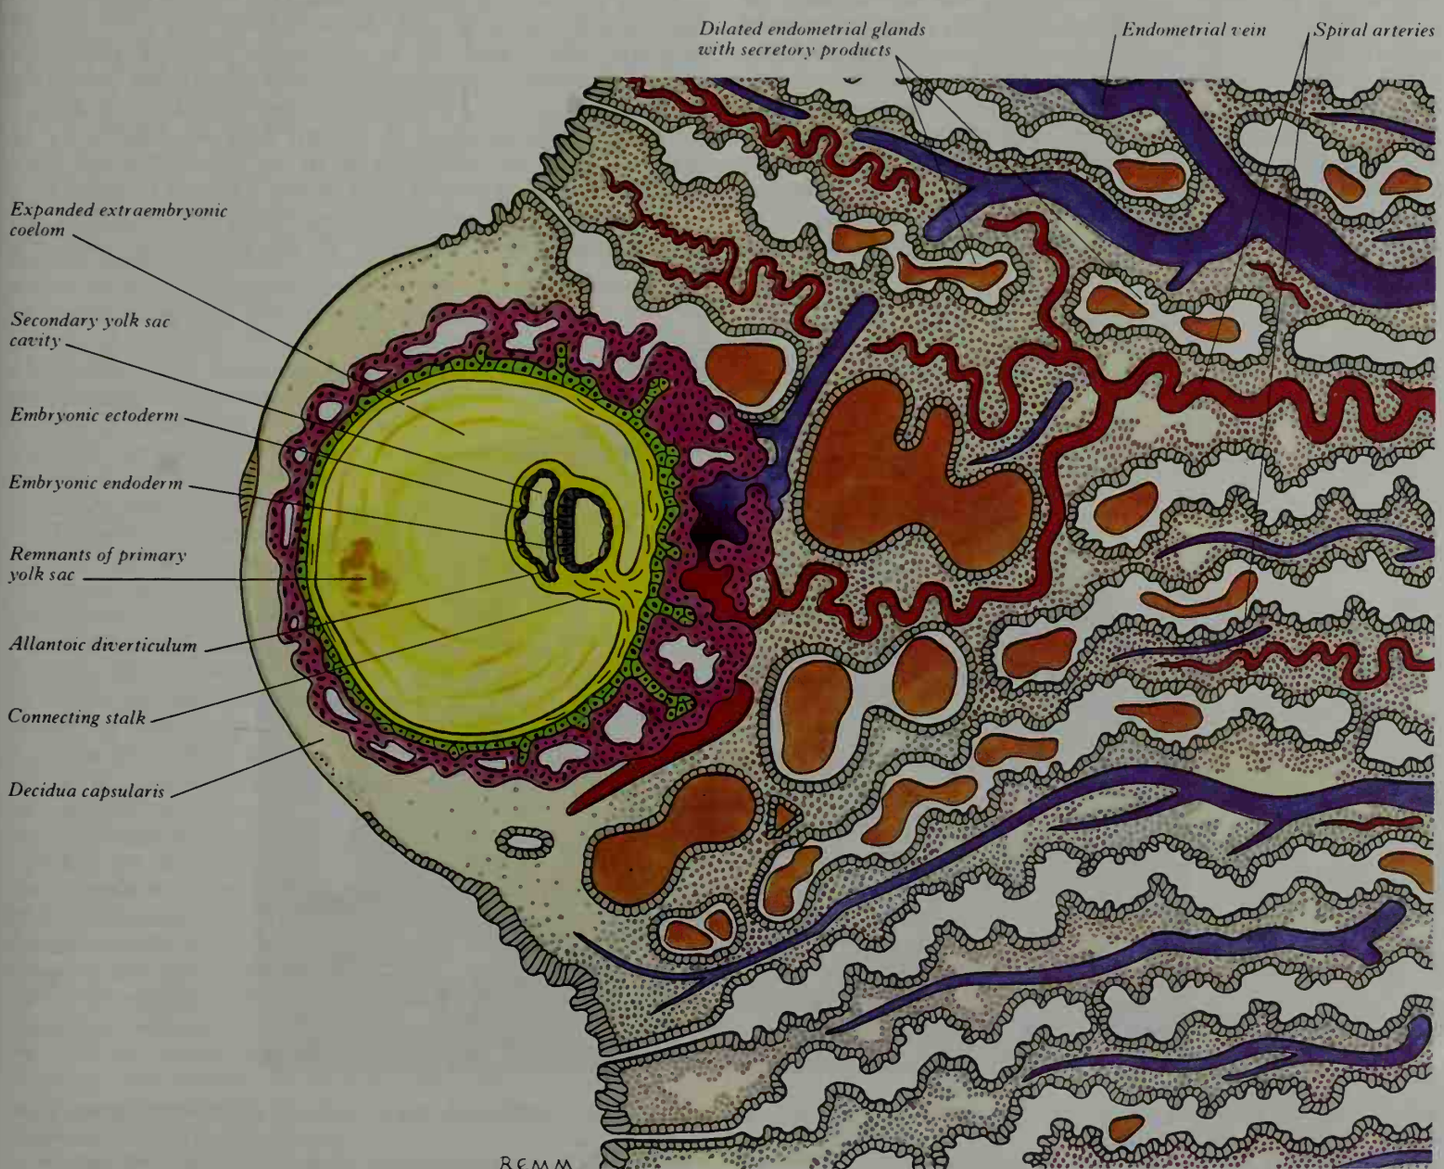
into a small but complete embryo. However, blastomeres isolated at the 4- or 8-cell stages often fail to continue normal development and are limited to the formation of simple *trophoblastic vesicles* which contain no inner cell mass and are therefore devoid of formative cells (Tarkowski 1965). Conversely, from the 2-cell to the morula stage, two cleaving zygotes may be fused, development proceeding to the formation of a single 'giant' embryo (**2**.4).

THE BLASTOCYST

Before the zona pellucida disappears, fluid, either secreted by the trophoblastic cells or derived from the uterine lumen, begins to accumulate within the morula. (Cell death of a number of deeply placed blastomeres has also been demonstrated in some mammals, but as yet, evidence for this phenomenon is lacking in man.) The intercellular spaces enlarge and coalesce to form a single fluid-filled *blastocyst cavity*. (It should be noted that the latter is not directly homologous with the *blastocoele* of primitive chordates, p. 76.) This cavity is largely bounded by *mural trophoblast cells*, except at one place where a clump of cells, termed the *inner cell mass* (*embryoblast* or *formative mass*) (**2**.18, 19) projects into the cavity. This is widely considered to represent the residue of totipotential cells, some of which, the *embryogenic cells*, are destined to form the body of the embryo proper (*see*, however, p. 81). The segmenting zygote has now been converted into a *unilaminar blastocyst*. Of a total of some 60 cells composing the blastocyst at this stage, only about 5 are formative cells; the remainder constitute the flattened (mural) trophoblastic

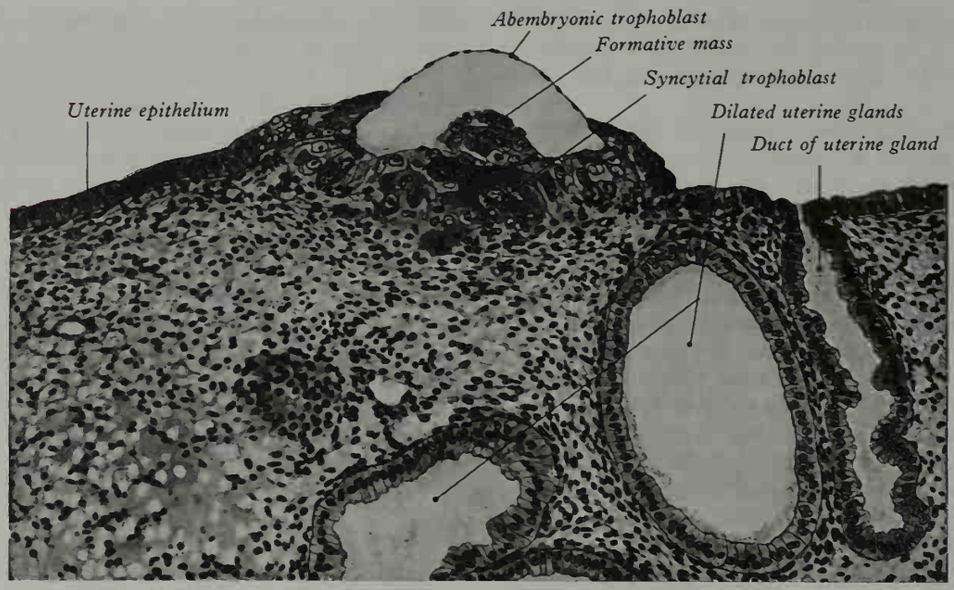
2.21 A composite schema of the major events in the ovarian cycle, ovulation, fertilization, tubal transport and cleavage, differentiation of blastocyst, implantation, early embryogenesis, and incipient placentation.

epithelium forming the wall of the vesicle (Hertig *et al.* 1954). The unilaminar blastocyst is formed by the end of the fourth or the beginning of the fifth day after ovulation and lies free in the uterine cavity (**2.21**).



The zona pellucida disappears during the fifth day after ovulation by which stage the blastocyst is about 130–140 μm in diameter. The cells of the inner cell mass have multiplied and form an irregular clump insinuated into the wall of the blastocyst where it is flanked by trophoblast. One blastocyst described in detail at this stage (Hertig *et al.* 1954) consists of 107 cells (**2.19**), of which 69 are *mural trophoblast cells*. Of the remainder, 8 are large *embryonic cells* constituting the formative mass, whilst the remaining 30 are *polar trophoblast* cells and lie around its margins. The latter are so named because they soon spread to cover the external aspect of the formative mass (at the *embryonic pole* of the blastocyst). At the same time, the inner aspect of the mass becomes lined by a single layer of polyhedral cells, the *embryonic endoderm* (also variously termed at this early stage, the embryonic *hypoblast* or *endoblast*).

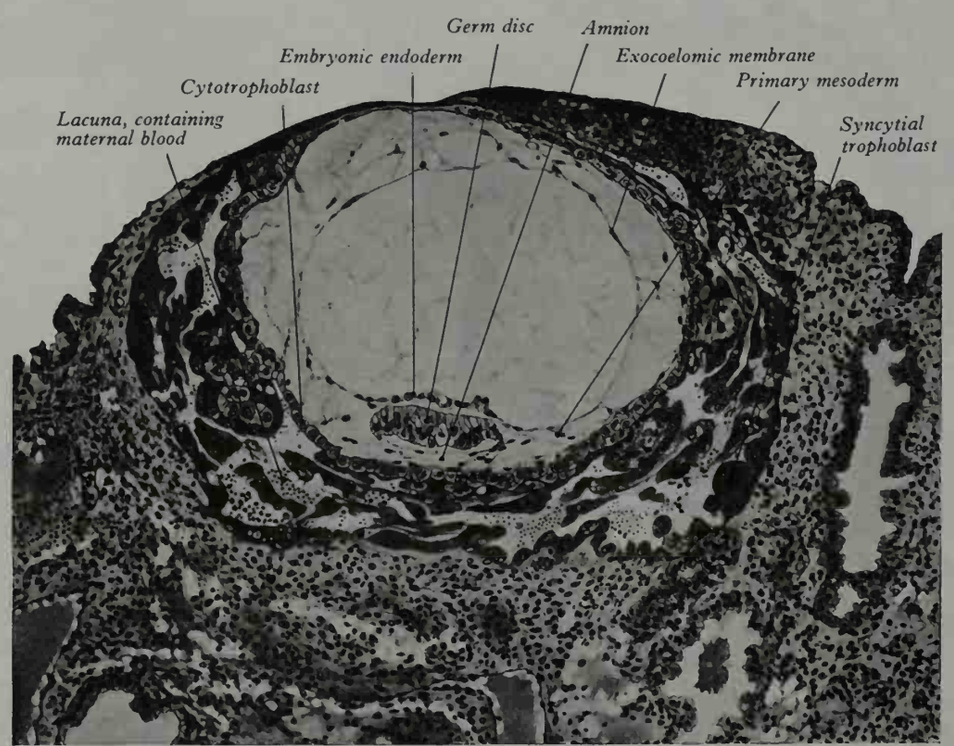
In the latter part of the sixth day after fertilization the polar trophoblast adheres to the uterine mucosa, exerting a histolytic action on its lining epithelium. As they engulf the degenerating uterine tissue, the trophoblast cells in this situation divide with great rapidity and their individual progeny fuse with each other (Boyd and Hamilton 1966) so that all trace of cellular definition is lost. Accordingly the formative mass becomes covered with a multinucleated mass of cytoplasm, the *syncytial trophoblast* (*syntrophoblast*), which continues to burrow into the stratum compactum of the uterine mucosa. As the blastocyst embeds more deeply the remainder of its trophoblastic wall undergoes a similiar change; but, at a slightly later stage, cell boundaries again appear on the inner or embryonic surface of the syncytial trophoblast. Thereafter the wall of the blastocyst consists of an inner cellular layer, the *cellular trophoblast* (*cytotrophoblast*), covered on its outer surface with syncytial trophoblast, which is thickest over the formative mass, i.e. at the area of deepest penetration or *embryonic pole*, and thinnest over the area most recently embedded or *abembryonic pole*.



The *site of implantation* is normally on the posterior wall of the uterus, nearer to the fundus than to the cervix, and may be in the median plane or to one or other side.

The youngest implanting human blastocyst hitherto recovered and described in detail (Hertig and Rock 1945) shows an early stage in the process. The polar trophoblast displays an extensive development of syncytium, which has destroyed a patch of uterine epithelium and underlying stroma (**2.22**). The blastocyst is not completely embedded and a portion of its wall, at the abembryonic pole still projects into the uterine lumen. The fertilization age is believed to be 7½ days (Hertig and Rock 1945).

In a slightly older specimen (Hertig and Rock 1945) (9½ days) the blastocyst is completely embedded. The syncytial trophoblast has undergone further proliferation and now covers the wall at the abembryonic pole as a thin layer. Irregular *lacunae* have developed in the syncytium which communicate with eroded maternal veins. The formative mass now consists externally of a thick plate of large, irregularly arranged cells, termed the *embryonic ectoderm* (*germ disc*, or *embryonic epiblast*) and internally of a single-layered sheet of *embryonic endoderm*, which inter-



2.21 (*continued*) Further expansion and differentiation of the blastocyst.

2.22 A human blastocyst (Carnegie, 8020), fertilization age 7–7½ days, in process of embedding in the uterine mucosa. (J. Rock and A. T. Hertig, *Am. J. Obst. Gynec.*, **44**, 1942, and **47**, 1944.) Magnification × *c.* 150. In the actual specimen the abembryonic trophoblast had collapsed on the formative mass but, for purposes of clarity; it has been shown projecting into the uterine cavity. (Drawn from a photograph by Dr. A. T. Hertig.)

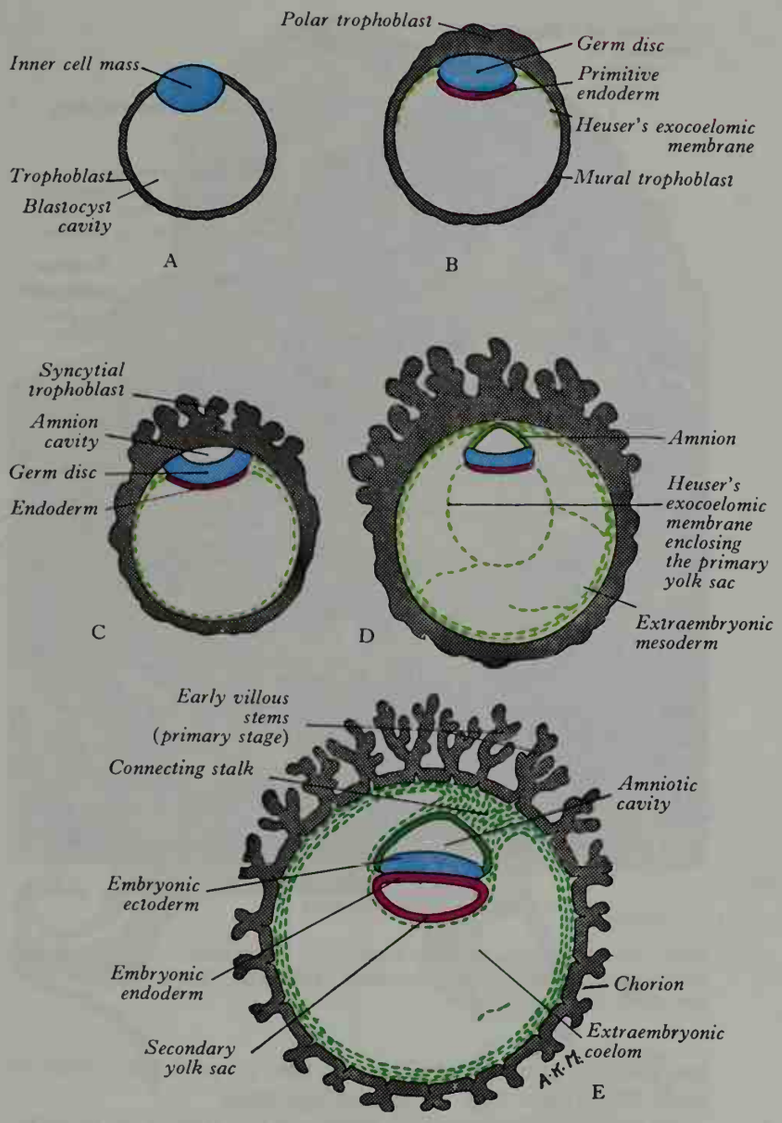
venes between the disc and the blastocyst cavity. On its external surface the germ disc is in process of separation from the trophoblast by the formation of a cavity, which will soon become the *cavity of the amnion* (**2.23**, 24, 25). Recently, re-examination of early rhesus monkey and human embryos has led to a modification of this view of amniogenesis (Luckett 1975). A *primordial amniotic cavity* develops by cavitation within the inner cell mass and initially has no direct relation with the overlying trophoblast. This occurs in 7-day human blastocysts. Subsequently the epiblastic roof thins and disappears forming a slightly cup-shaped germ disc which is surmounted by a transitory *tropho-epiblastic cavity*. The definitive amniotic epithelium forms by upfolding and proliferation of the margins of the epiblastic disc, the process being completed by 9 days.

In the immediately succeeding stages the walls of the blastocyst become *bilaminar* as its cavity becomes lined with a thin layer of flattened cells, which are in continuity with the embryonic endoderm around its margins and enclose a cavity now termed the *primary yolk sac*. It is uncertain whether these are cells derived from the cytotrophoblast or whether they are formed by an extension from the endoderm (as in the rabbit, dog and some other mammals). Whatever their origin, a variety of terms have been applied to this tissue layer—*extraembryonic hypoblast* and later, *extraembryonic endoderm*, or the *exocoelomic (Heuser's)*

2.23 A human blastocyst (Carnegie, 7700), fertilization age 12–12½ days, embedded in the stratum compactum of the endometrium. (A. T. Hertig and J. Rock, *Contr. Embryol.*, **29**, 1941.) Magnification × *c.* 105. Compare with **2.22** and note the development of the lacunae in the syncytial trophoblast, many containing maternal blood. Note that the primary yolk sac, which is surrounded by the exocoelomic membrane, does not quite fill the blastocyst cavity. The cells of the germ disc are now columnar in shape and form an ectodermal plate. (Drawn from a photomicrograph by Dr A. T. Hertig.)

membrane. The primary yolk sac, formed in this way (**2**.24), appears to meet a functional need in the selective transport of the fluid which the trophoblast absorbs carrying cytolytic products from the uterine mucosa, making them available for the nourishment of the germ disc at this stage.

The cells of the germ disc, hitherto arranged in an irregular manner, now dispose themselves in the form of a plate of columnar cells. At the same time extraembryonic mesodermal cells delaminate from the inner surface of the cytotrophoblast and intervene between it and the primary yolk sac. The wall of the sac (now often termed the *exocoelomic membrane*) becomes retracted from the wall of the blastocyst, although it usually remains connected to it near the abembryonic pole by strands of mesoderm. Descriptions of several human blastocysts (Stieve 1936; Odgers 1937; Dible and West 1940; Hertig and Rock 1941, 1945; Davies 1944) which have reached this *trilaminar* stage and are already completely embedded in the uterine mucosa are now available.

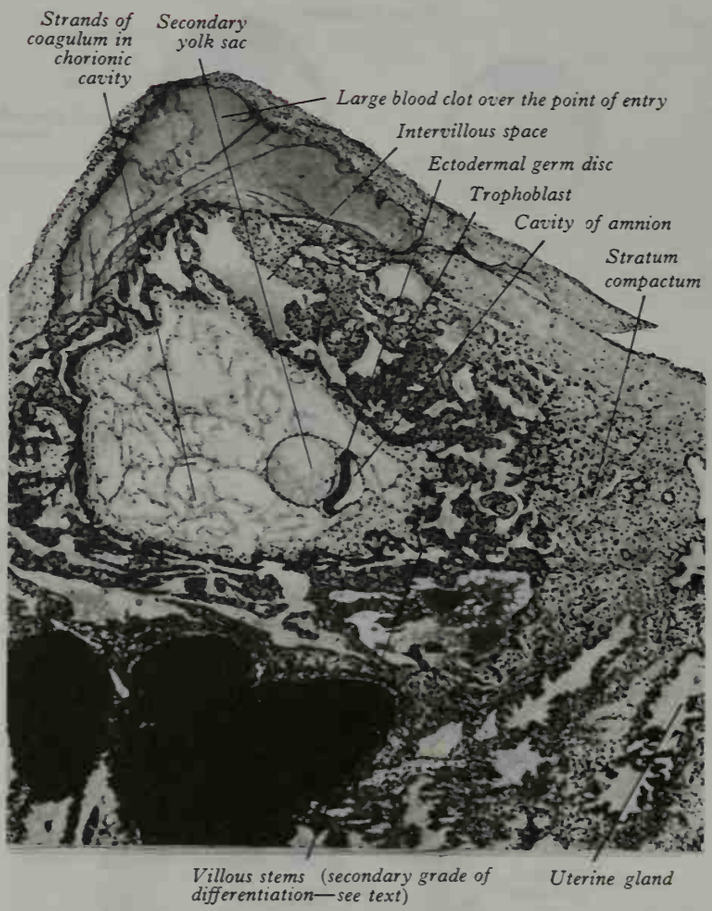


The stage depicted in **2**.23 corresponds almost exactly with the one shown diagrammatically in **2**.24D. The trophoblast is thickest over the embryonic pole and over the sides of the blastocyst, but is exceedingly thin over the abembryonic pole, the last part to be embedded. It is lined over most of its extent by a single layer of cytotrophoblast and the syncytial trophoblast contains numerous lacunae. Maternal blood from invaded vessels occupies the lacunae and serves as a new source of nourishment.

Within the trophoblastic vesicle, the cells of the germ disc have now been arranged as a columnar epithelium, the *embryonic ectodermal plate* or *disc*. Externally they are separated from the cytotrophoblast by the amnion, its cavity and some extraembryonic mesoderm; internally they are in close contact with the embryonic endoderm, although a distinct basement membrane forms a sharp line of demarcation. The embryonic endoderm consists of a single layer of low cuboidal epithelial cells, lining the ventral surface of the germ disc and forming the roof of the primary yolk sac, which is lined elsewhere by the exocoelomic membrane, and which contains fluid and some coagulum resulting from the effects of histological fixation. The interval between the trophoblast on the one hand, and the primary yolk sac and the developing amnion, on the other, is occupied by fluid in which are found extraembryonic mesodermal cells delaminated or delaminating from the cytotrophoblast, together with a certain amount of coagulum. This extraembryonic mesoderm soon forms a loose reticulum, the *magma reticulare*, in which a series of clefts develop and begin to coalesce. As this proceeds the trophoblastic wall of the blastocyst with its lining of mesoderm becomes a separate membrane, the *chorion*, and the general cavity of the blastocyst can therefore now be termed the *chorionic cavity* or *extraembryonic coelom*.

The cavity of the amnion with its roof of epiblastic 'amniogenic' cells and extraembryonic mesoderm, and its floor of embryonic ectoderm, now constitutes the *amnio-embryonic vesicle*. At first mesoderm connects chorion to amnion over a wide area, but as the continued development and coalescence of clefts in the mesoderm extends the extraembryonic coelem, this attachment soon becomes circumscribed (**2**.24E) and condenses to form a *connecting stalk* (body stalk) which forms a permanent connexion between the embryo and the chorion, and is the pathway along which the blood vessels of the embryo later establish communication with those of the chorion. Subsequently it becomes converted into part of the *umbilical cord* (*vide infra*).

While the connecting stalk is being defined, the primary yolk sac suffers a reduction in size, the mechanism of which is obscure, although it seems probable that part of its wall becomes drawn out by the mesodermal strands which anchor it to the abembryonic chorion, and which then loses its connexion with the rest of the sac. The resultant smaller cavity is that of the *definitive* (or *secondary*) yolk sac (**2**.24E, 25), but is often referred to simply as *the yolk sac*. Some investigators (Heuser and Streeter 1941), however, maintain that the secondary yolk sac is a new formation by a rearrangement of the embryonic endodermal cells on the deep surface of the germ disc.



In the immediately succeeding developmental stage, of which many examples are available, the chorionic cavity contains two hollow vesicles (the amnion and the yolk sac), each covered with

2.24A–E A Early blastocyst. B Differentiation of inner cell mass and development of primary mesoderm. C Formation of amniotic cavity. D Further development of amnion and primary yolk sac. E The primary yolk sac has become reduced in size to form the (secondary) yolk sac, which is covered externally with extraembryonic mesoderm. This is the condition found at the end of the second or the beginning of the third week. Compare with **2**.25. The trophoblastic shell and maternal tissues have been omitted.

extraembryonic mesoderm, by which they are connected to the chorionic wall (**2**.25, 33A). Only the cells where the two vesicles are in contact with each other contribute to the formation of the body of the embryo, and it is therefore this region which is termed the *bilaminar embryonic disc* (*embryonic shield* or *area*).

It is noteworthy that of the multitude of cells derived from the fertilized ovum *at this stage*, only a relatively small number take part in the formation of the embryo, while the vast majority form its covering and nourishing membranes, and certain other extraembryonic structures to be noted later. (Hypotheses concerning the causal mechanisms of this early differentiation have been critically examined in relation to development in the mouse—Herbert and Graham 1974.) The ectodermal cells of the germ disc are columnar and separated from the endoderm by a basement membrane. By the third week the ectoderm takes the form of three or four interlocking rows of cells continuous round its margins with the cells of the amnion which are flatter and more elongated, and form only a single stratum, which is covered externally with a layer of extraembryonic mesoderm. The endodermal cells of the disc are flattened, but those lining the rest of the yolk sac vary in shape, and patches of cubical or low columnar cells are found, especially on its caudal wall. Except in

2.25 An advanced human blastocyst, embedded in the stratum compactum. Estimated age, 13·5 days. (Hertig and Rock 1942.)

two localized situations, to be noted later (p. 117), the endoderm never forms more than a single layer of cells.

An inconstant feature of the embryo at this stage is the presence of a mesodermal stalk connecting the amnion to the trophoblast which may contain an *amniotic duct*, extending from the amniotic cavity, to end blindly near the trophoblast. In reptiles, and in many mammals, the amnion arises by a process of folding around the periphery of the embryonic disc. The amniotic duct of the human embryo has been interpreted as the homologue of the point of closure of these folds (but it has also been suggested that its presence depends on the chance occurrence of a trophoblastic lacuna which breaks through into the amniotic cavity).

Concomitant with the changes which transform the zygote into a morula, the latter is slowly carried along the uterine tube by the action of the cilia of its lining epithelium and probably by gentle waves of muscular contraction which perhaps also generate currents in the tubal fluid. Passage along the tube covers a period of about three days, and the morula is then transformed into a blastocyst which remains free in the uterine cavity for a further three days before implantation. During this interval the uterine mucosa is preparing for the reception of the blastocyst (p. 126). The disappearance of the zona pellucida, after the formation of the blastocyst, allows the trophoblast cells to come into direct contact with the uterine mucosa and initiate implantation.

ECTOPIC IMPLANTATION

Implantation of the blastocyst normally occurs in the endometrium of the uterine body, more frequently on the posterior wall somewhere near the fundus, but may occur elsewhere in the uterus, or in an *extrauterine* or *ectopic* site. Implantation near the internal os results in the condition of *placenta praevia* with its attendant risk of severe antepartum haemorrhage (p. 136).

Alternatively, the zygote or segmenting morula may be arrested at any point during its migration through the uterine tube, and implant in its wall. Previous tubal inflammatory episodes may predispose to such tubal arrest, and it has also been suggested that congenital abnormalities of the tube, tubal tumours, transperitoneal migration of an ovum from one ovary to the opposite tube, delayed ovulation, and psychological stress which may cause tubal spasm, are additional predisposing factors (Woodruff and Pauerstein 1969).

Nidation in the intramural part of the tube often results in early abortion of the conceptus, whereas if it occurs elsewhere in the tube, development often proceeds for about two months and is then usually followed by tubal rupture with death of the embryo and severe intraperitoneal haemorrhage—a grave surgical emergency. However, slow rupture of the tube may occur, accompanied by a further implantation of the conceptus into any adjacent peritonealized surface (*secondary abdominal pregnancy*), which again ultimately leads to rupture of the surface with similar consequences.

Primary ovarian or *abdominal* pregnancies have also been described, in which it has been presumed that the fertilization occurred in the vicinity of the ovary; most cases, however, are probably of the secondary type following a slow tubal rupture or a slow extrusion of the conceptus through the abdominal ostium of the tube.

Apart from their important clinical implications, such conditions emphasize the interesting fact that the conceptus can implant successfully into tissues other than a normal progestational endometrium. Further, prolonged development can occur in such sites and is usually terminated by a mechanical or vascular accident, and not by a fundamental nutritive or endocrine insufficiency, or by an immune maternal response.

Differentiation of the Embryonic Area

Near the end of the second week, the embryonic area thus consists of an almost *circular*, *bilaminar disc* which separates the cavity of the amnion from that of the secondary yolk sac. As we have seen, the amniotic aspect of the area consists of a thick plate of columnar embryonic ectodermal cells, 2–4 cells thick, which is continuous around its margins with the flattened cells lining the amniotic cavity. A single layer of rather flattened polyhedral endodermal cells forms the roof of the secondary yolk sac; this roof is quite closely applied to the superjacent ectodermal plate, a basement membrane intervening, and it is continuous peripherally with the cuboidal or columnar cells lining the secondary yolk sac. At this stage no mesodermal cells are found between the ectoderm and endoderm of the embryonic area, but thin strata of extraembryonic mesoderm clothe the outer surfaces of the amnion and secondary yolk sac, and line the chorion (p. 124)—the space bounded by these various mesodermal layers constituting the *chorionic cavity* or *extraembryonic coelom*.

The walls of the amnion on the one hand, and that of the yolk sac on the other, may now be defined as extraembryonic *somatopleure* and *splanchnopleure* respectively. The former consisting of an epithelial layer (trophoblast or amniotic lining) associated with a layer of *somatopleuric extraembryonic mesoderm*, whilst the latter comprises the endodermal epithelial lining of the yolk sac together with *splanchnopleuric extraembryonic mesoderm*. At a *junctional zone* surrounding the margins of the embryonic area, where the walls of the amnion and yolk sac converge, the somatopleuric and splanchnopleuric layers of mesoderm are continuous.

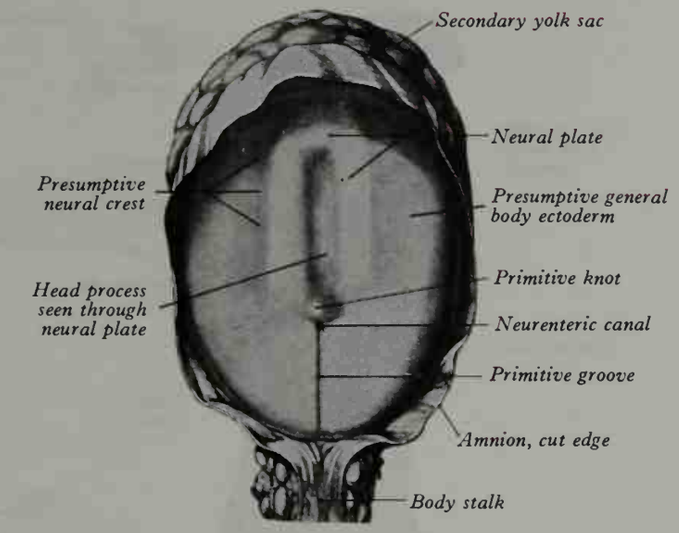
At the early stage the embryonic area is radially symmetrical, with no specialized features distinguishing its future cephalic, caudal and lateral borders, but with the extensions of the extraembryonic coelom noted above, and the increasing separation of the amnion from the overlying chorion, the mesodermal connecting stalk becomes increasingly defined, and its embryonic attachment is soon limited to a zone which marks the future *caudal edge* of the embryonic area.

The first change within the embryonic area itself occurs near the opposite (*cephalic*) edge, where, in a localized region, the endoderm in the yolk sac roof thickens, forming an oval plate of large vesicular cells, the *prechordal plate*, which at the later stage contributes cells to the general head mesenchyme (p. 120) and

which, together with the closely applied superjacent ectoderm, forms the transient *oropharyngeal membrane*. The attachment of the body stalk and the position of the prechordal plate have now defined the *plane of bilateral symmetry* of the embryonic area.

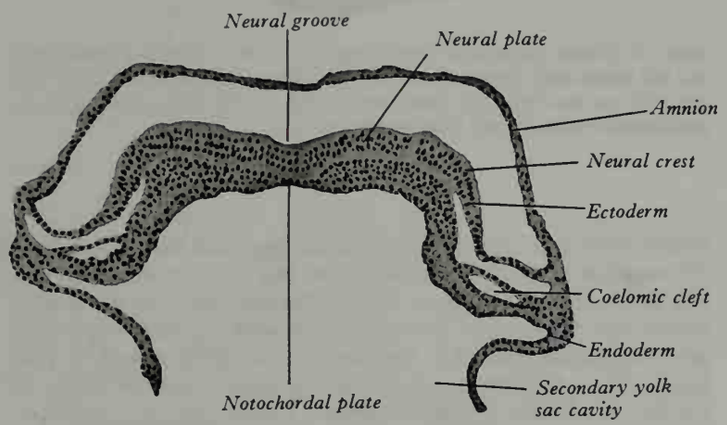
During the immediately succeeding stages the embryonic area changes from a circular *bilaminar* disc to first an oval, and then a pear-shaped *trilaminar* one as a third *mesodermal layer* becomes interposed between the embryonic ectoderm and endoderm. The long axis of the oval and pear lie in the future cephalo-caudal axis of the developing embryo, whilst the pear-shaped outline is narrow caudally and expanded at the cephalic end. These shape changes accompany the emergence of proliferative zones in the caudal midline of the primitive ectoderm of the embryonic area—a linear *primitive streak* with, at its cephalic end, a *primitive knot*. From the former generations of *intraembryonic mesodermal cells*, and from the latter an axial *head process* (ultimately forming the notochord), pass between the ectoderm and endoderm (*vide infra*).

Presumably (based on the evidence of comparative studies, p. 83), under the primary inductive influence of the chorda-mesoderm, the central regions of the ectoderm which overlies it initiates the formation of a *neural plate*, the primordium of the central nervous system (**2**.26, 27). The margins of the plate are surrounded by a strip of presumptive *neural crest* tissue (p. 115) which is, again, surrounded peripherally by the layer which will form the general body ectoderm. These various regions will now be considered further.



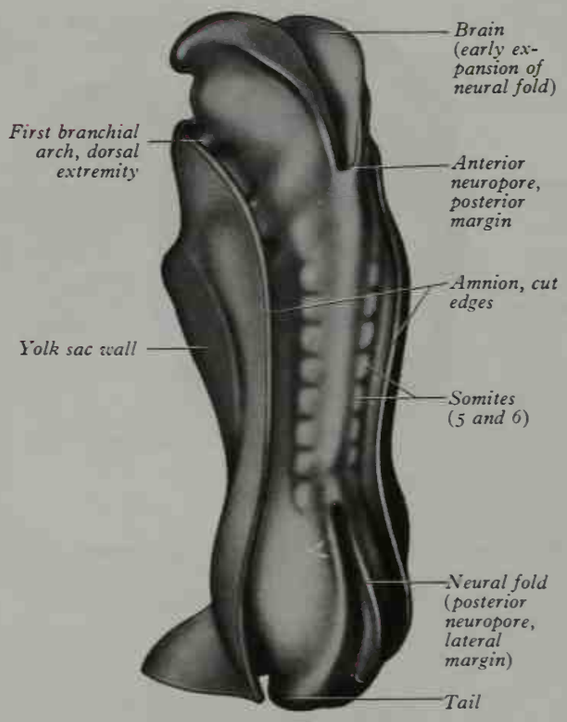
As noted elsewhere (p. 83) many experimental embryologists consider that the totipotency of the fertilized mammalian oöcyte, and initial blastomeres, suffers a stepwise reduction, as the determination and differentiation of the various embryonic regions proceeds. Alternative views have also been advanced—*see* p. 84.) Despite the relative paucity of experimental analyses, because of technical difficulties, on mammalia, it is widely held that by the blastocyst stage, the vast majority of the cells have already suffered a severe restriction in their developmental potency, being destined to form extraembryonic structures (p. 74), whilst the pluripotent cells are restricted to the embryonic area. It has been proposed (Streeter 1942) that, as the changes outlined above occur, these pluripotent cells become progressively circumscribed, first in the caudal part of the oval embryonic area, and then as a narrowing midline strip in the caudal end of the increasingly pear-shaped area, i.e. the site of formation of the *primitive streak* which, as development proceeds, becomes more obvious as a linear opacity when viewed from the amniotic aspect (For more recent *experimental* data on mammalia *see* Herbert and Graham 1974.)

In the early stages of development the living tissues are greyish and translucent, but any localized thickening due to cellular proliferation naturally interferes with the translucency and causes a localized opacity as in the case of the primitive streak, indicating that rapid multiplicative growth is occurring throughout its length. At its headward end a further area of exceptionally active growth forms a knob-like thickening which is termed the *primitive knot* or *Hensen's node* (**2**.26) and at this point the ectoderm is fused with the endoderm.



From the primitive knot a rod-like process of cells grows headwards in the midline separating the presumptive neural plate from the subjacent roof of the yolk sac until its cranial tip reaches the caudal margin of the prechordal plate. This is termed the *head process* (*notochordal process*), which is the forerunner of the skeletal axis of the body. This initially solid rod of cells now becomes canalized, and caudally the canal breaks through on to the ectodermal surface at the posterior end of the primitive knot. The endodermal cells lying ventral to the head process disappear, and the head process then becomes, briefly, a constituent part of the roof of the yolk sac in the median plane. The cells forming the floor of the canal of the head process break down so that the canal communicates freely with the yolk sac, and, at its caudal end, a temporary communication is established between the yolk sac and the amniotic cavity. This connexion, which pierces the embryonic area at the primitive knot, is the *neurenteric canal*. At this stage a transverse section across the embryonic area cranial to the primitive knot shows that, in the median plane, the roof of the yolk sac is, for a time, formed by the cells of the head process (**2**.27), and this intercalation, which forms the *chordal or notochordal plate*, extends forwards to include the region which will subsequently form the roof, or dorsal wall, of the pharynx. Later, these cells of the head process become separated from the endoderm and form the *notochord*, the roof of the yolk sac being repaired by the fusion of the adjoining endodermal cells. Subsequently the cells of the notochord develop around them a homogeneous sheath, and the continued proliferation of cells within the sheath results in the formation of a solid but flexible rod, which becomes surrounded by mesoderm to form the primitive or *blastemal vertebral column* (p. 140).

During the earlier part of this period another important change affects most of the embryonic area. From the sides of the primitive streak occurs an intensely active multiplicative cell growth. The cells formed spread laterally, forwards and backwards until they extend over the whole embryonic area (*with the exception of most of the median plane*). They insinuate themselves between the ectoderm and the underlying endoderm and produce a third layer, which constitutes the *intraembryonic mesoderm*. (For a review of experimental data of these stages of development in higher vertebrates consult Bellairs 1971.)



The primitive streak is the principal, but not the only source of intraembryonic mesoderm; it also receives accessions from the

2.26 A human embryo, 1·16 mm long. The amnio-embryonic vesicle has been laid open widely, most of the amnion having been removed. The embryonic area is exposed in almost its whole extent and shows an early stage of differentiation. Estimated age, 19 days. (W. C. George, *Contr. Embryol.*, **30**, 1942.)

2.27 Transverse section of a human embryo, about 19 days old. (Embryo: Bryce-McIntrye, *Trans. Roy. Soc. Edin.*, **53**, 1924.) The canal of the head process has broken into the yolk sac at this level and the notochordal plate is incorporated in the roof of the gut. Observe that the coelomic clefts have appeared in the lateral plates of the mesoderm, and that they do not communicate with the extraembryonic coelom. The neural groove is shallow and the amnion is restricted to the dorsal and lateral aspects of the embryo.

2.28 A human embryo, 2·1 mm long, with nine somites. Viewed from the left lateral and dorsal aspects. (From a model by Eternod.) Nearly all the yolk sac has been cut away, and at the caudal end a portion of the amnion has been excised to show the tail region.

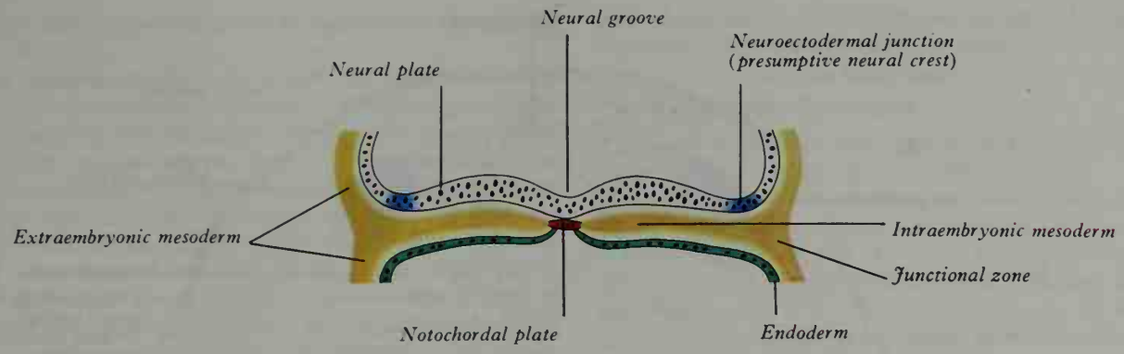
neural crest (p. 115) particularly in the head and branchial arches (Hörstadius 1950), and the latter also receive contributions from the thickened endoderm of the prechordal plate. As mentioned above, this plate forms an integral part of the future oropharyngeal membrane, and it is probably involved in inductive processes of cranial structures (termed a *head organizer region* by earlier workers) during further embryonic development. Similarly, in the midline at the opposite end of the embryonic area, a patch of endoderm thickens and becomes closely applied to the overlying ectoderm, between the caudal tip of the primitive streak and the attachment of the body stalk, to form the future *cloacal membrane*.

As the streams of intraembryonic mesodermal cells radiate from the margins of the primitive streak (**2**.31), they separate the ectoderm and endoderm of the embryonic area, and soon approach to become confluent with extraembryonic mesoderm around the margins of the area, i.e. at the *junctional zone* where the splanchnic and somatic strata of extraembryonic mesoderm merge. The streams passing in a cephalic direction flank the differentiating head process (later the notochord), skirt the margins of the prechordal plate, and then converge medially to fuse in the midline beyond its cephalic border. This transmedian mass is the *cardiogenic mesoderm* in which the heart and pericardium are to develop. Around the extreme cephalic margin of the embryonic area, the cardiogenic mesoderm fuses with the junctional zone of extraembryonic mesoderm mentioned above, and this region of the latter will eventually form the *septum transversum* and *primitive ventral mesentery* of the gut and their derivatives (p. 119).

The intraembryonic mesoderm which streams caudally from the primitive streak skirts the margins of the cloacal membrane and then converges to become continuous with the extraembryonic mesoderm of the connecting stalk.

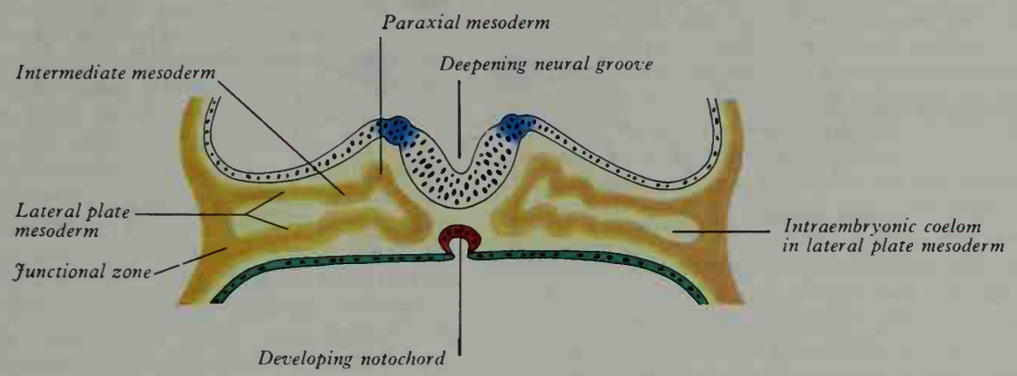
The ectodermal thickening of the *neural plate* from which most of the central nervous system develops, corresponds precisely in length to the underlying developing notochord. Thus it extends from the cranial border of the primitive knot to the caudal border of the future oropharyngeal membrane, but it also extends laterally to cover the medial strips of intraembryonic mesoderm. As it grows, its margins become raised (**2**.27, 28, 29) as the *neural folds*, with a longitudinal, midline *neural grove* between them.

The neural folds become particularly prominent at the anterior end of the area and the walls of the groove become expanded (**2**.27). This enlargement is the first sign of brain formation. It is not a continuous enlargement, however, because two transverse constrictions indicate a division into three parts—the *prosencephalon* or *forebrain*, the *mesencephalon* or *midbrain*, and the *rhombencephalon* or *hindbrain*. As we have seen, between the cephalic margin of the forebrain and the cardiogenic mesoderm, the ectoderm and the endoderm are in contact over a small area forming the *oropharyngeal membrane* (**2**.33). As the neural groove deepens, its dorsal edges come into contact with each other and fuse to convert the groove into a sagittal slit-like canal (**2**.28, 29). It should be noted that as the edges of the groove approximate they carry with them the adjoining general body ectoderm and, when the process of fusion occurs, like fuses with like, i.e. ectoderm with ectoderm, and neural tissue with neural tissue to form a *neural tube*. The process is effected first in the hindbrain or upper cervical region (**2**.28) in the latter part of the third week, and extends both headwards and tailwards, until only a small opening is left at each end. These are the rostral and caudal *neuropores*; the former closes in the middle and the latter towards the end of the fourth week. The cells which lie in the line of fusion of the dorsal edges of the neural plate constitute the *neural crest* (**2**.29), the history of which will be considered in a subsequent section (p. 115).



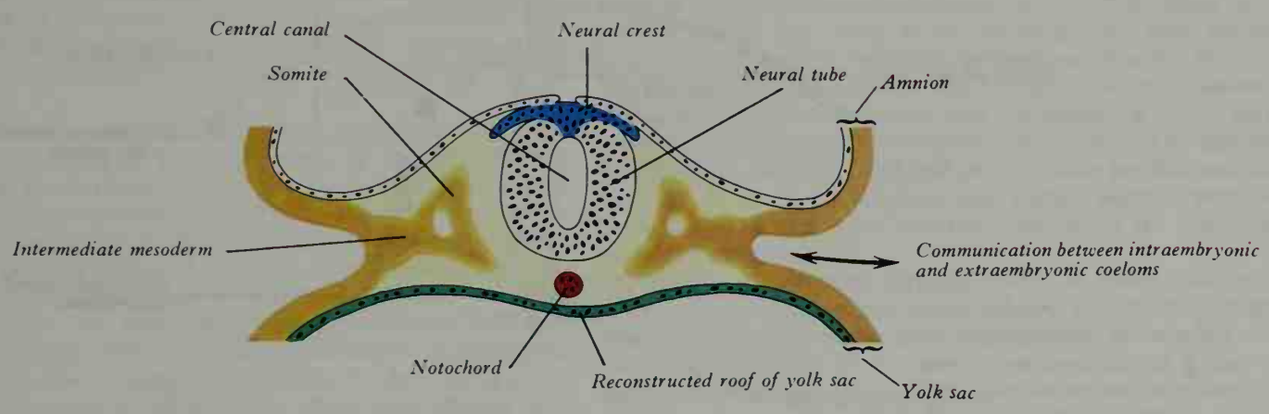
From initiation, the walls of the neural groove and tube are bathed by the fluid in the amniotic cavity (*liquor amnii*) and presumably are, in part, dependent on it for their nourishment whilst the neuropores remain open. It is perhaps significant that closure of the neuropores coincides with the establishment of a blood vascular circulation for the neural tube.

The fusion of the dorsal lips of the neural plate in the region of the brain results in the formation of three zones termed, somewhat inappropriately, the *primary cerebral vesicles* (*see* p. 163). The walls of these vesicles become thickened and develop into the nervous tissues and neuroglia of the brain, and their cavities are modified to form the ventricles of the brain. In some important sites, however, the walls of the forebrain and hindbrain vesicles do not develop nervous tissue but remain thin and are modified to form *choroid plexuses* (p. 169). The remainder of the tube forms the spinal cord, its cavity persisting as the central canal (see also p. 157).



Meanwhile, throughout the extent of the notochord the intraembryonic mesoderm becomes arranged into three zones: (1) a thickened medial portion which lies immediately lateral to the grooved neural plate and notochord, the *paraxial mesoderm* (**2**.30), (2) a narrower *intermediate mesoderm*, situated lateral but directly continuous with the paraxial mesoderm, and (3) a flattened *lateral plate* which extends from the intermediate mesoderm to the periphery of the embryonic area where it is continuous with the extraembryonic mesoderm on the outer surfaces of the amnion and the yolk sac, i.e. at the *junctional zone* of mesoderm mentioned above.

THE EMBRYONIC LAYERS



The appearance of the intraembryonic mesoderm and its three major divisions completes the first stage of differentiation of the embryonic area. The embryo now consists of an outer protective layer, the ectoderm, an inner nutritive layer, the endoderm, and an intermediate layer, the intraembryonic mesoderm, which is available primarily as a muscle-forming layer. It is clear from their history and their early differentiation that these layers are of considerable phylogenetic and ontogenetic significance, but too much stress must not be laid on their independence from one another. The differentiation at this stage does not leave the constituent cells of the three layers with potencies so limited that complete divergence occurs in subsequent development. The developmental potential of the individual cell layers are reduced from the pluripotent condition found at an earlier period, but not to such an extent that the potencies of the cells of one layer are entirely different from those of the two remaining layers. Further, during subsequent development of the various organ systems,

derivatives of the different layers are often closely interlocked and are interdependent in terms of fundamental *morphogenetic mechanisms* (pp. 85–91).

However, the contributions of the three layers in the human embryo to the formation of the different sytems and organs may, for convenience, but summarized as follows.

The primitive embryonic ectoderm consists of columnar cells, which become cubical towards the periphery of the embryonic area. It gives origin to: (1) the epidermis and the lining cells of the glands which open on it, and the appendages of the skin, the hair and nails; (2) practically the whole of the nervous system, including the cranial and spinal ganglia, the sympathetic ganglia and the posterior lobe of the hypophysis cerebri; (3) the chromaffin organs; (4) the anterior lobe of the hypophysis cerebri; (5) the epithelium of the cornea, conjunctiva and lacrimal glands; (6) the lens; (7) the plain muscle of the iris; (8) the neuro-epithelium of the sense organs; (9) the epithelium lining the nose and the paranasal sinuses, the roof of the mouth, the gums and the cheeks; (10) the salivary glands and the enamel of the teeth; (11) the epithelium lining the lower part of the anal canal and that of the terminal urethra.

The primitive embryonic endoderm consists at first of flattened cells, which subsequently become columnar. It gives origin to: (1) the epithelial lining of the whole of the alimentary canal, with the exception of those portions already ascribed to the ectoderm; (2) the lining cells of the glands which open into the alimentary canal, including the liver and the pancreas, but excluding the salivary glands; (3) the epithelium lining the auditory tube and the tympanic cavity; (4) the epithelium of the thyroid and parathyroid glands and the thymus; (5) the lining epithelium of the larynx, trachea and the smaller air passages, including the alveoli and the air saccules; (6) the epithelium of most of the urinary bladder and much of the urethra; (7) the epithelium of the prostate.

The intraembryonic mesoderm gives origin to the remaining organs and tissues of the body. These include: (1) all the connective and sclerous tissues; (2) the teeth with the exception of the enamel; (3) the whole musculature of the body, both striated and unstriated, with the exception of the musculature of the iris; (4) the blood and the blood vascular and lymphatic systems; (5) the urogenital system, with the exception of most of the urinary bladder, prostate and uretha; (6) the cortex of the suprarenal glands and the mesothelial linings of the pericardial, pleural and peritoneal cavities.

THE EMBRYONIC TISSUES

The cells of the embryo become arranged at this early stage into two fundamental types of tissue, *epithelial* and *mesenchymatous*, and, despite regional modifications introduced as the various

tissues develop, these types persist in large measure throughout life.

Epithelial tissues are those in which the cells are closely packed, with narrow intercellular clefts containing minimal extracellular material, and subsequently the cells usually show inter-cell surface specializations such as desmosomes, tight junctions, gap junctions, etc. (pp. 7–10). Characteristically, they clothe internal and external surfaces as simple or compound cellular sheets which separate phases of differing composition (e.g. the external environment and the subepithelial tissue fluids; intravascular and extravascular fluids, and so forth). Traffic of materials in the intercellular clefts between cells is limited, and passage occurs across the cells and their limiting membranes, which function as energy-dependent selective barriers, enhancing the passage of some materials and impeding the passage of others.

The majority of the derivatives of the embryonic ectoderm and endoderm listed above retain their epithelial character throughout life. The third germ layer, mesoderm, also contributes many tissues of an epithelial type (although they may also be termed endothelia or mesothelia depending upon their topographic site). These include the visceral and parietal mesothelia of the coelomic cavities, many of the derivatives of the intermediate mesoderm such as the pro-, meso-, and meta-nephroi and their ducts, the paramesonephric (Müllerian) duct system, and the cortex of the suprarenal gland. Further, after first passing through a mesenchymatous stage (*vide infra*) many mesodermal cells contribute to the formation of the widespread endothelial cell layers which line the blood and lymphatic vascular systems. Still other mesothelia develop to line the various synovial cavities of the many joints, bursae and tendon sheaths, the anterior chamber of the eye and the periotic perilymphatic space of the internal eye. The myotome of mesodermal somite origin (p. 118) also maintains an epithelial arrangement throughout the early stages of its development.

Mesenchyme, a name first introduced almost a century ago (Hertwig 1881), forms the remaining tissue of the early embryo, occupying all the regions between the various epithelial layers described above. In contrast it consists of a loosely arranged tissue with wide extracellular spaces containing copious extracellular fluid which carries a variety of hydrated mucosubstances (p. 51), suspended in which are widely spaced, amoeboid, primitive *mesenchymal cells*. The latter usually appear stellate in fixed and stained preparations, they often show some degree of phagocytic ability, and they have retained a potentiality for developing into a wide array of cell types in different sites. Many mesenchymal cells are derived from various regions of the early intraembryonic mesoderm, e.g. from the lateral plate where they form the core between the limiting epithelia of the splanchnopleure and somatopleure, and from the dermotome and sclerotome of the mesodermal somites (p. 118).

Mesenchymal cells are, however, not exclusively of mesodermal origin; it is probable that the extraembryonic mesenchyme of the yolk sac and chorion receive contributions from the neighbouring endoderm and cytotrophoblast respectively. Within the embryonic body considerable accessions are also received, particularly in the head region from the neural crest and the endodermal prechordal plate.

In subsequent development mesenchymal cells differentiate into many different types of tissue including: the general and specialized connective tissues (cartilage, bone, dentine) and their many types of attendant cell (p. 258); smooth visceral, cardiac and, in some sites, striated muscle; the endothelium of the blood and lymphatic vascular systems; the various blood-forming sites, lymphoid tissue, bone marrow, spleen and the remaining elements of the reticulo-endothelial and macrophage systems; the tissues of joints including their synovial cells and those of bursae and tendon sheaths; finally the sheaths of nerves, muscles and the periostea of bones.

SUBREGIONS OF THE EMBRYONIC LAYERS

In addition to the general summaries of the derivatives of the primitive embryonic layers given above, it may also prove convenient here to indicate the principal *subregions* of these layers and their main contributions to the developing embryo. (Inevitably this involves some repetition.)

The Embryonic Ectoderm

This may be divided into (a) general body ectoderm; (b) neural plate; (*c*) neural crest; (*d*) ectodermal placodes.

General body ectoderm gives rise to: (1) most of the cutaneous epidermal cells; the secretory, duct-lining, and myoephithelial cells of sweat, sebaceous, and mammary glands; the hairs and nails; (2) the epithelia of the cornea and conjunctiva, and the secretory and duct-lining cells of the lacrimal gland; (3) the respiratory nasal epithelium; the epithelia lining the paranasal sinuses, lips, cheeks, gums and palate; the secretory and duct-lining cells of the nasal, labial, palatine, general oral and salivary glands; (4) the embryonic enamel organ and dental enamel; (5) the epithelial lining of the external acoustic meatus and external epithelium of the tympanic membrane; (6) the epithelial lining of the lacrimal canaliculi, sac and nasolacrimal duct; (7) the epithelium of the lower anal canal and terminal urethra.

Neural plate cells give rise to: (1) all the neurous of the *central* nervous system; these include not only those neurons wholly confined to the central nervous system, but also those somatic motor and preganglionic efferent neurons with somata within the central system and axons which pass out into the peripheral nervous system; (2) the macroglial cells, i.e. varieties of astrocyte and oligodendrocyte; (3) generalized ependymal cells lining the ventricles, aqueduct and central canal of brain and spinal cord; (4) specialized ependyal cells, including tanycytes, those covering the choroid plexuses, and distinctive regions of the third ventricle such as the subcommissural organ; (5) cells belonging to the APUD series (the term is an acronym for cells showing characteristic amine handling properties—Amine Precursor Uptake and Decarboxylation—the evolution and modification of the concept is discussed more fully elsewhere—p. 1454, and at other appropriate points throughout the volume). These include pinealocytes, magnocellular and parvocellular peptide-secreting neurons of the hypothalamus, and certain adenohypophyseal cells; (6) all retinal cells, and the epithelia of the iris, ciliary body and processes.

Neural crest cells, first forming a strip of tissue flanking the neural plate, then *migrating* widely, often in well-defined streams, and subsequently forming local aggregations, or invading other tissues, give rise to: (1) the sensory neurons of the dorsal root ganglia of the spinal nerves; (2) many of the sensory neurons of the ganglia of the trigeminal, facial, vestibulocochlear, glossopharyngeal and vagal cranial nerves (other cranial nerves may have transient populations—*see* p. 174); (3) the principal postganglionic autonomic neurons of both sympathetic and parasympathetic moieties, including the enteric plexuses, ganglionated sympathetic chains, and other ganglionic aggregates associated with, for example, the cardiac, coeliac, mesenteric, renal and vesical plexuses; (4) many specialized peripheral sensory receptor cells (see also placodes below); Schwann cells, the perisomatic satellite cells of sensory ganglia, the 'glial' elements of autonomic ganglia and peripheral receptors; (5) the basal regions of the neurocranium, and viscerocranium (p. 141), in particular the trabeculae cranii and cartilages of the branchial arches, and possibly the osteogenic elements that become associated with these cartilages; (6) the dentine-producing osteoblasts of the tooth germs; probably admixed with mesenchyme from other sources, crest cells may contribute to the special visceral striated muscles derived from the branchial arches, and to the smooth muscle of the branchial vessels; (7) some, at least, of the meningeal pia-arachnoid; (8) cells belonging to the APUD series (*vide supra*, and p. 1454). These include: thyroid parafollicular (C) cells derived from ultimobranchial tissue, classical chromaffin tissue (phaeochromocytes of the adrenal medulla, paraganglia and para-aortic bodies, and other outlying masses—*see* **8**.204), varieties of small intensely fluorescent (SIF) cells associated with sympathetic ganglionic neurons, the glomus (type I) cells of the carotid body (and probably many other functionally similar sites throughout the body), and finally both dermal and epidermal melanoblasts, and other epidermal, non-melanoblastic dendritic cells; (9) contributions to connective

tissues throughout the body. For a review of neural crest *see* Leikola (1976).

Ectodermal placodes are specialized patches of ectodermal cells (the named placodes being the olfactory, otic, dorsolateral, epibranchail, and lental) that invaginate, sometimes coming into close association with cells from other sources. They all have some characteristics in common with the neural crest and give rise to: (1) the receptor, and probably sustentacular cells of the olfactory part of the nasal mucosa; (2) the epithelial walls of the membranous labyrinth, and the specialized receptor cells of its utricular and saccular maculae, and the ampullary crests of its semicircular ducts; (3) *some* of the primary sensory neurons of the trigeminal, facial, vestibulocochlear, glossopharyngeal, and vagal cranial nerves (although their precise contribution to these in the *human* embryo needs further clarification); (4) the crystalline lens of the eye; (5) some members of the APUD series, in particular the parathyroid chief cells: certain authors prefer to regard the cells of the adenohypophysis as having a placodal origin through the medium of the ectodermal anlage of Rathke's pouch; and similar considerations may apply to the parafollicular cells of the thyroid, through the anlage of the ultimobranchial body (the latter may therefore imply the existence of endodermal 'placodes').

It may be noted here, that despite cautious suggestions made over a decade ago (Pearse 1966), only 6 of the 40 cell varieties now accepted as belonging to the APUD series have definitely been shown to stem from the neural crest. Thus the large number of varieties of enterochromaffin cells present in the mucosae of the stomach and intestines, in the pancreatic islets, and other varieties found in the bronchial mucosa, the lining epithelium of the urethra and prostatic parenchyma, have an uncertain origin. Their progenitors have been hypothecated as 'neuoendocrine-programmed ectoblastic cells', and a foregut endodermal origin has been postulated for the gastro-intestinal/pancreatic varieties (Pearse 1977). (For a further discussion of this topic and the introduction of the term 'paraneuron' *see* p. 1454, and refer to Fujita 1976.)

The Embryonic Mesoderm

This may be divided into, as noted above, *paraxial* mesoderm, *intermediate* mesoderm and the *lateral* plate. The paraxial mesoderm, as is detailed further below, segments into a longitudinal series of mesodermal somites, and each somite subdivides into a sclerotome, dermotome, and myotome. The intermediate mesoderm forming a longitudinal, cord-like, cylindrical mass, which is continuous medially with the somites, and laterally with the lateral plate, may best be considered as a cranio-caudal series of subregions—cervical, thoracic, lumbar, and sacrococcygeal. Clefts appearing in the cardiogenic mesoderm and lateral plate coalesce to form the intraembryonic coelom (*vide infra*). The latter separates the lateral plate into somatopleuric (body wall) and splanchnopleuric (enteric) layers, which line or cover the ectoderm and endoderm, and their derivatives, respectively. As it enlarges, the intermediate mesoderm projects into, and also forms a partial boundary for the coelom, whilst the *zones of continuity* between the somatopleuric and splanchnopleuric mesoderm, after much differential growth, excavation, repositioning, and in some places adhesion, become sculpted to form the definitive gastric, enteric, hepatic and splenic mesenteries. The epithelial or mesenchymatous nature of these various zones are discussed further below and in subsequent pages.

The paraxial mesoderm, through the medium of the somites, forms: (1) the vertebrae and their associated joints and ligaments, including much of the intervertebral discs; the ribs, costal cartilages, sternal plates (ultimately manubrium, sternebrae and xiphoid process), by migrations from the sclerotomes: cells from the latter probably contribute to the dura mater; (2) the dermotomic cells migrate ventrolaterally, admixing with neural crest cells and somatopleuric lateral plate mesoderm and, together with the costal elements, form the bulk of the tissues of the body wall (*vide infra*); (3) the cells of the myotomes, by migration, subdivision, rearrangement, and sometimes fusion of cell masses from neighbouring myotomes, ultimately differentiate into the striated musculature of the trunk (it appears that the limb muscles, and lingual muscles, although segmentally innervated, develop *in situ*, with little obvious migration from the myotomes); (4) perineural mesenchyme, of uncertain, but possibly myotomic origin, provides the microglia of the central nervous system.

The intermediate mesoderm through the intermediaries of the nephrogenic cord, genital ridge and overlying medial coelomic mesothelium forms: (1) the rudimentary pronephric, and fully functional meso- and meta-nephric renal corpuscles and nephric tubules; (2) the mesonephric (Wolffian) duct and its derivatives—the vesical trigone, ureter and renal calices and collecting tubules in both sexes; male testicular duct complexes (p.217), epididymis, ductus deferens, seminal vesicle, ejaculatory duct, and a small area of prostatic urethra; and merely rudimentary vesicular, tubular and duct systems are formed in the female (p. 217); (3) the paramesonephric (Müllerian) duct and its derivatives—the female uterine tube and uterus, the development of the vagina being more conjectural; vestigial testicular structures and prostatic utricle in the male; (4) in both sexes, the whole of the gonadal tissues with the exception of the sex cells (gonocytes) themselves; (5) from the medial coelomic bay, and encroaching on to the mesonephric ridge, the cortex of the adrenal gland; (6) the connective tissue framework, capsule, mesothelial covering and, where appropriate, the mesenteries of all the foregoing.

The lateral plate mesoderm becomes split, as noted above, by the appearance of the intraembryonic coelom, into somatic and splanchnic layers (p. 118), the somatic mesothelial lining of the coelom forming the serous parietal pericardium, pleura and peritoneum, whilst the splanchnic mesothelial lining forms the serous epicardium, pulmonary pleura, and the visceral peritoneum that wholly or partly clothes the various abdominal and pelvic organs. The *somatopleuric mesenchyme*, as mentioned above and elsewhere, receives accessions from the neighbouring neural crest, and is also admixed with invading cells from adjacent dermotomes, myotomes and (in the thoracic region) sclerotomes. Thereafter mesenchymatous condensations of heterogeneous origins appear, and growth and differentiation transform them into the osseous, cartilaginous, muscular, vascular, lymphatic and connective tissues of the body wall. As the appropriate spatio-temporal patterning of these tissues is occurring, they gradually receive the terminals of ingrowing bundles of axonal processes (and their accompanying Schwann cells) growing from the neuroblasts of the ventral lamina of the neural tube, and from the neuroblasts of the primordial spinal and autonomic ganglia. Similar tissues and transformations are involved in the formation of the limbs, the early limb buds consisting of an external covering of ectoderm and a mesenchymatous core of mixed origin.

The splanchnopleuric mesenchyme clothes the endodermal gut tube, including the endodermal cloaca, allanto-enteric diverticulum, and their various subdivisions and glandular derivatives. Its cells grow and differentiate into the non-striated muscle, connective, vascular, lymphatic, and adipose tissues of the walls of the stomach, small and large intestines, urinary bladder (excluding the trigone), and also the walls of (all but the finest terminal) biliary and pancreatic duct systems. Similar tissues are provided by splanchnopleuric mesenchymal cells in the walls of the tracheo-bronchial tree down to its finest pre-alveolar passages, but with the addition of cartilage as far as the commencement of the bronchiolar system. Most of these tissues receive the ingrowing terminals of post-ganglionic sympathetic axons, and preganglionic parasympathetic terminals from the vagus (foregut and midgut and their derivatives) and the pelvic parasympathetic nerves (hindgut). Corresponding regions are invaded by postganglionic parasympathetic neuroblasts derived, it is presumed, from the vagal and sacral neural crest respectively.

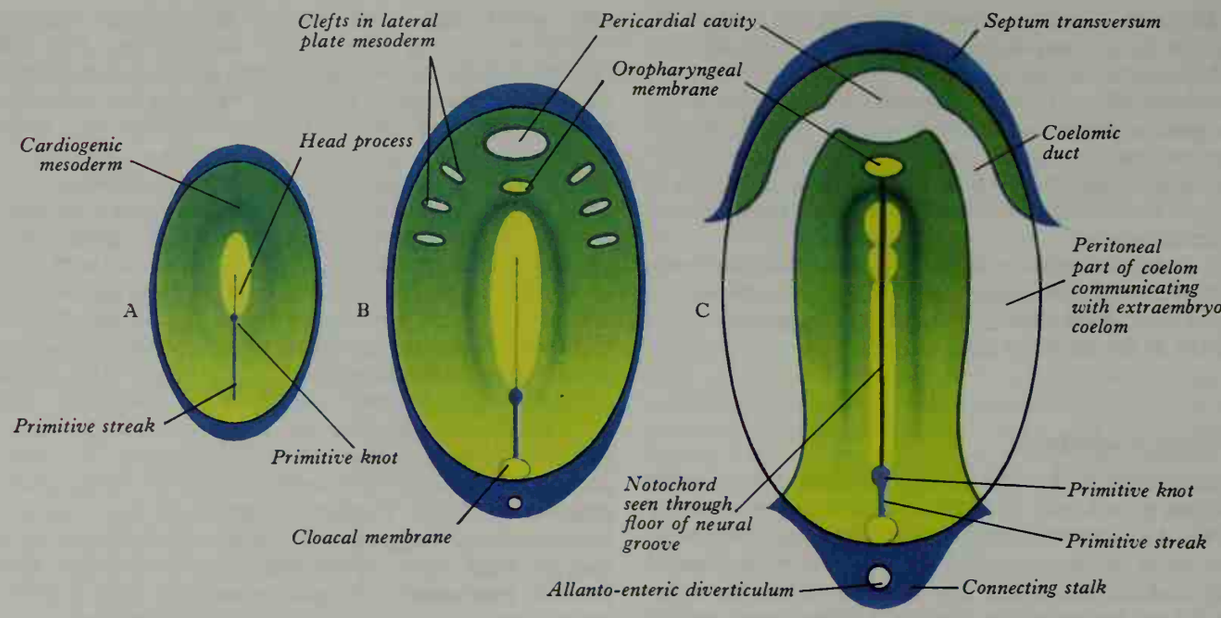
It should be noted that vascular venous differentiation in the splanchnopleuric mesenchyme caudal to the developing diaphragm, leads to numerous radicles draining virtually the whole of the subdiaphragmatic gut, liver, pancreas and spleen, and these gradually combine to form the hepatic portal vein. In the primitive pericardial region, similar mesenchyme, including its covering mesothelium, form all the non-nervous tissues of the heart. The spleen differentiates in the mesenchyme of the dorsal mesentery of the stomach (dorsal mesogastrium).

It should also be stressed that in the ventrolateral walls of the

embryonic pharynx *no coelomic cavity* develops, so that in the branchial arches there is *unsplit* lateral plate mesenchyme that has received substantial additions from the cranial neural crest, and possibly also from adjacent sclerotomes and dermotomes. Thus, whilst it has become customary to loosely classify many branchial structures as 'visceral' or 'special visceral' it is by no means clear in mammals in general, and particularly in mankind, which of these sources of mesenchyme predominates in the anlage of any specific tissue derivative.

Finally it may be mentioned that the splanchnopleuric mesenchyme of the yolk sac, liver, and spleen are the earliest loci of red blood cell formation, preceding the appearance of progenitor cells in the red bone marrow.

The Embryonic Endoderm



The main derivatives of the embryonic endoderm have already been listed above, and will be further detailed in subsequent sections: to avoid excessive repetition, therefore, only some additional points or as yet unresolved questions will be mentioned here. Thus: (1) whilst in general it is usually stated that the endoderm forms the epithelium of the whole alimentary tract, and its associated glands, from stomatodeum to proctodeum, its precise extent is less certain cranially, and the origin of some of the epithelial cell types cannot be regarded as proven. The epithelia of the lips, gums, parotid glands, cheeks, dental enamel, and anterior part of the hard palate are accepted as definitely of *ectodermal* origin; similarly, most authorities accept that the lingual epithelium and that of the lingual glands are endodermal; the exact site of the transition line between the two is not yet established. It must be stressed that the line does not necessarily correspond to any particular outstanding topographic landmark such as the oropharyngeal isthmus or linguogingival sulcus, and authorities differ concerning the ectodermal or endodermal status they ascribe to the submandibular and sublingual salivary glands. In contrast, the generally accepted caudal limit of the hindgut endoderm is at the level of the anal 'valves'. (2) The endoderm of the remainder of the post-oral foregut forms the great variety of epithelia that characterize the various zones, recesses, diverticula and glands of the pharynx, and the general, glandular, and duct-lining epithelia of the oesophagus, stomach, and proximal duodenum. Some parts of the embryonic pharyngeal lining form endocrine glands that lose all connexion with the gut, whilst other regions become associated with specialized localizations of lymphoid tissue. (3) The origin of the hair cells of the lingual, palatal, pharyngeal and laryngeal taste buds (neural crest or 'neurally-programmed' foregut endoderm) is uncertain, but in addition to their sensory receptor function, they have been classified as members of the APUD neuroendocrine series, and dubbed paraneurons (Fujita 1976). (4) The lymphoid-associated endodermal derivatives constitute *Waldeyer's ring*: characteristically their epithelial surfaces are uneven (showing undulations, folds, crypts, fossulae, clefts or sinuses); they include the nasopharyngeal tonsil (adenoid), the (auditory) tubal tonsils, the palatine tonsils, and the lingual tonsil. (5) The pharyngeal epithelia range from respiratory, mucus-secreting, ciliated, columnar epithelium which lines the upper nasopharynx, the environs of the opening of the auditory tube, and the superior part of the dorsal surface of the soft palate, together with the larnygeal vestibule, to the non-keratinized stratified squamous epithelium which lines the rest of the pharynx and palate. (6) The epithelial lining of the auditory tube, tympanic cavity with its mesentery-like mucosal folds and internal lamina of the tympanic membrane, and of the tympanic antrum, is derived from endoderm (p. 1194) and ranges from tall columnar and ciliated, through cuboidal to simple squamous in different locations. (7) Other pharyngeal, endodermal, derivatives include the general mucous glandular and duct-lining cells; the main follicular and parafollicular cells of the thyroid (from different locations); parathyroid secretory cells (debate persists concerning their origin—Fujita 1976; Pearse 1977); and the cytoreticulum and concentric corpuscles of the thymus. (8) Little is to be added to the widely held view that the great majority of the epithelial cells, glandular and duct-lining cells of the oesophagus, stomach, jejunum, ileum, colon, rectum, and upper anal canal are of endodermal origin: similar considerations applying to the hepatocytes, and duct-lining epithelia of the biliary duct system, and to the pancreatic acinar and duct-lining cells: again the majority of epithelial cells—ranging from tall columnar ciliated and mucus-producing, to an extremely attenuated simple squamous type—that line the whole of the tracheobronchial-alveolar respiratory tree, are endodermal in origin. A similar derivation is also accepted for most of the transitional epithelium lining the urinary bladder and urethra, and for the parenchymal secretory cells of the prostate and lesser urethral glands. In almost all these locations, however, as intimated above, are numerous cell types loosely termed *enterochromaffin cells*: characteristically these cells show properties of *receptor mechanisms* on their surfaces, and the production of *neuroendocrine secretions* and *neurotransmitter-like* substances. (Not all the cells postulated as enterochromaffin have, as yet, fulfilled all these criteria.) Particular interest is currently focused upon the pancreatic islet cells and the so-called neuro-insular complex (p. 1371). Further comments on these matters will be found under the appropriate organs in subsequent sections: see also pp. 1348, 1364. (9) Finally, reference must be made to the possible relationship between endodermal cells and the haemopoietic stem cells (pp. 60, 63), and to the origin of the primordial sex cells (p. 1412).

SEGMENTATION OF THE MESODERM

In the embryos of all vertebrates (**2**.3) the intraembryonic mesoderm becomes incompletely subdivided by a longitudinal groove into a *paraxial part* and a *lateral plate*, on each side of the midline (**2**.29). The mesoderm in the floor of the groove which connects these two parts is the *intermediate mesoderm*, most of which subsequently forms the *nephrogenic cord* (p. 210). Soon after the appearance of this longitudinal groove the paraxial mesoderm becomes subdivided into prismatic blocks by a series of transverse grooves. This process is termed the *segmentation of the mesoderm*, and the blocks of paraxial mesoderm so formed are known as *mesodermal somites* (*primitive segments* or *metameres*). Commencing at the end of the third or the beginning of the fourth week in the region of the hindbrain, the process extends in a *cranio-caudal direction*, additional somites being laid down as the embryo grows in length, until 42–45 pairs are present (p. 224). The most cranial four or possibly five somites lying alongside the hindbrain participate in the formation of the skull and are termed the *occipital somites*. However, other workers (de Beer 1937; Sensenig 1957) have suggested that originally nine somites were involved in the elaboration of part of the skull. The remainder flank the spinal cord and usually number 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and 8–10 coccygeal. Variations in this sequence may occur, usually involving either an additional segment or a missing segment in either the thoracic, lumbar or sacral regions, a variation in one region often being accompanied by a compensatory variation in a neighbouring region. The first occipital pair are often asymmetric in their degree of development, and one or both may be partly or completely suppressed. Many workers hold that mesodermal masses which are serially homologous with the segmented paraxial mesoderm arise beside the cranial tip of the notochord in association with the development of the extrinsic ocular muscles (p. 152). (For experimental data concerning mesodermal segmentation in higher vertebrates consult Bellairs 1971.)

In the *human embryo* it is only the *paraxial* mesoderm alongside the notochord which is physically segmented, but in view of the obviously segmental arrangement of the nerves of the spinal cord and their areas of distribution to the various embryonic layers, it is reasonable to suppose that the segmentation of the other structures is present although obscured.

This basic *metameric segmentation* is a characteristic feature of the whole phylum *Chordata* and is particularly well seen in the primitive miolecithal forms in which, after gastrulation (p. 76 and **2**.3), the mesoderm arises as a series of evaginations from the archenteron, which form independent, paired, segmental, coelomic, mesodermal pouches. These expand, separating the ectoderm from the endoderm until they meet dorsal and ventral to

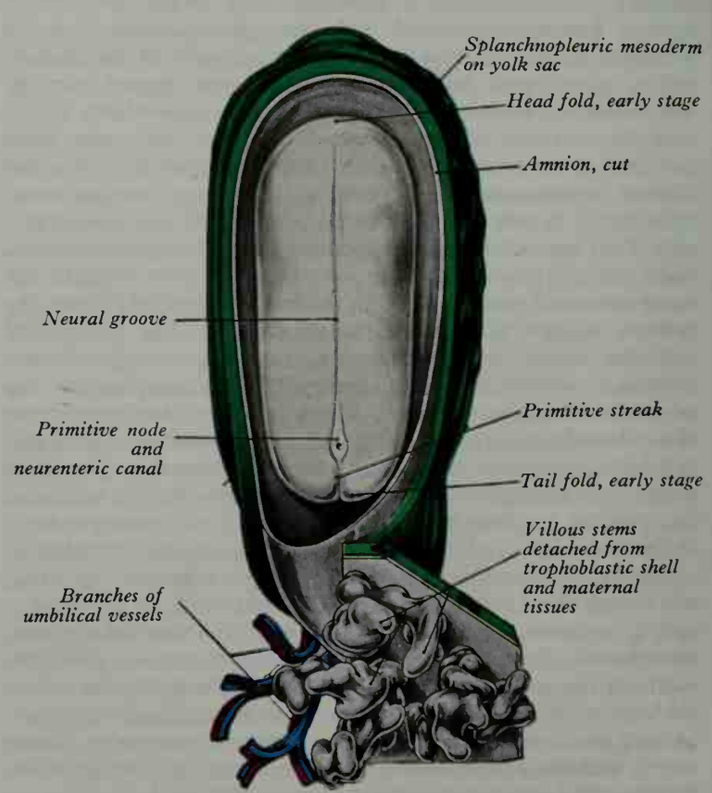
2.31A–C Diagrams to illustrate the formation of the intraembryonic coelom—the embryonic area is viewed from the dorsal aspect and the early stages of head and tail fold formation are not shown.

A The intraembryonic mesoderm (green) becomes continuous with extraembryonic mesoderm (blue) around the periphery of the embryonic area. At the headward end the cardiogenic mesoderm extends from side to side across the median plane, it is continuous with extraembryonic mesoderm which will form the septum transversum; the region of the developing neural plate (yellow) is devoid of mesoderm.

B The pericardial cavity (uncoloured) has appeared in the cardiogenic mesoderm, and a series of clefts (uncoloured) has appeared in the lateral plate mesoderm on each side. The oropharyngeal and cloacal membranes which are devoid of mesoderm are shown in yellow.

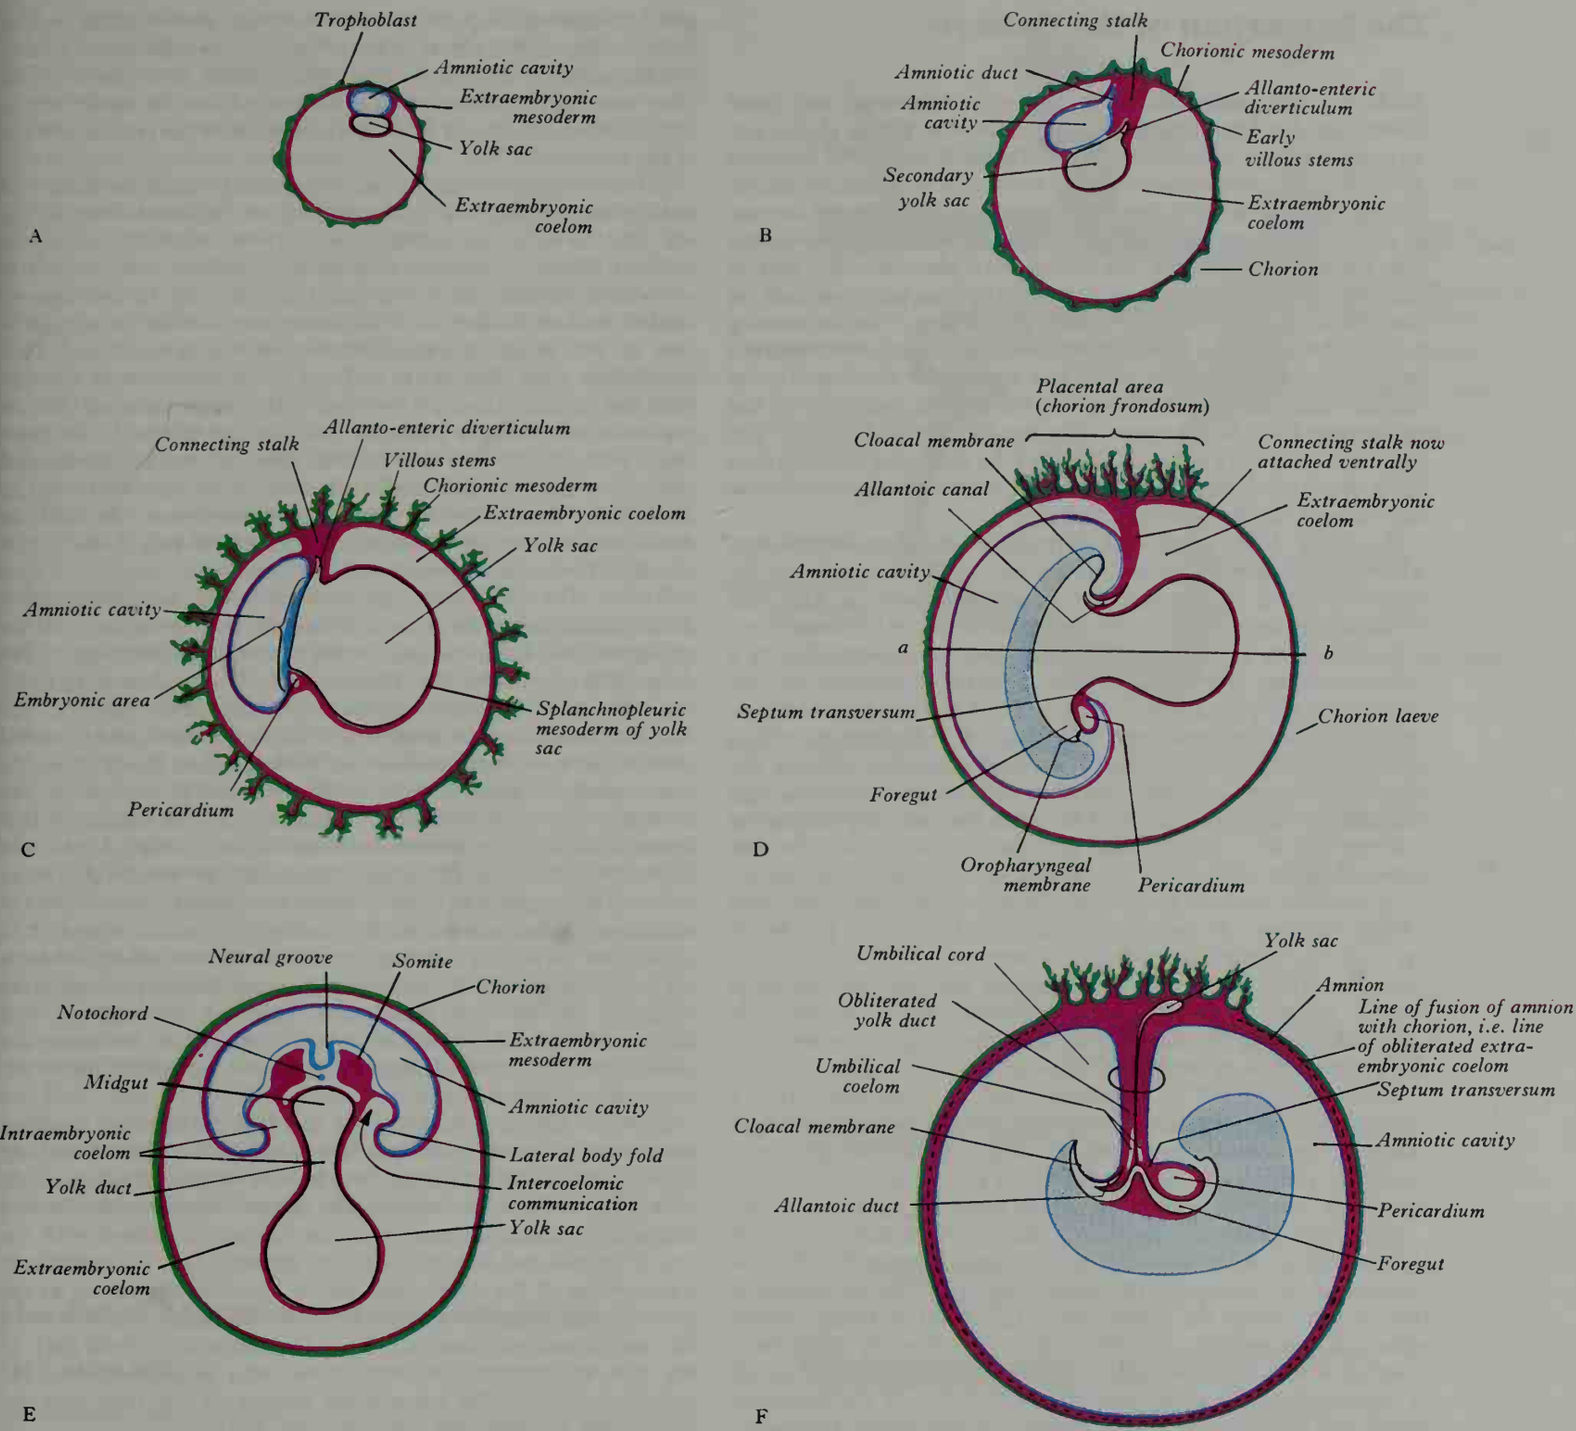
C The clefts have extended and become confluent with each other and with the pericardial cavity forming a coelomic duct on each side. In the caudal part of the area additional clefts have formed, coalesced and broken through into the pleuropericardial canals and into the extraembryonic coelom. Part of the coelomic duct will form the pleural coelom.

the gut as permanent dorsal and (often temporary) ventral mesenteries. It is quite evident that in these forms the metameric segmentation involves not only paraxial structures, but the intermediate mesoderm and both somatopleure and splanchnopleure (and the coelom itself).



THE SOMITE

A typical human *mesodermal somite* consists of tightly packed (epithelioid) cells and at first contains a transient central cavity termed the *myocoele* which is, however, soon obliterated by cells proliferated from its walls. The cells of the ventromedial part of the somite constitute the *sclerotome*. They become mesenchymatous and migrate medially to provide the tissue from which the axial skeleton is ultimately derived (p. 138). The cells of the dorsolateral part of the somite constitute the *dermomyotome*. Spindle-shaped cells proliferate from its margins to form a tightly packed cellular mass on its medial aspect, the *muscle plate* or *myotome* (p. 154). The remaining epithelially arranged cells constitute the *skin plate* or *dermatome* (**2**.29D). The myotome is the forerunner of much of the striated musculature of the body (p. 154), and after it has commenced differentiation, the cells of the dermatome lose their epithelioid character and become mesenchymatous. They spread to mix with the somatopleuric mesenchyme, and, probably with accessions from the neighbouring neural crest, lay down the foundation of the dermis (p. 155).



THE EARLY INTRAEMBRYONIC COELOM

In the intial stages of somite formation a midline cavity appears in the *cardiogenic mesoderm* and this cavity is the first indication of the *intraembryonic coelom*. As segmentation of the mesoderm proceeds, a number of clefts are also formed on each side in the lateral plate mesoderm. The clefts expand and gradually coalesce, and the lateral plate therefore becomes divided into a *somatic* and a *splanchnic* layer (**2**.29, 31). The somatic layer, with its covering of ectoderm, constitutes the *intraembryonic somatopleure*, whilst the splanchnic layer, with the underlying endoderm, constitutes the *intraembryonic splanchnopleure*.

The lateral extremities of the cavity in the cardiogenic mesoderm extend caudally and link up with the coalescing clefts in the lateral plate, and as a result the intraembryonic coelom is formed as an inverted U-shaped tube, from which the pericardial, pleural and peritoneal cavities are subsequently developed. Around the periphery of the embryonic area the somatopleuric and splanchnopleuric mesoderms are continuous, at first both with each other and with the similar extraembryonic layers, at the *junctional zone* mentioned previously. Soon,

2.32 Dorsal aspect of a model (by Eternod) of a human embryo, 1·3 mm in length. (After Graf Spec.) Compare with **2**.34.

2.33A–F A A diagram showing an early stage in development of the human blastocyst. B A diagram illustrating the early formation of the allanto-enteric diverticulum and the definition of the connecting stalk. C A later stage of the development. Observe that the heart occupies the most anterior part of the embryonic area and is separated from the prosencephalon by the oral membrane. D The formation of the head and tail folds, the expansion of the amnion, and the delimitation of the umbilicus. E A transverse section along the line *ab* in **2.33**D. Observe that the intraembryonic coelom communicates freely with the extraembryonic coelom. F A later stage in the development of the umbilical cord.

It should be noted that whilst these diagrams, from an earlier edition, are useful for the general changes in disposition of the embryo and extraembryonic membranes, the modern view of development of the villous stems has been revised—consult text and **2.39**.

however, the process of cavitation in the lateral plate extends beyond the embryonic area, and the continuity between these layers is broken, and the intraembryonic coelom is now thrown into free communication with the extraembryonic coelom (**2.29**C, 31C). This process, however, only occurs in the lateral regions; it does not affect the pericardial area or the regions immediately adjoining it on either side, where the median *primitive pericardial cavity* now opens into bilateral *pericardioperitoneal canals* (*coelomic ducts*) (**2.** 31C). Accordingly, the junctional mesoderm around the cranial border of the embryo which will form the *septum transversum* and *primitive ventral mesentery* of the foregut (p. 200) remains intact.

The early formation of the coelom and its free communication with the extraembryonic coelom allows the fluid which fills the latter to gain access to the interior of the embryo. It therefore may act as a path for the passage of nutrients during the period which still has to elapse before the establishment of a blood vascular circulation (Streeter 1942). The walls of the coelom are formed of undifferentiated mesodermal cells (*mesoblasts*) which rapidly proliferate. From the mesoblasts of the somatopleure, together with those derived from the dermatome and some neural crest, the corium and subcutaneous tissues are formed. Splanchnopleuric mesenchymal cells, on the other hand, later differentiate into the muscles, blood vessels, lymphatics and connective tissues of the walls of the heart and gastro-intestinal tract.

It is not until a later stage that the mesoblasts which line the coelom itself become differentiated into the mesothelia which characterize the various serous membranes (pp. 37, 116).

The Formation of the Embryo

Hitherto, the embryonic area, initially bilaminar and later trilaminar, has been essentially a *flattened* disc which changes to an oval, and then a piriform outline. Towards the end of the third week, however, the embryo begins to assume its definitive shape. The immediate cause of this alteration is the difference in the rate at which adjoining areas are growing. The rate at the periphery fails to keep pace with the rate within the embryonic area, and, as the embryo is increasing more rapidly in its long axis, especially at its cranial end where the walls of the neural groove are expanding to form the forebrain, both extremities tend to project beyond the limits of the area (**2**.33). In this way a *head fold* is developed at the cranial extremity and a *tail fold* at the caudal extremity of the embryonic area. At the same time, and for similar reasons, right and left *lateral body folds* develop, and the extension of these four folds (**2**.33) gradually constricts off the embryo from the yolk sac and imparts its characteristic shape.

Resulting from head fold formation, the prosencephalon, which was hitherto separated from the cranial extremity of the embryonic area by the oropharyngeal membrane (p. 111) and pericardium, comes to lie at the extreme cranial tip of the embryo. This alteration in position of the forebrain is accompanied by a corresponding alteration in the relative positions of the membrane and pericardium (**2**.33 C–F). The former now lies on the *ventral surface* and forms the floor of a depression, which constitutes the primitive mouth or *stomatodeum*. Cranially the stomatodeum is bounded by the projecting forebrain, and caudally by the pericardium. The latter has not only altered its position relative to the cephalic extremity of the embryo but has also undergone a reversal of its surfaces, as will be examined below.

In addition to these positional alterations and reversals, head folding results in the inclusion within the embryo of a portion of the yolk sac termed the *foregut* (*proenteron*). The latter is now placed with the oropharyngeal membrane and pericardium on its ventral aspect, and with the hindbrain placed dorsally. It communicates at its caudal end with the *midgut* (*mesenteron*) through an opening termed the *anterior intestinal portal*.

The ventral bend of the head fold is associated with a correspondingly pronounced *midbrain flexure* which is concave ventrally and which underlies a projecting dorsal convexity (*midbrain prominence*) of the overlying ectoderm, seen to best advantage when the embryo is viewed from the side (e.g. **2**.59).

Before tail fold formation, the caudal end of the embryonic area is anchored to the trophoblast by the connecting stalk, which is covered on one aspect by the amnion (**2**.33C). The formation of the tail fold carries the connecting stalk round on to the ventral aspect of the embryo, so that it now assumes the permanent position of the umbilical cord. It will be remembered that the stalk is connected to the embryo at the caudal end of the primitive streak (but separated from it by the cloacal membrane, *vide infra*) and, in consequence the primitive streak also extends round towards the ventral aspect of the embryo to the region which later lies immediately behind the anal orifice. Some, however, hold the view that the primitive streak is continued into the rudimentary tail and does not appear in the perineum or on the ventral surface of the embryo.

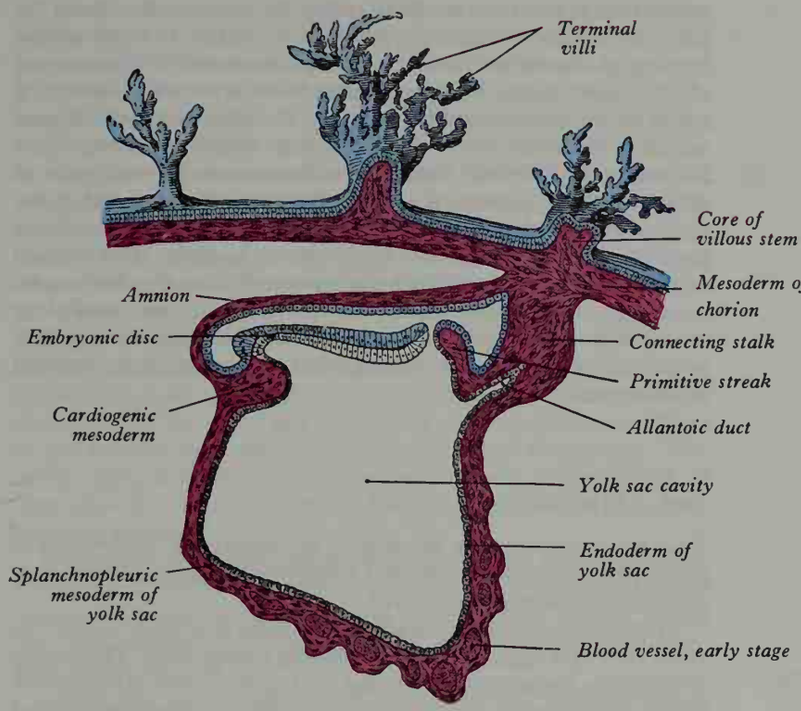
Just as a recess of the yolk sac is included within the head fold to form the foregut, so a corresponding part is included within the tail fold to form the *hindgut* (*metenteron*). But the similarity between these two included recesses goes further. A portion of the endoderm (earlier, the prechordal plate, p. 110) in the floor or ventral wall of the foregut is in direct contact with the ectoderm over an area which is termed the *oropharyngeal membrane*. This membrane soon disappears and the communication of the gut with the exterior through the mouth is thus established. In the region of the hindgut a similar relationship exists. As we have seen, even before the tail fold is defined, the ectoderm and endoderm are in contact with each other at the caudal end of the embryonic area, forming the *cloacal membrane*. As will be described later, this membrane subsequently breaks down in two places to form the *urogenital* and *anal orifices*.

Before the formation of the tail fold an endodermal diverticulum arises from the dorsocaudal portion of the yolk sac and grows into the mesoderm of the connecting stalk (**2**.33). This outgrowth constitutes the *allanto-enteric diverticulum* (**2**.35B). As the tail fold becomes defined the proximal part of the diverticulum becomes incorporated in the hindgut, and its distal portion persists as the *endodermal allantoic duct* (p. 123), which then communicates directly with the ventral surface of the hindgut. The region of the hindgut which lies caudal to this communication forms the *endodermal cloaca* (p. 202). As tail fold formation continues, the cloacal membrane progressively comes to lie in the ventral wall of the hindgut but it extends also on to the adjoining dorsal aspect of the connecting stalk, where it is associated with the allantoic portion of the allanto-enteric diverticulum (**2**.35C). Even before the latter is incorporated in the hindgut, the cloacal membrane becomes interrupted and shortened by the interposition of mesoderm between the endoderm of the diverticulum and the covering epithelium of the body stalk (Florian 1930).

Between the head fold and the tail fold the embryo becomes constricted off by right and left *lateral body folds*. The intervening dorsal portion of the yolk sac, which these folds gradually include within the embryo, constitutes the *midgut* (mesenteron). At first the midgut communicates freely on its ventral surface with the rest of the yolk sac, but the continued growth of the folds results in a narrowing of the connexion, which becomes drawn out as the *splanchnopleuric yolk stalk* (vitello-intestinal duct) which contains the *endodermal yolk duct* (**2**.33E,F). The remainder (distal part) of the yolk sac remains extraembryonic and is often termed the *umbilical vesicle*. The subsequent history of the duct and the vesicle will be dealt with later (pp. 122, 205).

THE NUTRITION OF THE EMBRYO

In the early stages of development the blastomeres derive their nourishment in part from the store laid up within the cell body of the primary oöcyte. Such stores are possibly maintained at a high concentration and are subsequently liberated in a more dilute form, for absorption, from the cavity of the blastocyst, and later the primary and secondary yolk sac cavities (p. 109). In addition, it is also assumed that the blastocyst derives nourishment from tubal and uterine secretions, and later, during the process of embedding, from products stemming from the lysed uterine tissues. There follows a period of about two weeks during which the embryonic disc is dependent on the nutriment it can obtain from the fluids which fill the cavities of the amnion, the coelom and the yolk sac. These fluids probably contain material absorbed by the trophoblast from the uterine tissues and the maternal blood, modified, perhaps, as they pass through the cellular walls of these various cavities. However, at an early stage in development these sources of supply are cut off. The lumen of the neural tube is isolated by the closure of the neuropores, the extraembryonic coelom becomes greatly reduced (**2**.33D, F) and is later shut off from the intraembryonic coelom, and the obliteration of the yolk duct separates the yolk sac from the gut. It therefore becomes imperative that some other source should be rendered available at an early stage. This involves the maternal circulation coming into close, although indirect, apposition with the developing embryonic circulation.



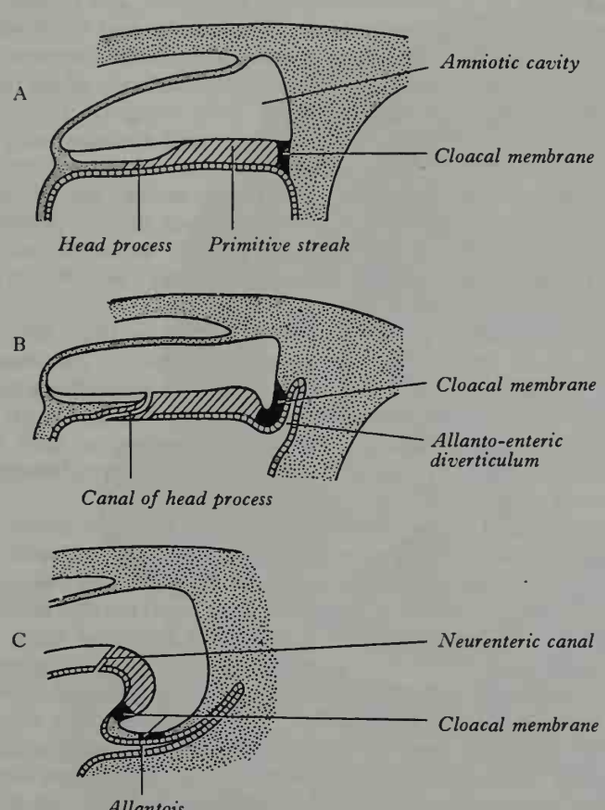
The differentiating mesenchyme in which the embryonic vessels and erythrocytes develop is termed *angioblastic tissue*, and it is probably first formed from the deepest layer of mesenchyme which clothes the endoderm of the yolk sac early in the third week (p. 109).

Slightly later, angioblastic tissue can also be recognized in the connecting stalk and in the mesenchyme of the chorion, and it

then appears also within the embryonic area. Tissue spaces form in the angioblastic tissue and the cells which line them differentiate into typical, flattened endothelial cells whilst adjoining spaces join to form capillary plexuses. While the yolk sac spaces are forming, small, localized groups of mesodermal cells project into them, soon to become cut off to form *blood islets*, the cells soon differentiating into embryonic erythrocytes (p. 180).

The vessels formed in the chorion soon establish an intimate relationship with the maternal circulation (p. 124). Vessels develop in the embryo as two longitudinal channels, which, at their headward ends, project into the dorsal wall of the pericardium. They are the rudimentary right and left dorsal aortae, and at their cranial ends, after curving ventrally in the lateral wall of the pharynx to reach the cranial end of the pericardium, they fuse, becoming continuous with the developing primitive tubular heart. At the caudal end of the embryo they traverse the connecting stalk as the rudimentary umbilical arteries and break up into capillaries in the chorion. The venules from the chorion converge on the stalk where they form the right and left umbilical veins, which run headwards in the somatopleure, close to the margin of the embryonic area, to reach the caudal end of the heart.

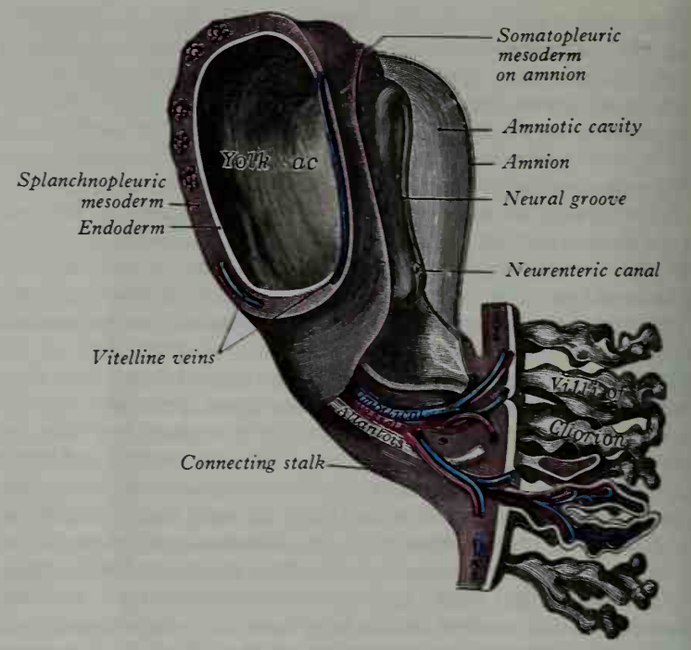
The pericardial cavity never communicates directly with the extraembryonic coelom, and at its cranial limit the somatopleure and splanchnopleure are continuous (**2**.76A). With the formation of the head fold the surfaces of the pericardium are reversed, and the original cranial aspect comes into intimate relation with the *ventral* wall of the foregut at the cranial border of the anterior intestinal portal (**2**.33C). As the caudal wall of the pericardium deepens dorso-ventrally, the mesenchyme between it, the gut and proximal yolk stalk forms a sheet, which is the *septum transversum*. Prior to reversal this mesoderm formed a U-shaped mass intervening between the pericardium and the extraembryonic coelom (p. 118). The septum transversum later plays an important part in the development of the diaphragm. At this stage it is bounded on its headward surface by the pericardium and on its caudal surface by the foregut; on its dorsal surface it is limited by the coelomic ducts, which connect the pericardium with the peritoneal cavity and on its lateral surface by the opening of the peritoneal cavity into the extraembryonic coelom. The umbilical and body wall veins, which run in the somatopleure, and the vitelline veins, which run in the splanchnopleure, meet one another in the junctional mesoderm of the septum transversum and so gain the venous end of the heart. Through these various channels the early embryonic circulation is established.



2.34 A sagittal section through the embryo which is represented in **2**.32. The cloacal membrane is not shown. (After Graf Spee.) Note that the concept of the chorionic villi as free-ending outgrowths from the chorion, as implied in this historic model, has since been discarded—*see* text for details.

The Fetal Membranes and Placenta

THE ALLANTOIS



The allanto-enteric diverticulum (**2**.33B, 34, 35) arises early in the third week as a solid, endodermal outgrowth from the dorsocaudal part of the yolk sac and grows into the mesoderm of the connecting stalk. It soon becomes canalized and, when the hindgut is developed, the proximal (enteric) part of the diverticulum is incorporated in its ventral wall and the distal (allantoic) portion remains as the allantoic duct and is carried ventrally to open into the ventral aspect of the cloaca or terminal part of the hindgut (**2**.33, 35). The diverticulum is lined with endoderm and is surrounded by the mesoderm of the connecting stalk, in which the umbilical vessels develop at a slightly later stage.

In reptiles, birds and many mammals the allantoic diverticulum develops into a vesicle which continues expanding into the extraembryonic coelom and forms a vascular organ to which the term *allantois* should perhaps be restricted. In the bird it projects to the right side of the embryo, and gradually spreads over the dorsal surface of the embryo as a flattened sac between the amnion and the chorion (serosa), and ultimately also spreads to surround the yolk sac. Its outer wall becomes applied to, and fuses with, the chorion (forming an *allantochorion*) which lies immediately inside the shell membrane. Blood is carried to the allantoic sac by the two *allantoic* (or *umbilical*) *arteries*, which are continuous with the primitive aortae and, after circulating through the allantoic

2.35A–C Three stages in the development of the cloacal membrane. (Florian 1930.) A Prior to the formation of the tail fold and the allanto-enteric diverticulum. B The tail fold is indicated and the allanto-enteric diverticulum has formed. The cloacal membrane now extends in relation with the enteric part of the diverticulum on to the dorsal aspect of the body stalk. C The tail fold is clearly defined. Mesoderm has become interposed between the ectoderm and endoderm over the proximal part of the allanto-enteric diverticulum and the cloacal membrane is thus broken up into two parts, of which only the proximal one persists. The mesoderm is shown stippled.

capillaries, is returned to the heart by the two *umbilical veins*. In this way the chorio-allantoic circulation, which is of the utmost importance in connexion with the respiration and nutrition of the chick, is established. Oxygen is taken from, and carbon dioxide is given up to the atmosphere through the porous egg-shell, and nutritive materials are at the same time absorbed by the blood from the yolk. With the formation of the amnion the embryo is, in most mammals, separated entirely from the chorion, and is not united to the chorion again until the allantoic mesenchyme spreads to become applied to its inner surface. The human embryo, however, is never wholly separated from the chorion, its caudal end being from the first connected with the chorion by means of a thick band of mesoderm named the *connecting stalk*, which accordingly may be regarded as precociously formed *allantoic mesoderm*.

2.36 A human embryo, 1·3 mm long. (From a model by Eternod.) The left wall of the yolk sac and most of the amnion have been removed, and some of the primary mesoderm of the connecting stalk has been cut away to show the allantois and the umbilical vessels. A portion of the chorion and some of the villi related to the decidua basalis are shown. (No true villous stems or cytotrophoblastic shell were shown in this early model.) The embryonic area is seen from the dorsal and left lateral aspects. Compare with **2.32**, which presents another view of the same model.

THE AMNION

This is a membranous sac which surrounds the embryo; it is developed in reptiles, birds and mammals (*Amniota*), but not in amphibia or fishes (*Anamniota*).

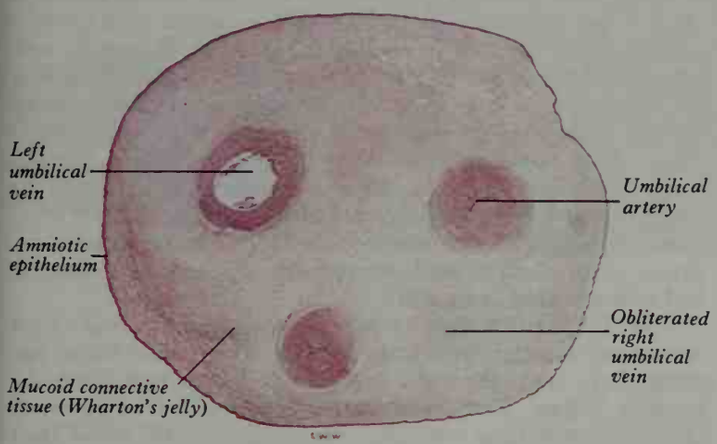
In the human embryo the amnion appears as a cavity within the inner cell mass adjacent to the overlying trophoblast. This cavity is roofed by a stratum of epithelial cells, and its floor is formed by the cells of the embryonic germ disc—continuity between the roof and floor being at the margin of the disc. (For details of the *epiblastic* origin of the roof cells *see* p. 109.) In the first half of pregnancy the epithelial cells are flattened and contain abundant glycogen; in later stages they become cuboidal or columnar over the placenta, the glycogen diminishes in amount and lipid globules appear in the cytoplasm (Goto 1959). Ultrastructurally, two types of amniotic epithelial cell have been described (Thomas 1965)—the 'Golgi type' and the 'fibrillar type'. The former is characterized by a pronounced Golgi apparatus, and a considerable content of rough endoplasmic reticulum and membrane-bound vesicles; the fibrillar cytoplasm of the latter contains few organelles. Possibly they are physiological variants of the same cell. Their free surfaces are beset with irregular microvilli embedded in a surface coat, whilst their deep surfaces rest on a basement membrane. The intracellular clefts present scattered desmosomes, but elsewhere the clefts widen and contain interlacing microvilli between which complex tubules penetrate the cell cytoplasm. These features suggest an active role in selective transport across the membrane (Lister 1968; Wynn and French 1968).

Externally the amnion is covered with a thin layer of somatopleuric extraembryonic mesoderm, which is continuous, at the margins of the disc, both with the splanchnopleuric extraembryonic mesoderm covering the yolk sac and with the intraembryonic mesoderm. Through the connecting stalk it is continuous also with the extraembryonic mesoderm lining the chorion (**2.33**).

Fluid, termed *liquor amnii*, occupies the amniotic cavity and increases steadily in volume, so that the sac gradually expands and encroaches on the extraembryonic coelom (**2.33**); this continues until the coelom is obliterated, except for a small portion which is included within the proximal part of the umbilical cord (the *umbilical coelom*). The liquor amnii increases in quantity up to the sixth or seventh month of pregnancy, and then diminishes somewhat; at the end of pregnancy it is usually about a litre. It provides a buoyant medium which supports the delicate tissues of the young embryo and allows free movement of the fetus during the later stages of pregnancy. It also diminishes the risk to the fetus of injury from without. It contains less than 2 per cent of solids, consisting of urea, inorganic salts, a small amount of protein, and frequently a trace of sugar.

The source of the amniotic liquid, whether fetal, maternal or both, is not finally settled. Its volume is regulated by a multiplicity of factors, both fetal and maternal, but it is suggested that normally it is predominantly fetal in origin in the normal (Davies 1960). In the early stages it resembles blood plasma in composition and is probably formed largely by transport across the amniotic membrane, but as pregnancy advances, it becomes progressively more dilute, presumably by the addition of fetal urine. It has been shown experimentally that there is a considerable and rapid flux of water across the amniotic membrane. There is rapid exchange between the amniotic fluid and maternal and fetal circulations, probably by way of the placenta and fetal kidneys. By the end of the third month the expanding amnion has extensive contact with the chorion and only these thin membranes separate the amniotic fluid from the decidua parietalis, the vessels in which may provide another route for the exchange of water and dissolved substances (Plentl 1958). A volume of amniotic fluid in excess of two litres is generally considered to be abnormal and constitutes *hydramnios*. A deficiency is termed *oligamnios*. Both conditions may be associated with fetal abnormalities. For example, fetuses with agenesis of the kidneys or atresia of the lower urinary tract are often associated with oligamnios.

It has been suggested that fetal swallowing of amniotic fluid is a normal occurrence, and also that respiratory movements may possibly aspirate some fluid into the fetal lungs. In either case the fluid may be absorbed into the fetal circulation and then pass the placental barrier into the maternal circulation. Cases of oesophageal atresia, or anencephaly, in which swallowing is impossible, or impaired, are often associated with hydramnios.



THE CONNECTING STALK AND UMBILICAL CORD

The connecting stalk (**2.33**) is, as we have seen, a mass of precociously formed allantoic mesoderm, which at first connects the caudal end of the embryonic area with the chorion. Proximally it surrounds the short allanto-enteric diverticulum but it is traversed throughout its length by the umbilical (allantoic) vessels. At first its dorsal surface is covered with the amnion and its ventral surface is bounded by the extraembryonic coelom. As a result of the folding of the embryo and distension of the amnion, the connecting stalk comes to lie on the ventral surface of the embryo, and its mesoderm approaches that of the yolk sac and its stalk. With continued expansion of the amnion, the extraembryonic coelom is largely obliterated (**2.33**), and its only remaining part surrounds the elongating yolk stalk, and this part still communicates freely with the intraembryonic coelom. The

mesoderm-covered surfaces of the head, tail and lateral body folds of the amnion now converge on the connecting stalk and yolk stalk (and their vessels), and the umbilical cord is formed as they meet one another (**2**.33) thus closing off the intraembryonic coelom.

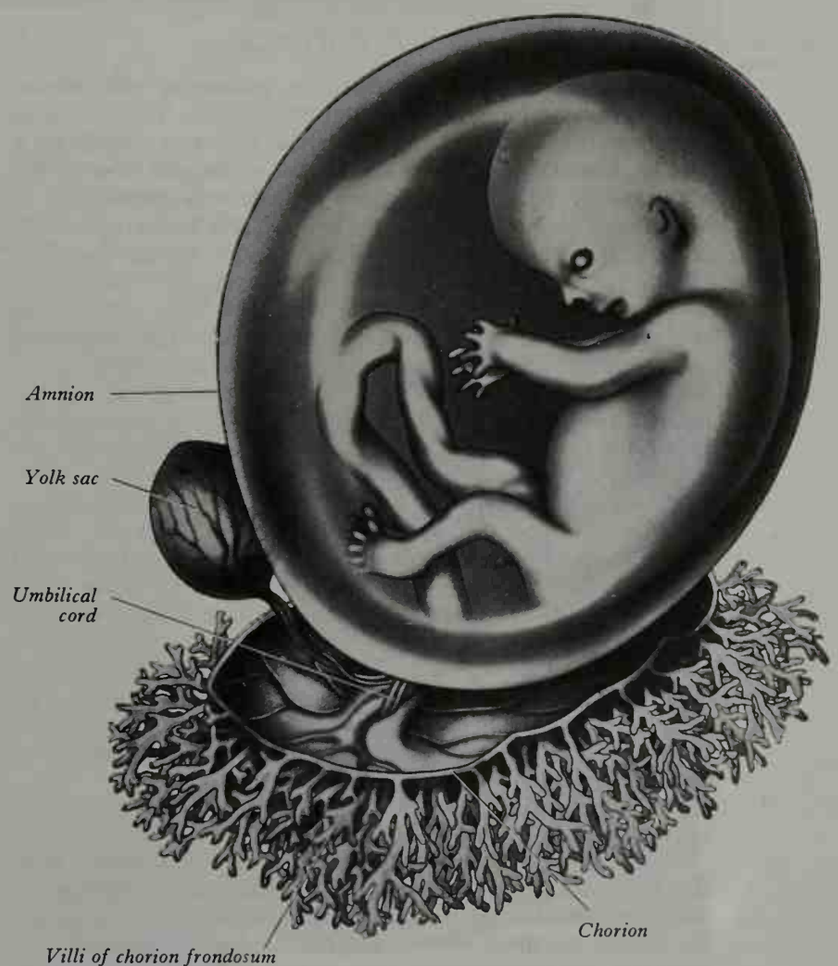
The umbilical cord (**2**.37) thus consists of an outer covering of flattened amniotic epithelial cells, containing in its interior a mass of mesoderm of diverse origins (*vide infra*). Embedded in the latter are two endodermal tubes—the yolk and allantoic ducts—their associated vitelline and allantoic (umbilical) blood vessels, and near its fetal end, the remains of the extraembryonic coelom mentioned above.

The *mesodermal core* is derived from the somatopleuric extraembryonic mesoderm covering the amniotic folds, the splanchnopleuric extraembryonic mesoderm of the yolk stalk which carries the vitelline vessels and clothes the endodermal yolk duct, and similar allantoic mesoderm of the connecting stalk which clothes the allantoic duct and carries initially two umbilical arteries and two umbilical veins. These various mesoderms fuse and are gradually transformed into the viscid, mucoid connective tissue (*Wharton's jelly*) which characterizes the more mature cord. The tissue consists of widely spaced fibroblasts separated by an extensive intercellular space filled with a copious matrix consisting of a delicate three-dimensional meshwork of fine

2.37 Transverse section through a human umbilical cord. Stained with haematoxylin and eosin. Magnification × *c*. 8.

collagen fibres surrounded by a dilute ground substance containing a variety of hydrated mucopolysaccharides. In specimens which have been excised *before* fixation and staining, the fibroblasts present stellate profiles, as they do in other areas of mucoid tissue when similarly prepared. However, it has been shown that if the tissue is fixed *before* any haemodynamic collapse and consequent modification of the jelly has occurred, the cells are long and strap-like and present a regular orientation (Parry 1970).

The part of the extraembryonic coelom (the *umbilical coelom*) included in the base of the umbilical cord acts as a sac which receives the normal *umbilical hernia* of the midgut, developing in the embryo between the sixth and tenth weeks (p. 200). After the disappearance of this hernia the extraembryonic coelomic sac is normally obliterated.



The yolk sac becomes caught between the amnion and chorion as they fuse near the placental attachment of the cord (**2**.33, 38, 46)—it continues to grow slowly and is sometimes found at term in this site, as a small vesicle usually less than 5 mm in diameter. The yolk stalk and its contained endodermal duct and accompanying vessels gradually elongate with growth in length of the umbilical cord. The duct and vessels slowly degenerate and they have usually disappeared by mid-pregnancy.

The endodermal allantoic duct which is confined to the proximal end of the growing cord, also elongates and thins, but may persist as an interrupted series of epithelial strands until term. At the umbilicus the proximal strand is often continuous with the median intra-abdominal *urachus*, which in turn continues into the apex of the bladder (p. 218).

Usually, the embryonic right umbilical vein disappears in the early months of pregnancy (and exceptionally only one artery may be present). The vessels of the umbilical cord are rarely straight but usually show a twisted conformation which may exist as either a right- or left-handed cylindrical helix. The number of turns involved may be relatively few or, at the other extreme, may even exceed 300. Their causation has been variously ascribed to unequal growth of the vessels, or to torsional forces imposed by fetal movements; their functional significance is obscure; perhaps their pulsations and contractions (*vide infra*) assist the venous return to the fetus in the umbilical vein. When fully developed the umbilical vessels, particularly the arteries, are provided with a strong muscular coat which contracts readily in response to mechanical stimuli. The outermost muscle bundles pursue an interlacing spiral course so that, when they contract, they produce shortening of the vessel and thickening of the media, with folding of the interna and considerable narrowing of the lumen. This action may account for the periodic sharp constrictions of contour—the so-called *valves of Hoboken* which often characterize these vessels.

When fully developed, the umbilical cord is on average some 50 cm long and 1–2 cm in diameter, but the length is subject to great variation (20–120 cm). Obstetrical complications during labour may be imposed by the possession of an exceptionally short or long umbilical cord.

Cords may also exhibit *knots* which may be 'true' or 'false'. True knots presumably follow some exceptional form of fetal movement *in utero*, and may embarrass the circulatory flow in the umbilical vessels. False knots are sharp variations in contour which may accompany an abnormally pronounced looping of one of the umbilical vessels, or it may correspond to a local accumulation of a mass of Wharton's jelly.

2.38 A fetus of about eight weeks, enclosed in the amnion, magnified about 2½ diameters. A part of the chorion frondosum with its branching villous stems is shown in the lower part of the figure. The villous stems have been detached from the basal plate, which is not shown here.

For variations in the placental attachment of the cord, *see* p. 136, and for further details of its morphology and an extensive review of the relevant literature, *see* Boyd and Hamilton (1970).

IMPLANTATION

As already stated (p. 103), fertilization occurs in the lateral or ampullary part of the uterine tube, and is immediately followed by cleavage. The segmenting zygote is conveyed along the uterine tube to the cavity of the uterus by the action of the cilia of the epithelial lining of the tube aided by muscular tubal contractions, the journey occupying about three days. On reaching the uterine lumen the morula becomes a blastocyst but is still surrounded by the zona pellucida. The disappearance of the zona and the formation of polar syncytial trophoblast over the region of the formative mass are necessary before implantation of the ovum in the uterine mucosa can occur (*see* pp. 103, 105 for details). In the interval between ovulation and the arrival of the blastocyst in the uterine cavity, changes also occur in the uterine mucosa which prepare it for implantation. These progestational changes will be detailed later (p. 128), but when they have occurred, the syncytial trophoblast adheres to the uterine mucous membrane, destroys the epithelium over the area of contact, and excavates a cavity in the mucous membrane in which the blastocyst becomes embedded. In a conceptus described by Bryce and Teacher (1908) the point of entrance was visible as a small gap closed by a mass of fibrin and leucocytes; in another described by Peters (1899) the opening was covered with a mushroom-shaped mass of fibrin and blood clot, the narrow stalk of which plugged the aperture in the mucous membrane. It is believed that this *operculum* represents a portion of the syncytial trophoblast cut off by the decidua capsularis (Böving 1963).

THE TROPHOBLAST AND CHORION

The structure actively concerned in excavating the uterine mucous membrane is the syncytial trophoblast. This increases rapidly in thickness over the embryonic pole and then forms a progressively thinner layer over the rest of the wall towards the abembryonic pole, as the blastocyst becomes embedded. It invades and digests the uterine tissues, and attacks the walls of the uterine (maternal) blood vessels (*see* **2**.23; p. 107, and consult Böving 1959, 1963). Lacunar spaces develop in the trophoblastic envelope and establish communications with each other. At an early period many of them contain maternal blood (**2**.23) derived from the dilated uterine capillaries and veins, the walls of which have been partially destroyed. As the conceptus grows and the lacunar spaces enlarge, becoming more confluent to form an early blood-filled *intervillous space*, their trophoblastic walls are converted at first into an *irregular* spongework, or *labyrinth*. With further growth, however, the main strands of trophoblastic syncytium assume a *radial* arrangement. Thus, from quite early stages, the intervillous space is *completely spanned* by these radial strands which undergo an orderly sequence of three main histological changes (*vide infra*). Such strands extend from the syncytial layer of the chorion (on the embryonic aspect of which is a layer of cytotrophoblast, lined by vascularized fetal mesoderm), across the intervillous space, to the layer of (peripheral) syncytium which is in close apposition to the excavated maternal tissues. Through spaces in the latter, extravasated maternal blood continues to enter the intervillous space.

The central core of each syncytial strand is now invaded sequentially by:

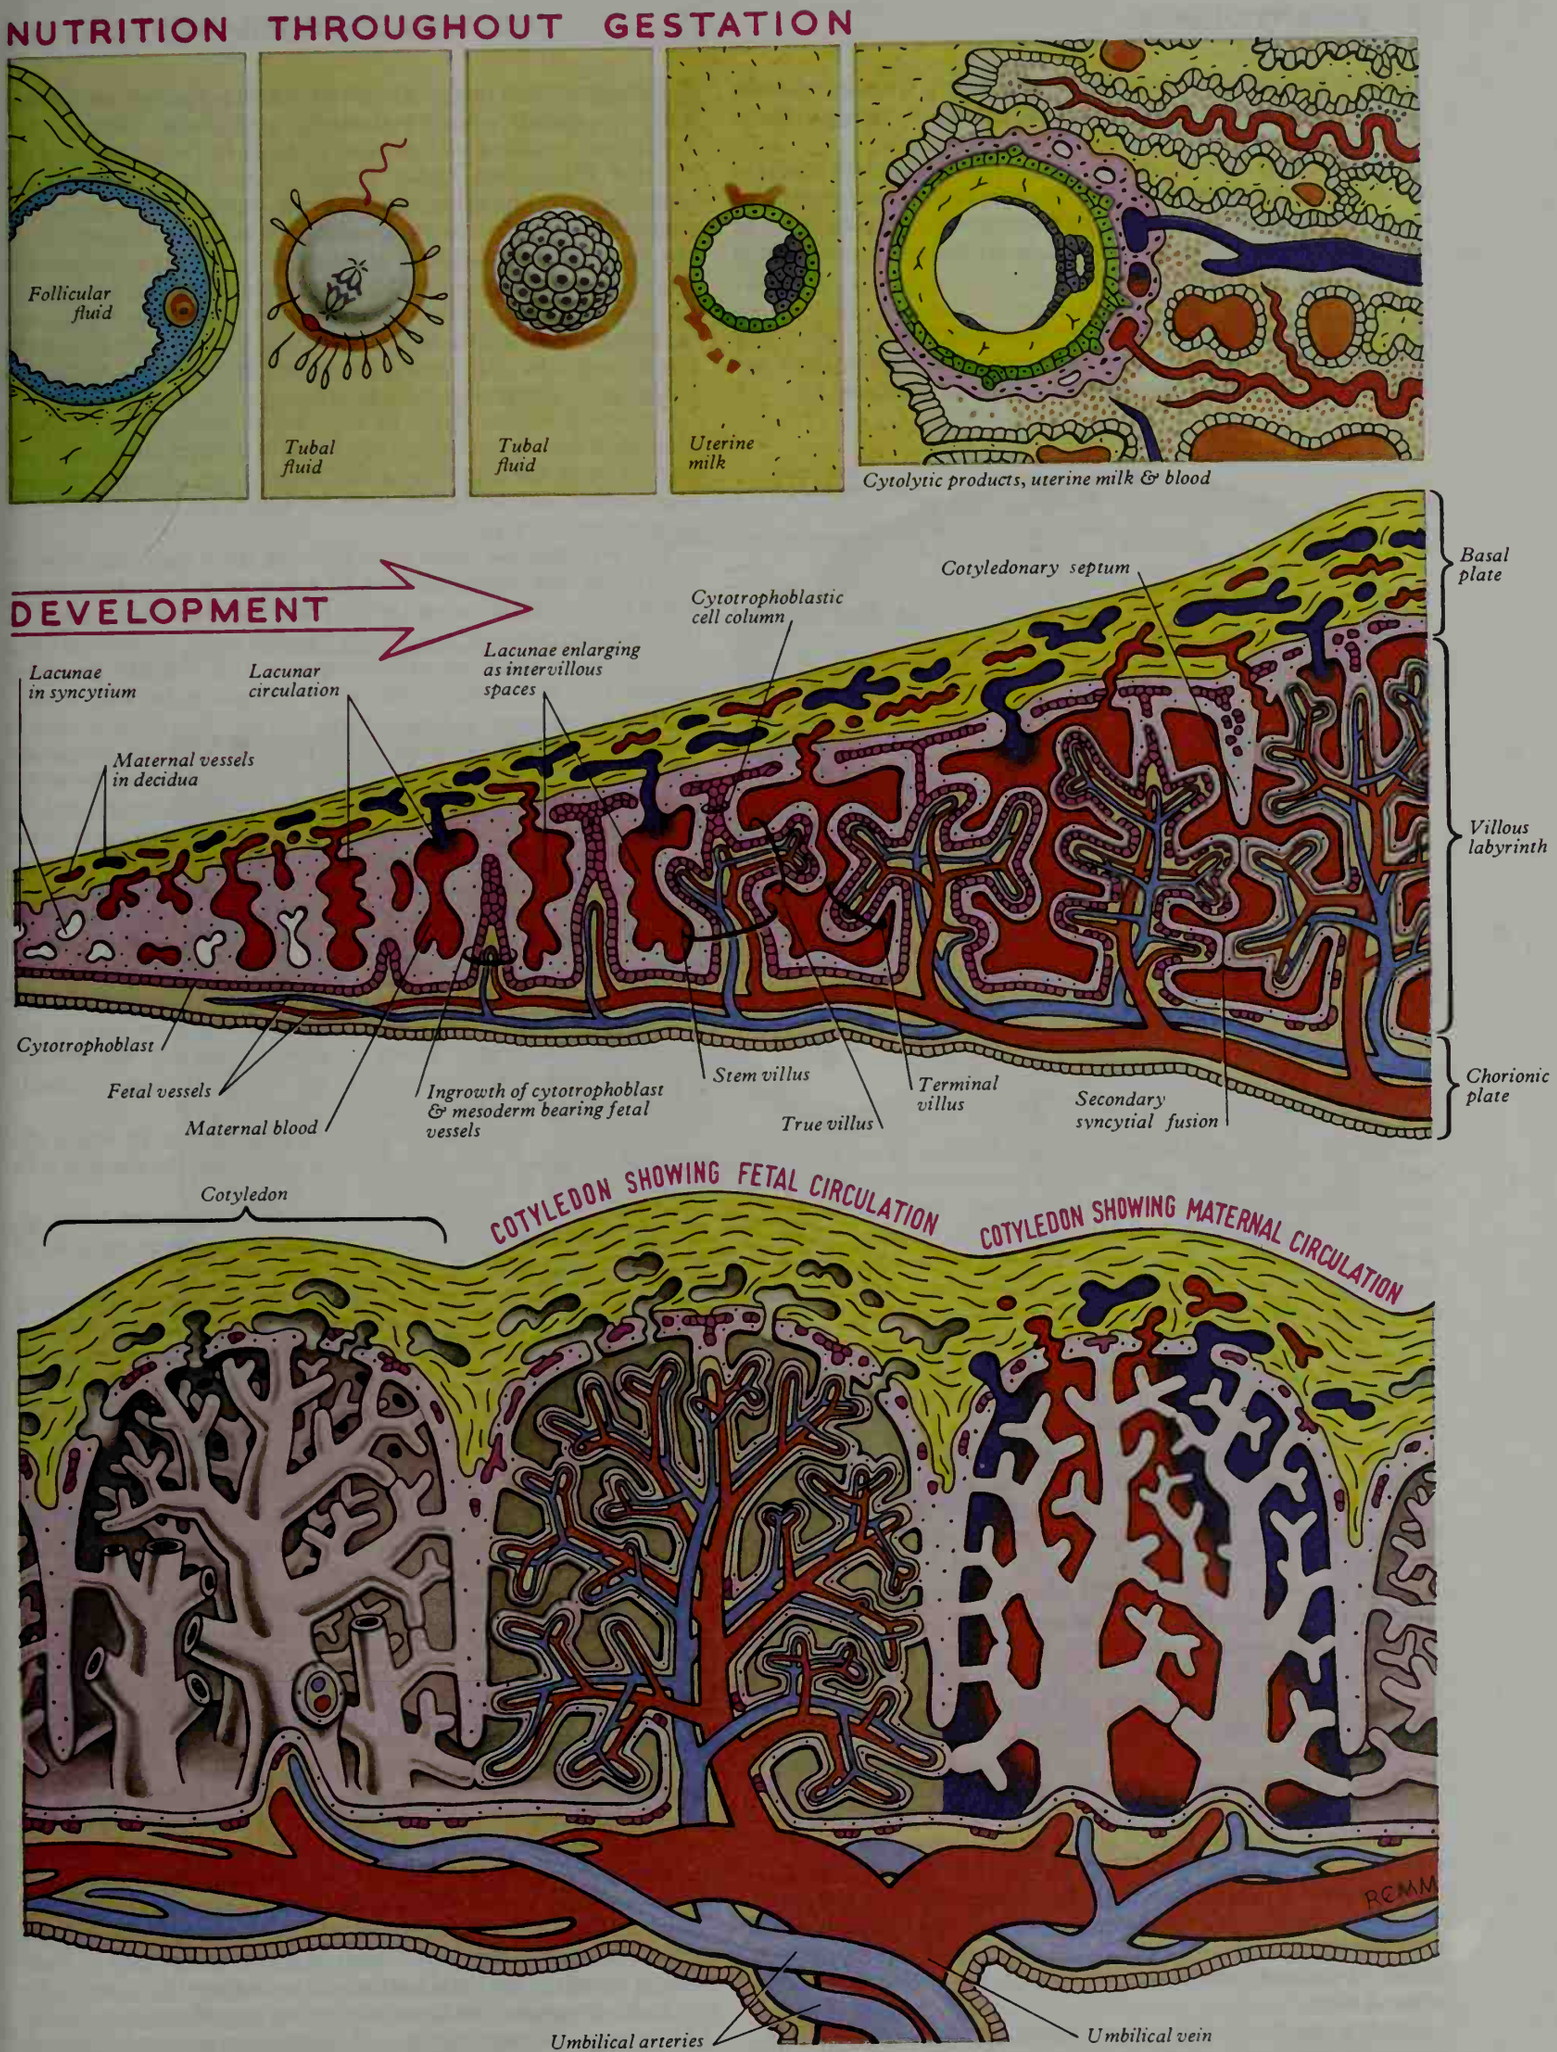
(1) A growing *column* of proliferating cells which extends from the chorionic cytotrophoblast and grows throughout the length of the strand until it reaches the syncytium on the maternal aspect of the intervillous space, *within which* it 'mushrooms' tangentially to meet and fuse with neighbouring outgrowths to form a spherical *cytotrophoblastic shell* around the conceptus (**2**.39).

(2) Each *cytotrophoblastic cell column* now develops, centrally, and throughout much of its length, a *core* of extraembryonic mesoderm. This never completely reaches the trophoblastic shell, and it is uncertain how much of this mesoderm is derived by *inflexion* and *invasion* from the chorionic mesoderm, or whether it arises by differentiation of the central cytotrophoblastic cells.

(3) Capillaries now differentiate within the mesodermal core (**2**.39) and soon establish connexions with the radicles of the umbilical vessels in the general mesoderm of the chorion.

The radial trabeculae undergoing these transformations are termed the *villous stems* and they, and their subsequent side branches, may be regarded as passing through the three grades of *histological differentiation* (primary, secondary and tertiary) just described (**2**.39). The term 'villous stem' is used here in preference to the traditional primary, secondary and tertiary chorionic *villi* because it is evident that, at this stage, there are no true villi (i.e. finger-like projections with a free tip which grow across the intervillous space to reach the maternal tissues).

Each villous stem now consists, from its chorionic base and throughout much of its extent, of a vascularized mesodermal core, covered by a single (*Langhans'*) layer of cytotrophoblast, which is again ensheathed by a layer of syncytium. Near the maternal end, however, it contains no mesodermal core but is formed of a solid *cytotrophoblastic cell column* which is continuous peripherally with the trophoblastic shell, and is surrounded by a layer of syncytium.



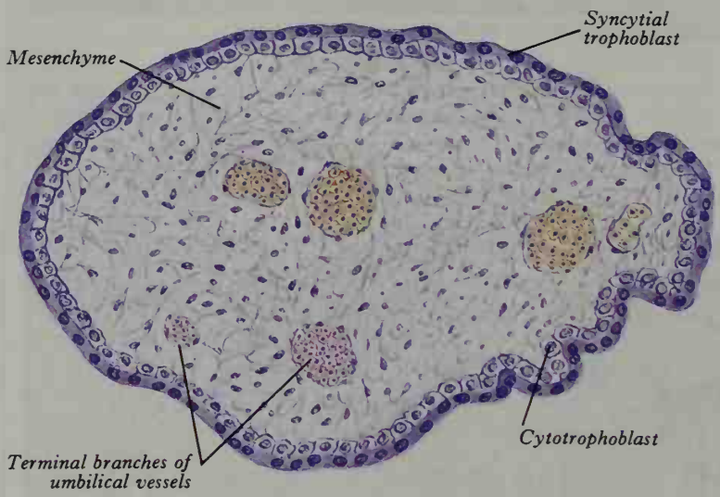
With continued development two major changes now ensue (**2**.39); firstly, increasing complexity and subdivision of the maternal ends of the villous stems and, secondly, the development of free side branches. Expansion of the whole conceptus is accompanied by *radial growth* of the villous stems and, simultaneously, an integrated *tangential growth* with expansion of the trophoblastic shell. As these changes occur, the attached maternal extremity of each villous stem undergoes a series of longitudinal divisions. Eventually each stem forms a complex consisting of a single *trunk* (*truncus*) attached by its base to the chorion, and from which arise distally, second and third order branches (which have been named *rami* and *ramuli* respectively—Stieve 1926). Each of the latter remains attached at its maternal end to the trophoblastic shell.

Now, for the first time, *'true' villi* with free tips make their appearance as outgrowths from the sides of the villous stems, and particularly from the rami and ramuli rather than from the truncus. These have been variously termed *free*, *terminal*, *absorption* or *fringing* villi, and it is predominantly across their walls that exchanges between the fetal and maternal circulations occur. Each terminal villus commences as a syncytial outgrowth which, as it continues to grow, is again invaded successively by cytotrophoblastic cells which then develop a core of fetal mesoderm; this is finally vascularized by fetal capillaries (i.e. each villus passes through primary, secondary and tertiary grades of histological differentiation). The terminal villi continue to form and branch, within the confines of the definitive placenta (*vide infra*) throughout gestation, projecting in all directions into the intervillous space, many of them making contact with those growing from adjacent villous stems. When this occurs some form of secondary adhesion or fusion may occur between their tips. Some earlier workers suggested that this may proceed to mesodermal or even vascular fusion between adjacent villi, but a recent survey of the available evidence strongly suggests that this does not occur to any appreciable extent and that any connexion between villi is limited to fibrinoid adhesion between their surfaces, or at most, fusion between their syncytial tips. As these changes proceed, the intervillous space, at first spanned by the early villous stems and their branches, and then increasingly permeated by growing free villi, is finally once again transformed into an exceedingly complex *labyrinth* of fine intercommunicating maternal vascular spaces.

The intervillous space, which contains the circulating maternal blood and is everywhere lined by syncytial trophoblast, is thus bounded:

(1) On its *fetal aspect* by a *chorionic plate*, consisting of syncytial, cytotrophoblastic and mesodermal layers of the chorion, the latter carrying the radicles of the umbilical vessels, and which is soon fused with the mesoderm of the expanding amnion.

(2) On its *maternal aspect* by a *basal plate* consisting of the peripheral syncytium that has been divided by the growth of the cytotrophoblastic shell into an inner layer enclosing the



2.39 Nutrition of oöcyte, zygote, morula, free and embedded blastocyst, embryo and fetus, throughout gestation. Blastocystic and placental development proceed from left to right. Aspects of mature placental structure and circulation are shown below.

intervillous space, and external masses which, together with the adjacent, modified and excavated uterine tissues, form a complex *junctional zone.*

(3) *Crossing it* from chorionic to basal plates, the main trunks of the *villous stems* dividing into their rami, ramuli, and associated complex of free terminal villi; the trunk and its branches may be regarded as the essential *structural, functional* and *growth unit* of the developing placenta.

Further consideration of the placenta must now be deferred until the preparation of the uterine tissues for the implantation and development of the blastocyst has been briefly described.

2.40 A transverse section of a terminal villus stained with haematoxylin and eosin.

CYCLICAL CHANGES IN THE UTERUS

Throughout the period of reproductive life (i.e. from about the 15th to the 45th year), except during pregnancy and lactation, a series of closely interrelated cyclical changes occur in the ovary, uterus and vagina. Each cycle extends over a period of about 28 days. In the *ovarian cycle*, which is described more fully elsewhere (pp. 93, 1424), one follicle usually reaches full maturity, ruptures and releases its secondary oöcyte during this period. The wall of the follicle is then transformed into an important endocrine gland, the *corpus luteum* (p. 1424). About ten days after ovulation the corpus luteum begins to regress, then ceases to function and is replaced by fibrous tissue.

The changes of the *uterine cycle (menstrual cycle)* chiefly involve the lining endometrium of the uterus and may, for convenience, be divided into four phases: (a) menstrual, (b) postmenstrual, (c) interval or proliferative, and (d) premenstrual or luteal (but see also below).

In the *menstrual (haemorrhagic) phase* the superficial part of the endometrium, next to the free surface, is shed piecemeal, leaving only the basal portion, adjacent to the uterine muscle (**2.42A**). Outwardly this phase is marked by a discharge of blood with necrotic epithelial débris from the uterus through the vagina. This discharge constitutes the *menstrual flow* and lasts a period of 3–6 days.

In the *postmenstrual (reparative) phase*, and even before the menstrual flow ceases, the epithelium from the persisting basal portions of the uterine glands grows luminally over the denuded surface of the endometrium. The endometrium is then 1–2 mm in thickness and lined by a low cuboidal epithelium. The glands are straight and narrow. The stroma is dense and contains small numbers of lymphocytes amongst its more general population of rather ill-defined spindle-shaped cells (**2.42B**). This phase lasts about 4 days.

During the *proliferative phase* which lasts about 10–12 days, there is a growth of the endometrium associated with the presence in the bloodstream of oestrogenic hormones (particularly *oestradiol*), an internal secretion produced by the ovary (**2.44A**). The endometrium thickens to about 2–3 mm. Mitoses are present and the glands become distinctly tortuous. Their lining epithelium becomes tall columnar (**2.42C**). In the later part of the interval phase clear spaces appear in the basal parts of the epithelial cells lining the glands. These vacuoles increase in size, occupy more of the cytoplasm, and the nuclei are displaced from the basal regions of the cells towards the lumina of the glands (**2.43**). Secretion is exuded into the lumen, and for a while the glands may be distended with secretion containing mucin and glycogen which can be demonstrated both in the cells and in the gland lumina by appropriate histochemical methods. At the end of the interval phase no mitoses are seen.

Ovulation occurs about 14 days *before the onset* of the next menstrual flow. The changes occurring in the premenstrual phase depend upon the presence in the bloodstream of the hormones, *progesterone* and *oestradiol*, both of which are secreted by the corpus luteum (**2.44A**).

The *premenstrual phase* occurs during the 7 days immediately prior to the next menstrual flow. The mucous membrane becomes much thicker and at the end of the phase may be 7–8 mm deep. In their middle portions, the glands become more voluminous and their walls are folded upon themselves so that tuft-like processes project into the lumen. This gives the glandular wall a saw-toothed appearance in longitudinal section. Secretion is seen in the lumen of the active parts of the gland. The gland epithelium which was tall and columnar at the commencement of the phase becomes frayed and worn down on their luminal aspects, and the nuclei resume their original basal position. The basal parts of the glands adjacent to the uterine muscle take little or no part in these changes. Later in the premenstrual phase characteristic changes appear in the interglandular stroma. These changes are most marked in the superficial part of the endometrium and around the blood vessels. Here the stromal cells, hitherto not clearly defined, become enlarged and swollen and for the first time definite cell outlines can be clearly seen. A few mitoses may be seen in the stroma at this stage. These changes constitute the *stromal premenstrual decidual reaction.* Three strata can now be clearly recognized in the endometrium (**2.42D**):

(1) *Stratum compactum*, next to the free surface in which the necks of the gland are but slightly expanded and the stromal cells show a distinct decidual reaction.

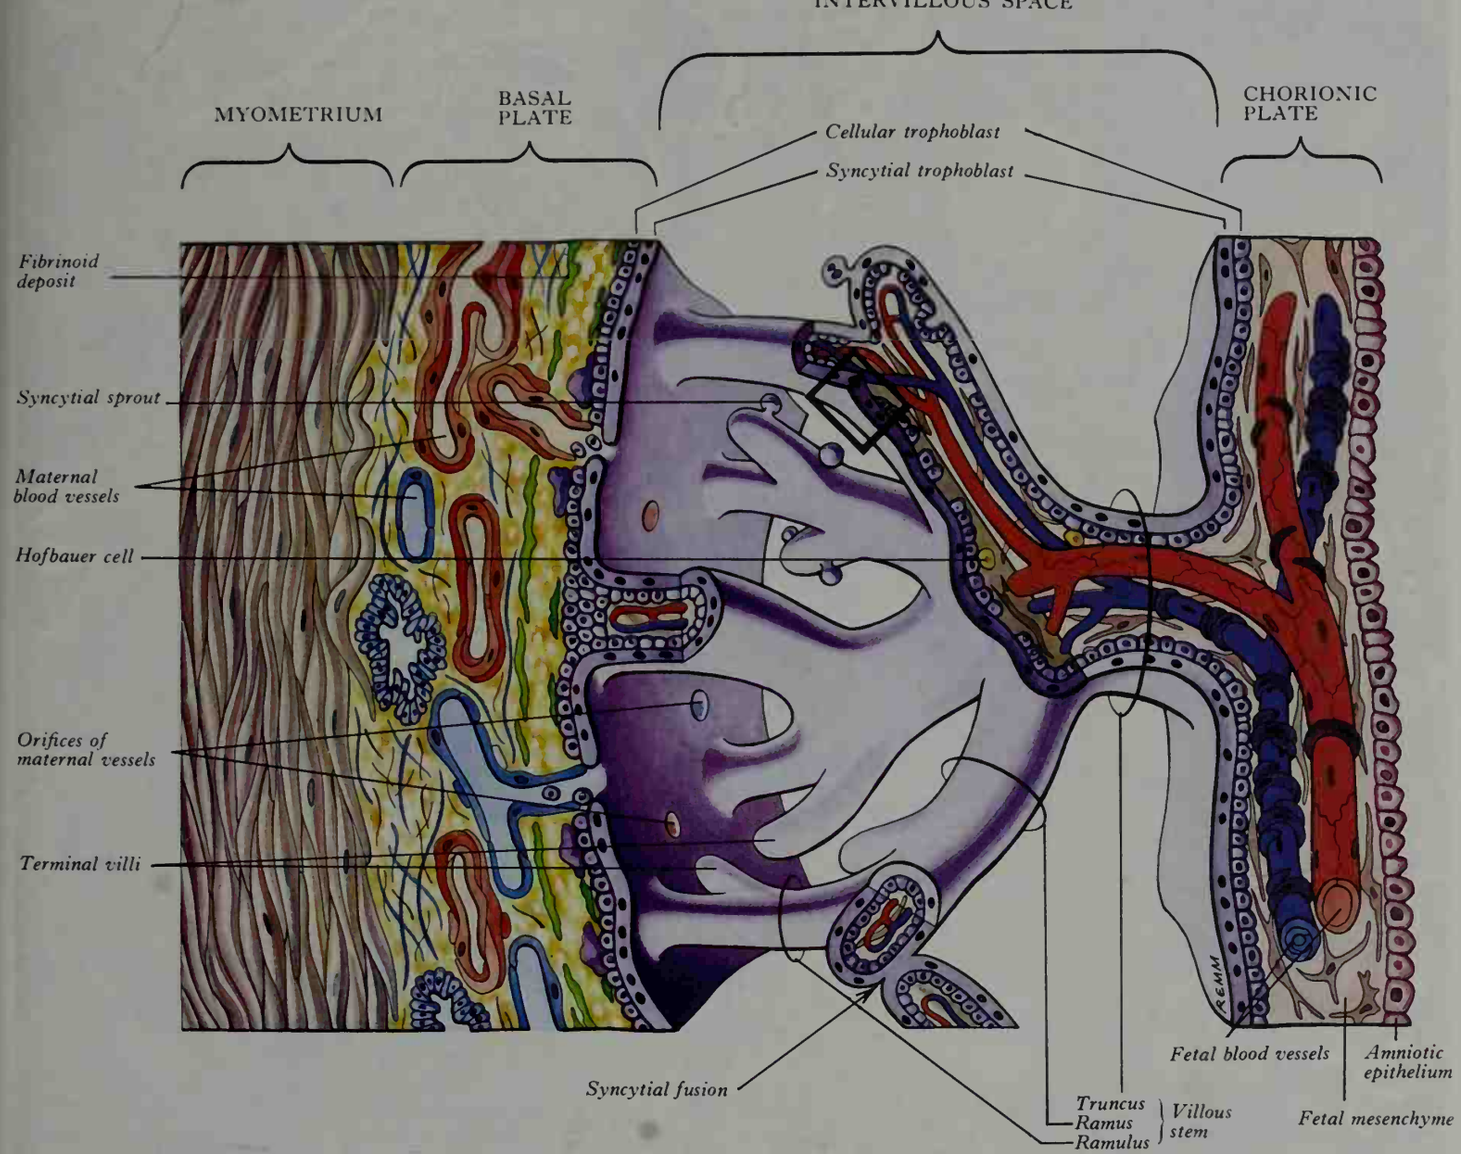
(2) *Stratum spongiosum*, where the uterine glands are tortuous, dilated and ultimately separated from one another by a small amount of interglandular tissue.

(3) A thin *stratum basale*, next to the uterine muscle containing the tips of the uterine glands embedded in an unaltered stroma.

In the last days of the premenstrual phase lymphocytes appear in the endometrium in increasing numbers. They are found between and beneath the surface epithelial cells, amongst the stromal cells and around and between the gland cells. Towards the end of this period as regression of the corpus luteum occurs, those parts of the stroma showing a decidual reaction and the glandular epithelium both undergo degenerative changes and the endometrium often diminishes in thickness. These degenerative changes precede the phase of bleeding.

During *menstruation* blood escapes from the superficial vessels of the endometrium forming small haematomata beneath the surface epithelium which raise it up. Blood and necrotic endometrium then begin to appear in the uterine lumen. The shedding of the endometrium starts at the surface and extends into the deeper layers. The amount of tissue lost is variable, but usually the stratum compactum and most of the spongiosum are desquamated.

The endometrium is regenerated from the stratum basale and that part of the spongy layer which remains, the surface epithelium being reformed with remarkable rapidity.



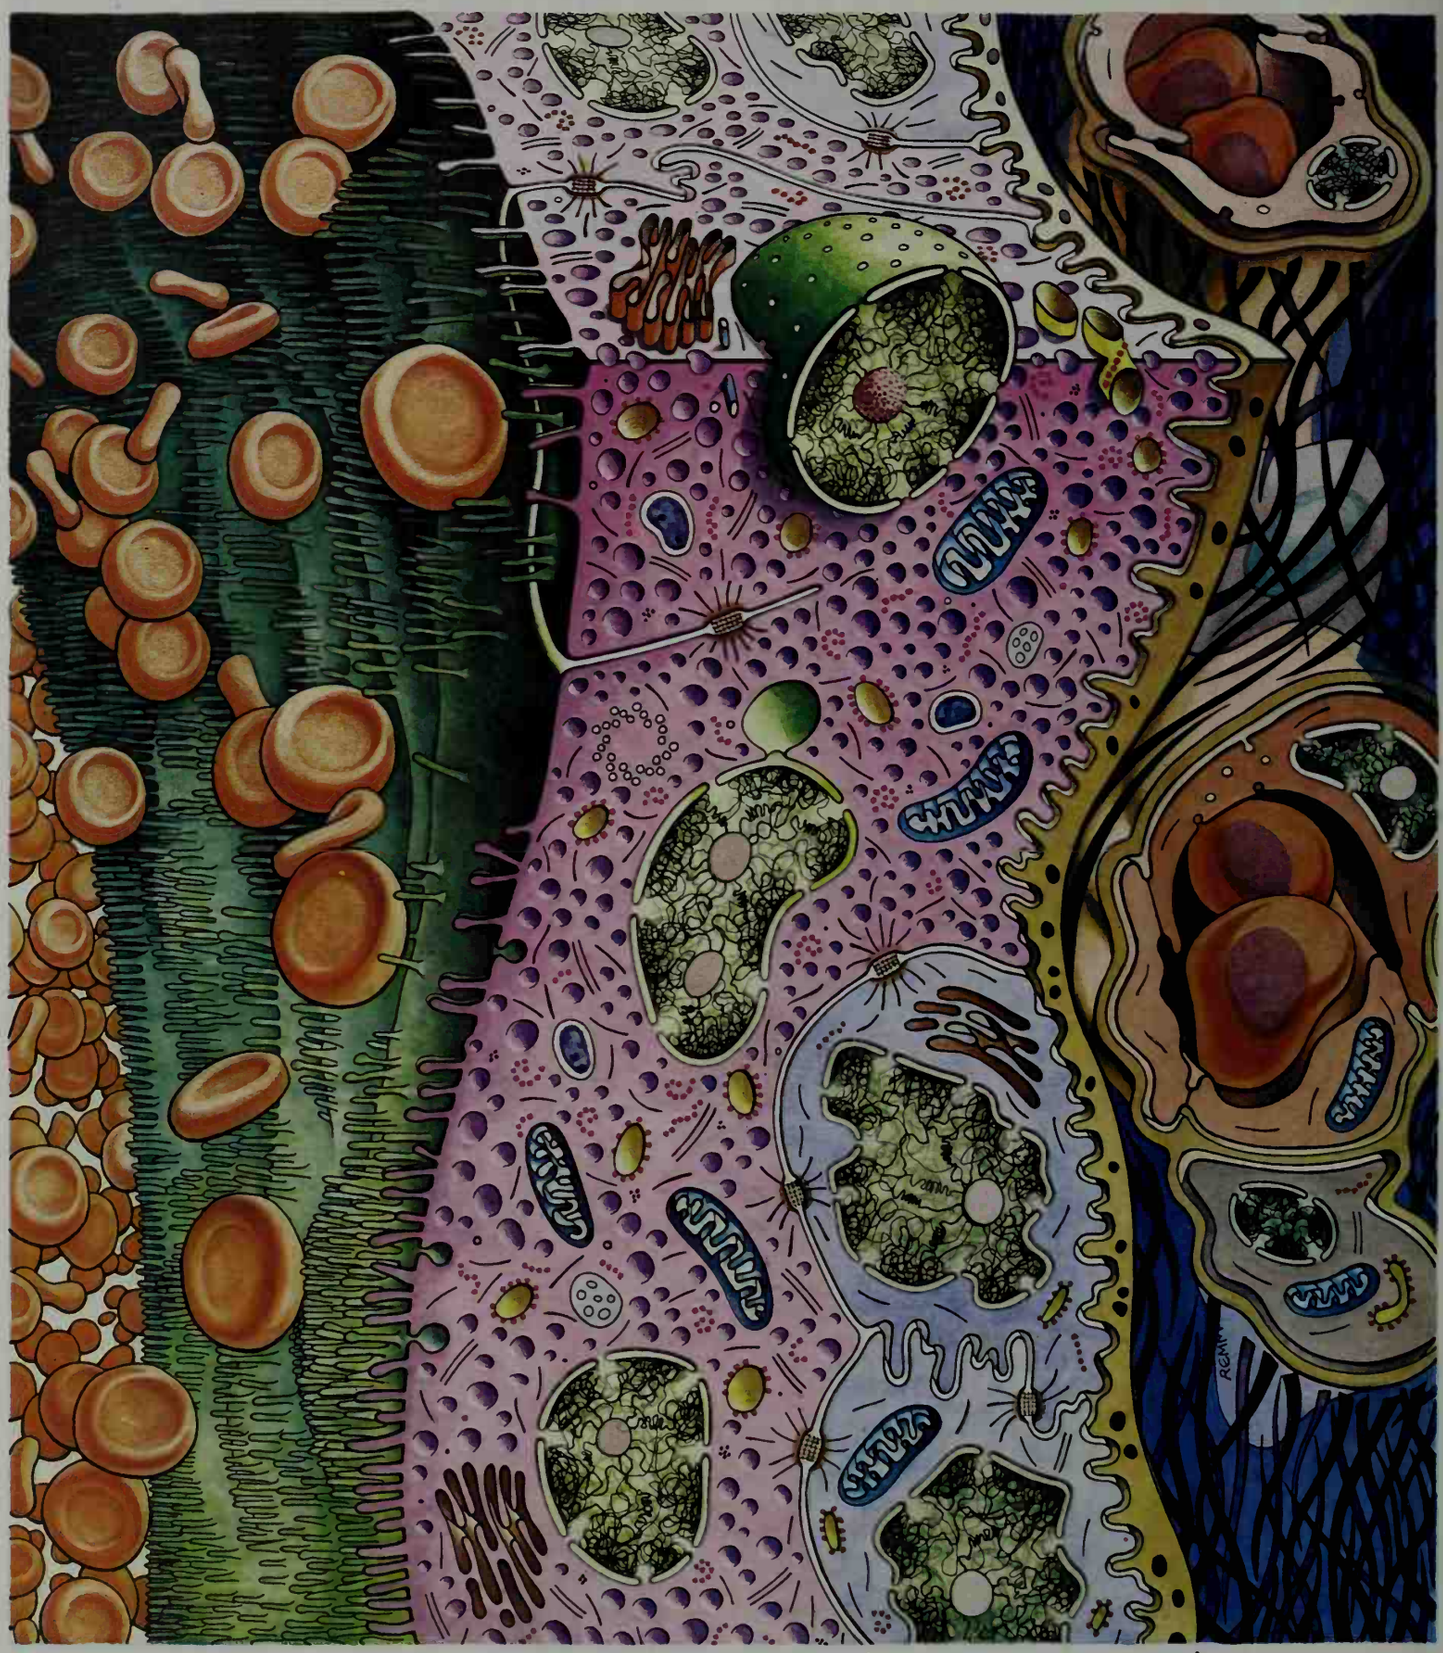
The *vascular bed* of the endometrium undergoes significant changes during the menstrual cycle. The arteries to the endometrium arise from a myometrial plexus and consist of short *straight* vessels to the basal portion of the endometrium and more markedly muscular *spiral arteries* to its superficial two-thirds. The venous drainage consists of narrow perpendicular vessels which anastomose by cross branches and is common to both the superficial and basal layers of the endometrium. The arterial supply to the basal part of the endometrium remains unchanged

during the menstrual cycle. The spiral arteries to the superficial strata, however, lengthen disproportionately, become increasingly coiled and their tips approach more closely to the uterine epithelium during the interval and, particularly, in the premenstrual phase of the menstrual cycle. This leads to a slowing of the circulation in the superficial strata with some vasodilation. Immediately before the menstrual flow these vessels begin to constrict intermittently causing stasis of the blood and anaemia of the superficial strata. During the periods of relaxation of the vessels blood escapes from the devitalized capillaries and veins, thus causing the *menstrual haemorrhage*.

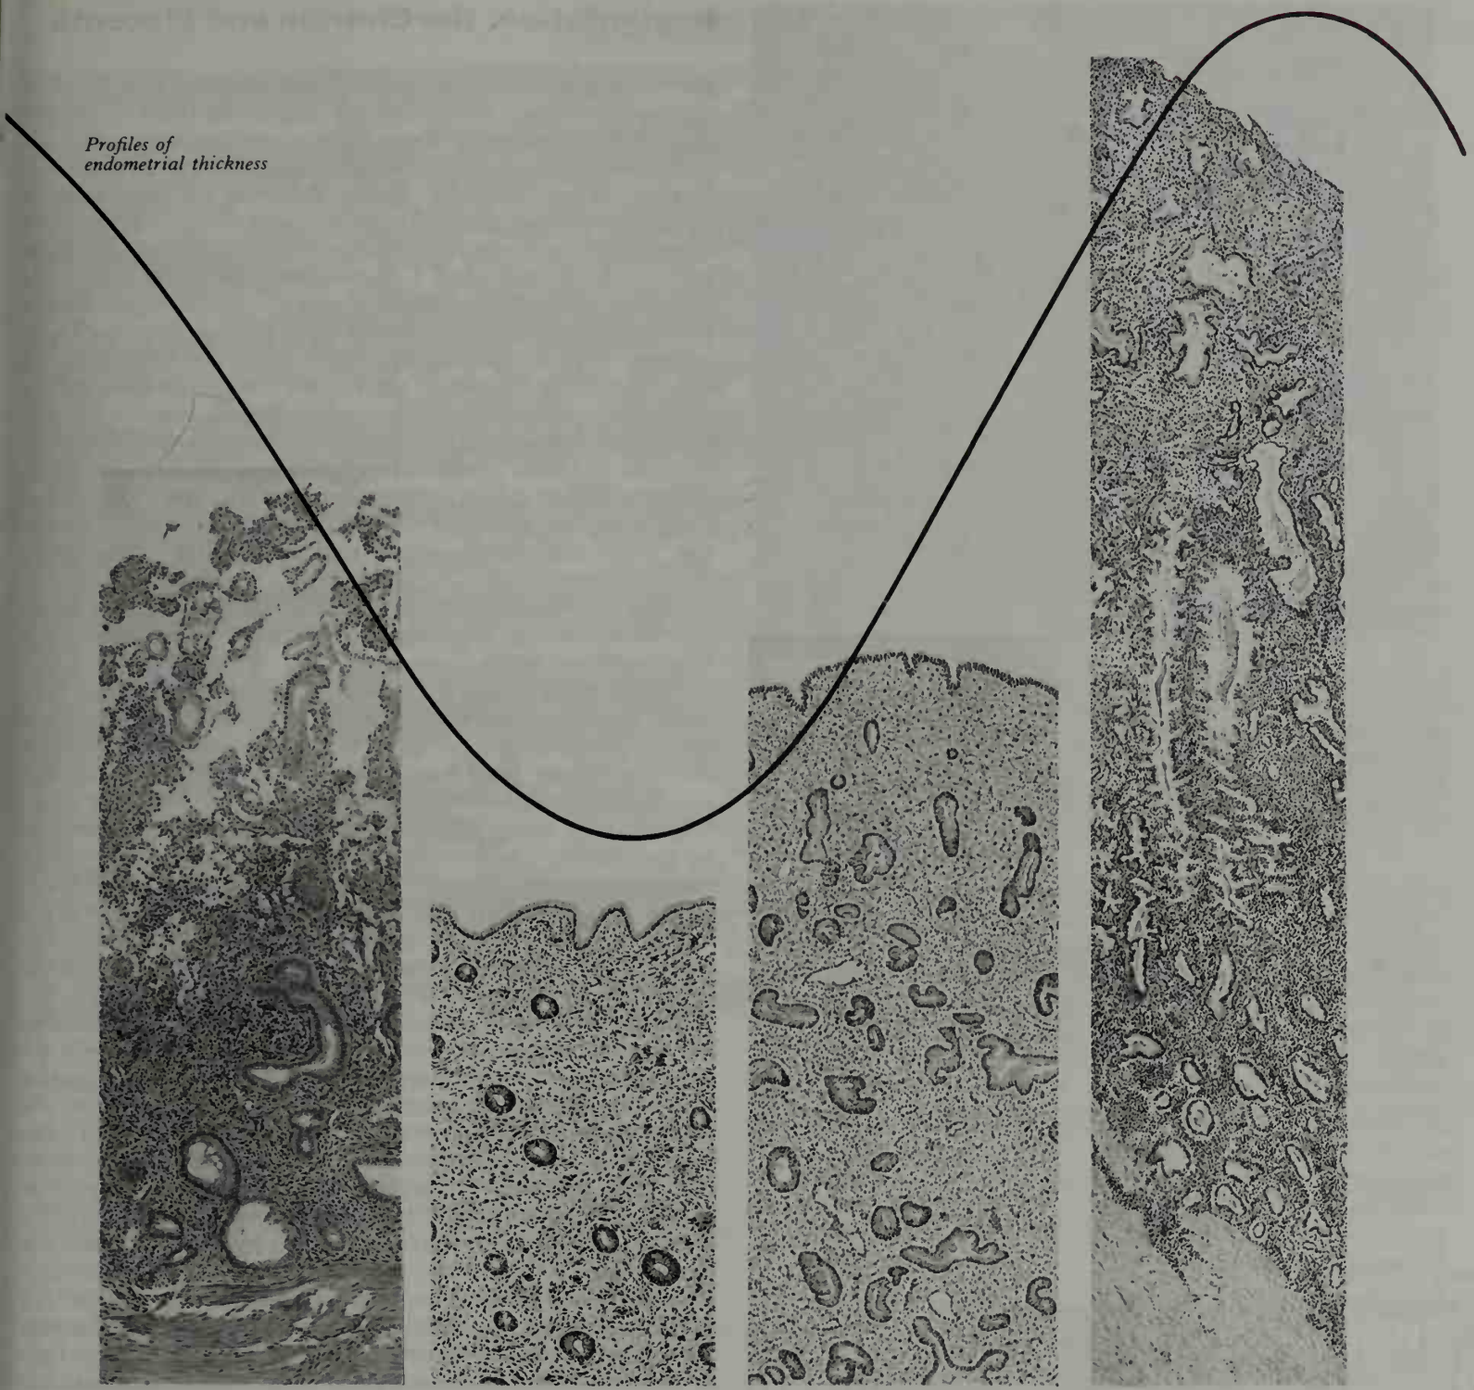
The changes in the endometrium leading to the hypertrophy of the premenstrual phase are a preparation for the reception of the blastocyst and result from the action of oestrogen and progesterone (2.44A). If fertilization of the ovum does not occur, the corpus luteum undergoes degenerative changes. The breakdown of the endometrium follows this cessation of function and is apparently due to the loss of the stimulating action of the progesterone and oestradiol (*see* p. 1424).

The uterine cycle may thus, alternatively, be considered as consisting of a *pre-ovulatory (follicular)* phase, which includes the postmenstrual and interval stages, and a *post-ovulatory (progestational* or *secretory)* phase, which includes the second half of the menstrual cycle, i.e. the premenstrual and menstrual stages. These two phases are of approximately equal duration, although there is a tendency for the pre-ovulatory phase to be more variable than the post-ovulatory phase. The former is largely under the control of oestrogens alone and the epithelial cells in this phase possess large microvilli, whilst their cytoplasm contains much rough endoplasmic reticulum, lipid globules, and lysosomes which become more numerous as the phase progresses. Histochemically the epithelium can be shown to contain large amounts of ribonucleoprotein and alkaline phosphatase, signifying the production and utilization of protein. In the post-gestational phase, which is under the control of the oestrogens plus progesterone, the above activity declines and the surfaces of the cells become irregular with microvilli and cytoplasmic processes, large vesicles appear in the apical cytoplasm and more numerous lysosomes are present. Acid phosphatases, malic and succinic dehydrogenases, cytochrome oxidase and adenosine triphosphatase are demonstrable and large amounts of glycogen and mucopolysaccharide are present, possibly signifying the utilization of carbohydrate (McKay *et. al.* 1956; Nilsson 1962).

A form of menstruation frequently occurs in the absence of



2.41A A schematic diagram to show the arrangement of the placental tissues. Note the chorionic and basal plates, and the intervillous space spanned by a villous stem and its divisions (truncus, rami and ramuli). The sectioned surfaces show the disposition of the fetal and maternal blood vessels, the amniotic epithelium, the cellular and syncytial layers of trophoblast and the complex junctional zone between the fetal and maternal tissues in the basal plate containing deposits of fibrinoid material and isolated masses of peripheral syncytium. Note also the presence of surface syncytial sprouts, a stromal trophoblastic bud and Hofbauer cells associated with a terminal villus, and syncytial fusion occurring between the tips of two terminal villi. See text for further details. The region enclosed in the rectangle is shown greatly enlarged in **2.41B**.

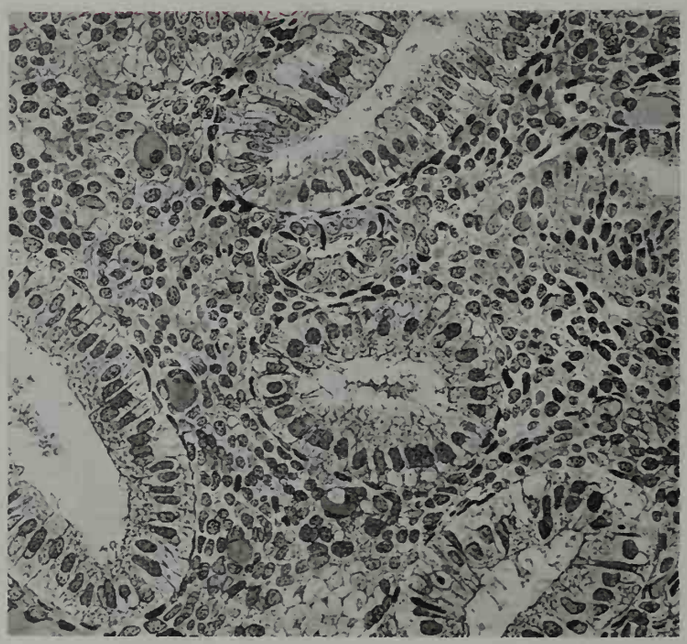


ovulation, particularly around puberty and also in women approaching the menopause (*anovulatory cycle*). Instead of liberating its ovum, the ripe follicle fails to rupture and undergoes degeneration. This is accompanied by a rapid reduction in oestrogen secretion with consequent breakdown of the uterine mucosa in the interval phase and in the absence of the changes evoked by the presence of progesterone in the bloodstream (this is termed an *oestrogen-withdrawal* bleeding—Corner 1938).

The Decidua

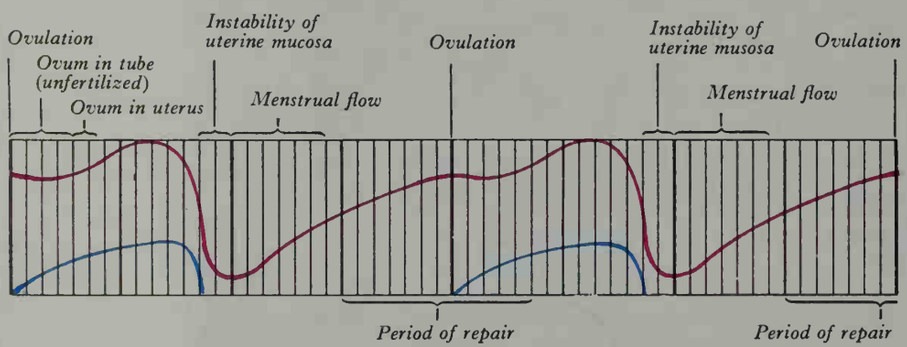
If fertilization and successful implantation occur, a hormone secreted by the trophoblast, *chorionic gonadotrophin*, prolongs the

2.41B A schematic diagram showing the detailed ultrastructural features of the tissues (enclosed in a rectangle in 2.41A) which intervene between the maternal and fetal blood streams. Note the contrasting architecture of the syncytial and the cellular trophoblasts, and the substantial basement membrane and delicate fetal mesenchyme which separate the trophoblast from the fetal vessels. For further description see text. (Based on data in Boyd and Hamilton 1970.)



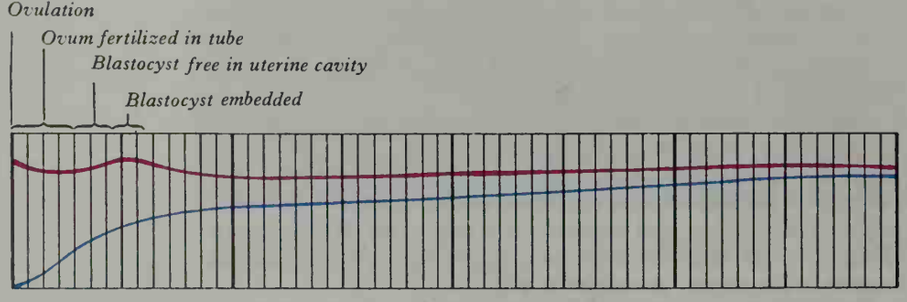
2.42 A–D Stages in the human menstrual cycle—the sections of the endometrium have all been reproduced at approximately the same magnification. The black line is a rough indication of the changes in endometrial thickness throughout the cycle. (Specimens kindly provided by the Shattock Museum, St. Thomas's Hospital Medical School.)

life of the corpus luteum, which continues to secrete progesterone (*see* pp. 1424–1425 and **2**.44B). Menstruation does not occur and the vascular endometrium, now known as the *decidua of pregnancy*, thickens further to form a suitable nidus for the conceptus. (Chorionic gonadotrophin also appears early in the urine and its presence here is used as a basis for many of the tests for early pregnancy.) The interglandular tissue increases in quantity; it contains a number of leucocytes, and is crowded with large round, oval or polygonal *decidual cells*. These are stromal cells which have accumulated glycogen and lipid in their distended cytoplasm. They continue to be conspicuous in the early stages of gestation but tend to regress in the later months. Their precise significance is uncertain. Possibly they offer a nutritive pabulum which is engulfed by the syncytial trophoblast but, on the other hand, they are often regarded as a defensive mechanism to protect the endometrium from excessive destruction. These changes are well advanced by the second month of pregnancy, when the three strata recognizable in the premenstrual phase, the stratum compactum, stratum spongiosum and stratum basale, are better differentiated and easily distinguished.



After the blastocyst is embedded, distinctive names are applied to different regions of the decidua. The part which covers the conceptus is the *decidua capsularis*; the part between the conceptus and the uterine muscular wall is named the *decidua basalis*, and it is here that the placenta is subsequently developed; the part which lines the remainder of the body of the uterus is known as the *decidua parietalis* (**2**.46).

Coincidently with the growth of the embryo and the expansion of the cavity of the amnion (p. 131), the decidua capsularis is thinned and distended (**2**.45, 46) and the space between it and the decidua parietalis is gradually obliterated. By the beginning of the third month of pregnancy the decidua capsularis and decidua



2.43 Section of human endometrium at about the seventeenth day of the menstrual cycle to show the accumulation of secretions in the basal parts of the epithelial cells lining the glands, resulting in displacement of the nuclei towards the lumen of the gland. Magnification × *c.* 300. Stained with haematoxylin and eosin. (Kindly lent by the Shattock Museum, St. Thomas's Hospital Medical School.)

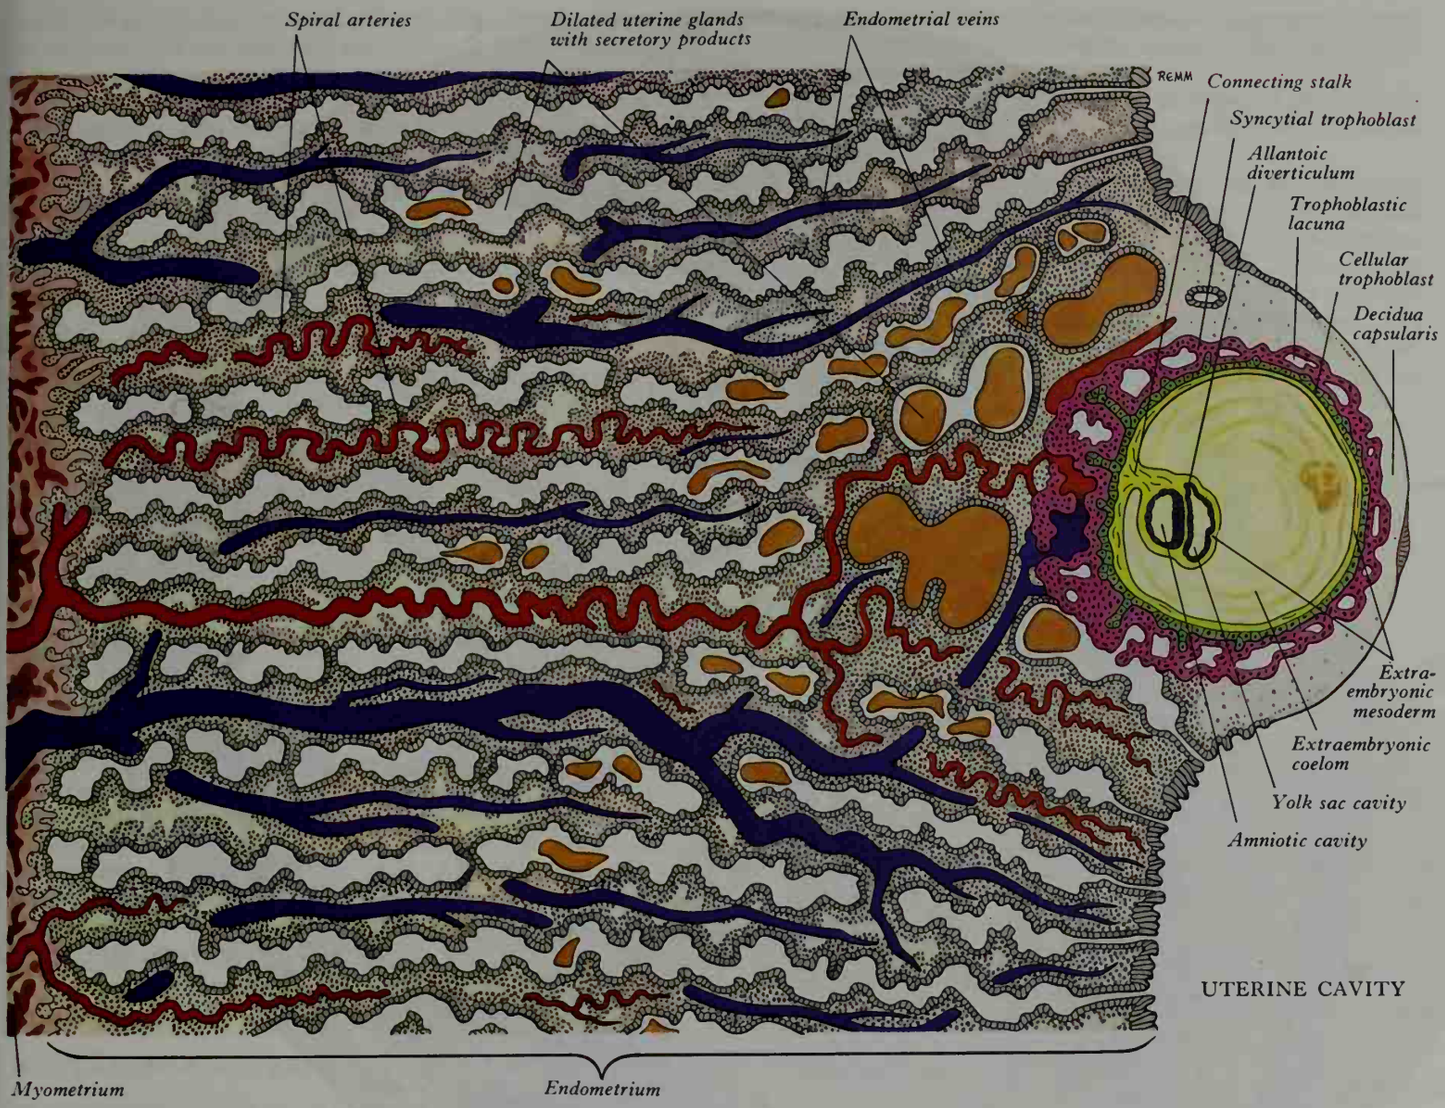
parietalis are in contact; by the fifth month the decidua capsularis is greatly thinned, while during the succeeding months (**2**.47) it virtually disappears, and the decidua parietalis also largely atrophies, owing to the increased pressure. The glands of the stratum compactum are obliterated, and their epithelium is lost; in the stratum spongiosum the glands are compressed, they appear as oblique slit-like fissures, and their epithelium undergoes degeneration; in the limiting or boundary zone, however, the glandular epithelium retains a cuboidal form.

2.44A Graphic representation of the menstrual cycle in the absence of fertilization.

The *red* lines show the graphs of the secretion of *oestrogenic* substances, and the *blue* lines show the graphs of *progesterone* secretion.

Implantation, the Chorion and Placenta

As we have seen elsewhere (p. 103), during the first series of cleavage divisions of the fertilized ovum, two distinctive groups of blastomeres emerge; one forms the inner cell mass including the *embryogenic cells*, and the other consists of the more numerous, smaller, rather flattened, polyhedral cells of the primitive *blastocystic trophoblast*. The latter spreads to cover the inner cell mass and consequently *polar* and *mural* regions of this trophoblast may now be distinguished. Comparative studies have shown that such cells in the blastocysts of a number of different mammals possess many features in common. They are characterized by the presence of short, irregular microvilli on their external surfaces, numerous invaginations of the plasma membrane between the microvilli, with adjacent micropinocytotic vesicles in the cytoplasm, and junctional complexes occur between the cells at the outer end of the intercellular clefts (Enders and Shlafke 1965). Their cytoplasm carries many mitochondria, a variably developed Golgi complex, glycogen clusters, lipid inclusions, lysosomes, free ribosome rosettes, but scanty granular endoplasmic reticulum.



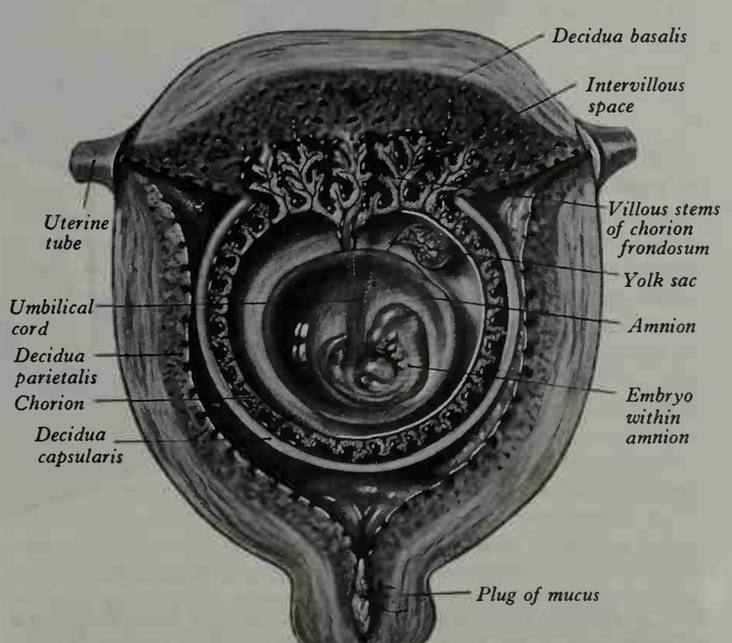
From the cells of this primitive layer all the elements of the chorion are derived, including the varieties of syncytium and also its mesodermal lining.

The method of origin of *syncytial trophoblast* was long debated, many workers holding that it arose by endomitosis of the primitive cells without cell division, but there is now an increasing body of evidence (Boyd *et al.* 1968) that it arises by proliferation of the cellular layer, with subsequent fusion of primarily independent cells on its external surface. The cellular layer itself persists, somewhat modified, as the germinal *cytotrophoblast* which, by multiplicative growth, can add additional cells which fuse with the overlying syncytium, may contribute cells to the underlying extraembryonic mesoderm, and which, by its continued growth, is an important factor in the expansion of the volume of the whole conceptus.

Six or seven days after ovulation the endometrium is well into the development of its secretory phase (p. 126), and with the disappearance of the fibrillary zona pellucida, and the elaboration of polar synctium, the stage is set for the implantation of the blastocyst. From comparative studies (Böving 1959) the mechanisms of implantation have been described as *muscular*, involving blastocyst transport (and spacing in polyovular species), *adhesive*, whereby the blastocyst becomes attached to the uterine mucosa, and *invasive*, the means by which it enters the uterine tissues. Whilst the earliest stages of human blastocyst attachment and penetration have not been available for study, a number of mammals, including primates (Wislocki and Streeter 1938), have been subjected to close scrutiny using the light microscope, and more recently a number of ultrastructural studies have been made (Reinius 1967; Nilsson 1967; Tachi *et al.* 1970).

Based on these accounts, early implantation is initiated by a close approach of the trophoblastic plasma membrane to the tips of the microvilli and irregular surface protrusions of the uterine epithelial cells. At these points the trophoblast surface often presents patches of 'bristle-coated' membrane, with adjacent cytoplasmic plaques having a crystalline substructure, with numerous neighbouring lysosomes. The microvilli shorten and disappear, and for a period there is a close mutual adaptation between the contours of the trophoblast and the uterine epithelial cell surfaces. The syncytium now send finger-like projections between adjacent epithelial cells towards the underlying basement membrane, the two layers becoming closely interlocked by the formation of numerous tight junctions between them. The epithelial cells now degenerate and are engulfed by the trophoblast, resultant cellular débris becoming enclosed in phagosomes within the trophoblastic cytoplasm. The subepithelial basement membrane is soon penetrated, with the development of oedema, hyperaemia and cell degeneration in the neighbouring stroma.

After interstitial implantation of the human blastocyst, the process of invasion continues with erosion, degeneration and phagocytosis of maternal vascular endothelium, glandular epithelium with secretory products, and decidual cells, until the



2.45 A diagram showing the general structure of the implanting blastocyst and its relationship to the tissues of the endometrium on the 15th day after fertilization. Note the arrangement and gradation in thickness of the syncytial trophoblast which has eroded the maternal tissues. Some of the deeper trophoblastic lacunae already contain maternal blood. Note also the active dilated uterine glands, the endometrial venous plexus, spiral arteries, and the stage of development of the cellular trophoblast, amnion, yolk sac, allantoic diverticulum, connecting stalk and the extraembryonic mesodermal layers lining the extraembryonic coelom. For further details see text.

blastocyst sinks into and occupies a ragged *implantation cavity* in the decidua.

The subsequent stages of development, which include the definition of the layers of the chorion (p. 124), the elaboration of syncytial trophoblast which is thick at the embryonic pole and thins towards the abembryonic pole and carries a lacunar circulation, and the principal stages in the development of the intervillous space, the villous stems and their branches, and the trophoblastic shell, have already been described (p. 124).

From the third week until about the second month of pregnancy the *entire chorion* is covered with villous stems which are thus continuous peripherally with the trophoblastic shell in close apposition with *both* the decidua capsularis and the decidua basalis. The latter, however, are stouter, longer and show a greater profusion of terminal villi. As the conceptus continues to expand, the decidua capsularis is progressively compressed and thinned, the circulation through it is gradually reduced and, accordingly, its related villous stems and villi slowly atrophy and disappear. This process starts at the abembryonic pole and by the end of the third month the abembryonic hemisphere of the conceptus is largely denuded. This continues until the whole chorion which is related to the capsularis is smooth (the *chorion laeve*); in contrast, the villous stems of the disc-shaped region of chorion related to the *decidua basalis* increase greatly in size and complexity (the *chorion frondosum*), and together the latter constitute the *definitive placental site*.

An exhaustive account of the growth, dimensional changes,

2.46 A plan of the gravid uterus in the second month. A placental site precisely in the uterine fundus as indicated in the plan is, however, rather unusual. (The dorsal, ventral or lateral wall of the corpus uteri is more usual.)

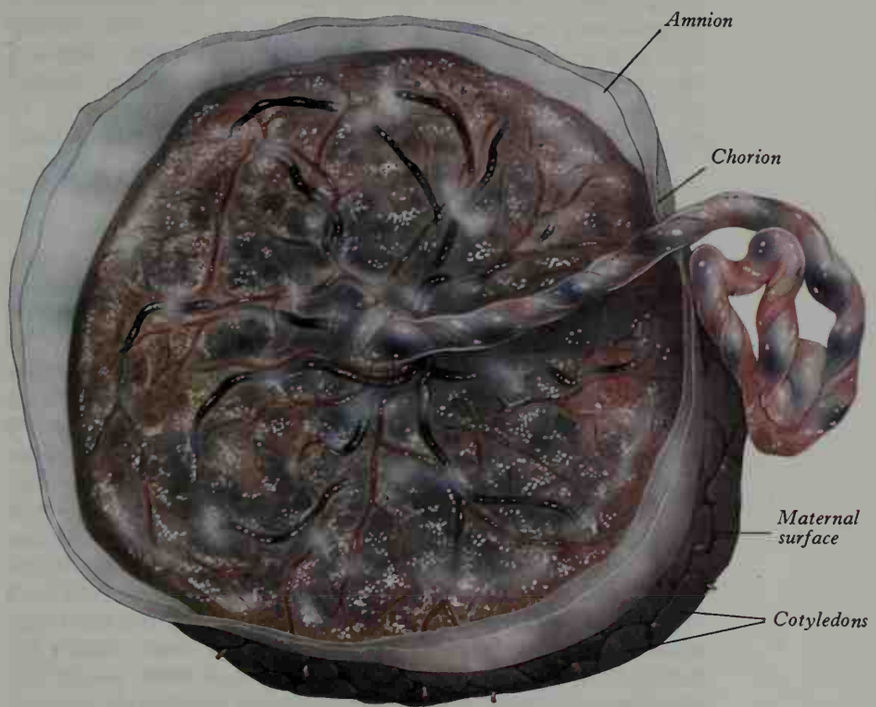
2.47 A diagram showing a full-term human fetus *in utero*, including a sectional view of the placenta, the amnion (mauve), chorion (green), uterine wall (orange), the umbilical cord and its contained vessels, the cervix with a plug of mucus in the cervical canal, and the rugose vaginal wall. Note the characteristic flexed posture of the fetus and its limbs, and the overall position within the uterus which the fetus commonly occupies (other positions, although less frequent, are, however, also quite common). Note also the single umbilical vein carrying oxygenated blood, the two umbilical arteries carrying deoxygenated blood, the arborization of these vessels in the chorionic plate (seen through the overlying amnion) and their branches which pass into the villous stems. The latter span the intervillous space and their trunci, rami, ramuli and terminal villi may be seen; incomplete placental septa project from the basal plate towards the chorionic plate. See text for further details.

vasculature and haemodynamics, cell varieties, ultrastructure and histochemistry of the placenta, and the physiological aspects of placental transfer and its status as a metabolic store and endocrine gland, lies beyond the scope of the present volume. What follows is necessarily an abbreviated account of selected topics, and the interested reader should consult the profusion of original papers devoted to these subjects (the classical volume by Professors J. D. Boyd and W. J. Hamilton (1970) provides an unrivalled source of information and an extensive bibliography). A more recent excellent survey of placental transfer mechanisms is to be found in Longo (1972).

Definition of the Human Placenta

The human placenta (Wislocki 1937; Hill 1932; Grosser 1936; Mossman 1937; Amoroso 1960) is defined as *discoidal* (in contrast to other shapes, e.g. *zonary*, *bidiscoidal*, *diffuse*, etc. seen in other forms). It is initially *labyrinthine* as the early villous stems are formed, but becomes secondarily *villous* with the development of generations of terminal villi, and finally, there is a partial return to a *labyrinthine* state as superficial adhesion or partial fusion occurs between the tips of a number of villi (*vide supra*). Maternal blood bathes the surfaces of the chorion which bound the intervillous space, and it is thus defined as *haemochorial*, distinguishing it from the different grades of fusion between the maternal and fetal tissues which exist in many other forms (*epitheliochorial*, *syndesmochorial*, *endotheliochorial*, and even an approach to a *haemoendothelial* condition but with the vascular endothelial basement membrane and a fine layer of perivascular connective tissue persisting). The chorion is vascularized by the allantoic blood vessels of the body stalk and the human placenta is termed *chorioallantoic* (whereas in some forms a *choriovitelline* placenta either exists alone or supplements the chorioallantoic variety). Finally, the human placenta is said to be *deciduate* because maternal tissue is shed with the placenta and membranes at term as part of the afterbirth (*vide infra*).

THE PLACENTA AT TERM



The expelled placenta (**2**.48), is a flattened discoidal mass with an approximately circular or oval outline, with an average volume of some 500 ml (range 200–950 ml), average weight about 500 gm (range 200–800 gm), average diameter 185 mm (range 150–200 mm), average thickness 23 mm (range 10–40 mm), and an average surface area of about 30,000 mm². It is, of course, thickest at its centre (the original embryonic pole) and rapidly diminishes in thickness towards the periphery where it is continuous with the chorion laeve.

Macroscopically, its *fetal* or *inner surface*, which is covered by the amnion, is smooth, shiny and transparent, and the mottled appearance of the subjacent chorion, to which it is closely applied, can be seen through it. The umbilical cord is usually attached near the centre of the fetal surface and the branches of the umbilical vessels radiate out under the amnion from this point, the veins being deeper and larger than the arteries. Beneath the amnion and close to the attachment of the cord, the remains of the yolk sac can sometimes be identified as a minute vesicle with a fine thread—a vestige of the yolk stalk—attached to it.

The *maternal surface* is finely granular and mapped into some fifteen to thirty lobes by a series of fissures or grooves. The lobes are often, somewhat loosely, termed *cotyledons* (but see also below), and the grooves themselves correspond to the bases of incomplete *placental septa* which become increasingly prominent from the third month onwards, and extend from the maternal aspect of the intervillous space (the basal plate) towards, but do not quite reach, the chorionic plate. The septa form initially as ingrowths of the cytotrophoblastic shell, with a covering of syncytium, but from the fourth month they develop a complex core derived from the maternal tissues which includes reticulin fibres and associated cells, decidual cells, remnants of glandular epithelium, occasional blood vessels, and deep to the cytotrophoblast, a stratum of fibrinoid material. Later cytotrophoblastic cells often penetrate into this stratum at various points with a resultant admixture of the fetal and maternal tissues, and in the later months of pregnancy, patches of central degeneration occur in many septa, which, incidentally, increases the difficulty of histological interpretation.

The nature of the maternal surface of the expelled placenta is of course determined by the tissue plane of separation of the placenta at parturition.

Recent studies of the human placenta include morphometric analysis (Laga *et al.* 1973), surface architecture using scanning electron microscopy (Fox and Agrafojo-Blanco 1974), ultrastructural studies of angioarchitecture (Sheppard and Bonnar 1974), and the possible mechanisms whereby the maternal placental circulation is controlled (Bruce and Abdul-Karim 1974). The ultrastructure of biopsies taken from placental uterine beds, which were presumed to be normal, has been reviewed by Robertson and Warner (1974).

2.48 The fetal surface of a recently delivered placenta, drawn from a coloured photograph kindly provided by Mr. E. F. Gibberd. The maternal surface is exposed in the lower and right corner of the figure. Note the small branches of the uterine artery and the series of grooves. Note also the amnion and chorion which have been cut away near the placental margin.

Separation of the Placenta

After delivery of the fetus the placenta becomes separated from the uterine wall, and together with the so-called 'membranes' is expelled as the *afterbirth*. Separation takes place along the plane of the stratum spongiosum and extends beyond the placental area, detaching (1) almost the whole remaining thickness of the largely degenerate, confluent, decidua parietalis and decidua capsularis, (2) the chorion laeve, and (3) the amnion. These three layers are partially fused together and are continuous with the placenta at its margin; they constitute the *membranes* familiar in obstetrics. The process of separation requires rupture of many uterine vessels but their torn ends are closed by the firm contraction of the muscular wall of the uterus after delivery of the placenta and membranes, and thus, under normal circumstances, postpartum haemorrhage is limited in amount. When the placenta and membranes have been expelled, a thin layer of stratum spongiosum is left as a lining for the uterus, but it soon undergoes degeneration and is cast off in the early part of the puerperium. A new epithelial lining for the uterus is then regenerated from the remaining stratum basale.

Placental Lobes and Lobules

The placental *lobes* are demarcated by the grooves on its maternal surface, and they correspond in large measure to the major branches of distribution of the umbilical vessels, particularly well

seen in specimens X-rayed after intravascular injection of radio-opaque media. However, the application of the term cotyledon to these major lobes does not correspond directly to its usage in comparative placentology.

Particularly in those forms with a diffuse kind of placentation, the whole chorion does not bear villous structures evenly, for these are restricted to a large number of scattered discontinuous patches (*fetal cotyledons*) with non-villous chorion between them. These fetal cotyledons come into apposition with similarly distributed discrete areas of endometrium (the *maternal cotyledons* or *uterine caruncles*); the combination of one fetal unit with its associated maternal unit is termed a *placentome*.

The fetal cotyledon of the human placenta evidently corresponds to a major villous stem and its branches; early in pregnancy, the chorion bears some 800–1,000 of such stems, but as pregnancy advances, with the formation of the chorion laeve and possibly some fusion between adjacent stems, the number is progressively reduced until only about 60 persist in the placental area in the last months of pregnancy. However, this number is distributed between the 15–30 lobes, i.e. each lobe (or 'cotyledon' of obstetrics) contains 2–4 major villous stems and is to be regarded as compounded of this number of *placentomes* or *lobules*.

THE PLACENTAL TISSUES

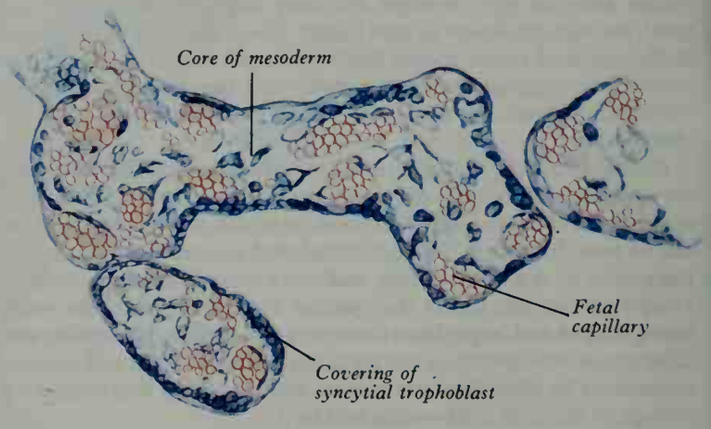
These are arranged as a chorionic plate, a basal plate, and between the two, the villous stems, their branches, and the intervillous space (**2**.41, 47).

The chorionic plate is covered on its fetal aspect by the amniotic epithelium, the cells of which have been briefly described elsewhere (p. 122), followed by a connective tissue layer carrying the main branches of the umbilical vessels, then a diminishing layer of cytotrophoblast, and finally, the inner syncytial wall of the intervillous space. The connective tissue layer is derived from fusion between the mesoderm-covered surfaces of the amnion and chorion, and is more fibrous and less cellular than the Wharton's jelly of the umbilical cord, except near the larger vessels. The latter radiate and branch from the cord attachment (with variations in the branching pattern), until they reach the bases of the trunks of the villous stems, which the branches enter and then arborize within their rami, ramuli and terminal villi. There is no cross anastomosis between the vascular trees of adjacent stems, but in contrast, the two umbilical arteries are normally joined by some form of substantial transverse (Hyrtl's) anastomosis at, or just before they enter, the chorionic plate.

The basal plate consists, from the fetal to the maternal aspect, of: (1) the syncytium (and perhaps in patches, maternal tissue) which forms the outer wall of the intervillous space, (2) Rohr's stria of fibrinoid, (3) what remains of the cytotrophoblastic shell, (4) Nitabuch's stria of fibrinoid, (5) the remains of the decidua.

The striae of fibrinoid are irregularly connected together, and strands pass from Nitabuch's stria into the adjacent decidua. The latter contains basal remnants of the endometrial glands, large and small decidual cells scattered in a connective tissue framework which also supports an extensive venous plexus. These deeper layers of the basal plate also contain a variety of *giant cells* which may possess either multilobate nuclei or are in fact multinucleate. Their origin has been disputed, but the majority probably have a fetal origin, either arising by the isolation of masses of peripheral syncytium, or by growth from the cells of the cytotrophoblastic shell. For some, however, a maternal origin cannot be excluded. Their role is uncertain but they may be one source of placental hormones. In this regard, the possession by the cytotrophoblastic cells in this region, of prominent nucleoli, a particularly basophilic cytoplasm rich in RNA, and varieties of cytoplasmic inclusions (Dallenbach-Hellweg and Nette 1964), both acidophil and basophil, may also be related to an endocrine secretory role.

Throughout the second half of pregnancy the basal plate is thinned and becomes progressively modified, with a relative diminution of the decidual elements, and with an increasing deposition of fibrinoid and admixture of fetal and maternal derivatives. It is, as we have seen, through the deeper decidual layers of the plate that separation of the placenta occurs at parturition, and through its various layers the maternal blood vessels approach and reach the intervillous space. In the earlier stages of development the spiral arteries of the endometrium do not open directly into the intervillous space until the fifth or sixth week, after which they pass through the plate and open through gaps in the cytotrophoblastic shell and peripheral syncytium. The terminal parts of the vessels are dilated, lose their muscular walls by degeneration, and present a hypertrophy of their lining endothelium. Proliferations of cytotrophoblast often grow back for some distance along their lumina (Hamilton and Boyd 1960).



The veins which drain the blood away from the intervillous space pierce the basal plate and join tributaries of the uterine veins. The presence of a marginal venous sinus, which has hitherto been described as a constant feature, occupying the peripheral margin of the placenta and communicating freely with the intervillous space, has not been confirmed.

In the macaque monkey, radio-opaque material injected into the aorta passes in spurts or jets to the intervillous space and at sufficient pressure to drive it towards the chorion, thus preventing a short circuit of arterial blood into the venous openings. The openings of the coiled arteries show intermittent activity, probably due to alternating constriction and relaxation of the arteries themselves. Myometrial contractions alter the pressure in the intervillous space and promote placental venous drainage (Ramsey *et. al.* 1963; Martin 1965).

The Structure of a Villus

The terminal villi are the essential structures involved in exchanges between the mother and fetus, and, accordingly, the tissues which separate the fetal and maternal blood in this site are of considerable functional importance, and numerous investigations have been carried out on them.

Each villus is composed of a core of connective tissue bearing fetal capillaries and separated by a basement membrane from the ensheathing cyto- and syncytial trophoblast which is bathed by the maternal blood of the intervillous space (**2**.40, 41, 49). Cohesion between the cells of the cytotrophoblast and also between this layer and the syncytium is provided by numerous desmosomes between their apposed plasma membranes.

2.49 Part of a section of a branching terminal villus in a mature placenta (ninth month). Note the close approach of many of the fetal capillaries to the subepithelial basement membrane; see text for details.

In the early stages, the cytotrophoblast forms an almost continuous layer on the basement membrane, but after the fourth month it gradually expends itself producing syncytium (Midgley *et al.* 1963). As it becomes reduced the syncytium is related to the basement membrane over an increasingly large area, and at the same time itself becomes progressively thinner, but cytotrophoblastic cells, usually disposed singly, can, however, be identified until term.

The cells of the villous cytotrophoblast (*Langhans' cells*) are pale-staining with only a slight basophilia. Ultrastructurally, they

show a rather electron-translucent cytoplasm, bearing relatively few free polysomes, little granular endoplasmic reticulum, but a number of large mitochondria, a fairly extensive Golgi apparatus, microfilaments particularly in association with the desmosomes, and occasional vacuoles and dense inclusions. Between the desmosomes, the cell membranes of adjacent cells may be smooth and straight, or they may undulate, and are separated by a featureless gap of some 20 nm. Sometimes the intercellular gap widens to accommodate microvillous projections from the cell surfaces; in addition the gap occasionally contains patches of fibrinoid.

In contrast, the syncytial cytoplasm is more strongly basophilic and possesses many ultrastructural features which distinguish it from the cytoplasm of the Langhans' cells. Where the plasma membrane adjoins basement membrane it is often complexly infolded into the cytoplasm, whereas the surface bordering the intervillous space is beset with numerous long microvilli, the cores of which show linear densities. These microvilli are responsible for the appearance of a brush border seen with the light microscope.

The syncytial cytoplasm is exceedingly complex and more electron-dense than that of Langhans' cells. It contains a wealth of free ribosomes, cisternae of granular endoplasmic reticulum, scattered representations of the Golgi complex, a cytoskeleton of microfilaments, and a profusion of vesicles and vacuoles, some smooth and some coated, of a wide size range, numerous lysosomes, phagosomes and other electron-dense inclusions. It is evidently not, as was earlier claimed, a simple homogeneous layer functioning as a semipermeable membrane, but an intensely active tissue layer across which all transplacental transport must occur.

Glycogen is held to be present in both layers of the trophoblast at all stages but it is not always possible to demonstrate it by histochemical means. Lipid droplets are also present in both layers and free in the core of the villus. In the trophoblast they are found principally within the cytoplasm but also occur extracellularly between cytotrophoblast and syncytium, or between the individual cells of the cytotrophoblast, and also in the basement membrane. These droplets may represent fat in transit from mother to fetus, their numbers diminishing with advancing age. Membrane-bound granular bodies of moderate electron-density also occur in the cytoplasm, particularly in the syncytium; some of these are probably secretion granules of hormones or hormone precursors and are believed to arise in the Golgi apparatus. The lysosomes and phagosomes are evidently concerned in the degradation of materials engulfed from the intervillous space.

In the core of the villus there are fibroblasts, large phagocytic cells termed *Hofbauer cells* which are more numerous in early pregnancy, many plasma cells and free lipid granules. Electron microscopy shows the presence of fine collagen fibres which are thicker and collected into bundles in the villous stems. The fetal vessels include arterioles and capillaries. Their endothelial cells contain fine filaments in the cytoplasm, and they may present bulbous projections into the lumen (Rhodin and Terzakis 1962; Terzakis 1963; Iklé 1961, 1964). They are surrounded externally by the usual periendothelial basement membrane (p. 627).

The characteristics of both syncytium and cytotrophoblast, however, vary considerably from the brief account just given in sites other than a villus and at different stages of development, and for such details original sources should be consulted. There are, however, certain specialized regions of the villous syncytium which should be mentioned.

Many villi show localized ingrowths of syncytium (with some associated cytotrophoblast) into their mesodermal cores; these are termed *stromal trophoblastic buds*. They may remain attached by stems to the overlying trophoblast, or become detached to lie free, and they may even approach and project into the lumina of the fetal blood vessels. In the latter situation they may be a source of the syncytial masses which have been described in the blood of the umbilical vein. The frequency and fate of such fetal cellular emboli is uncertain. On the free surface of the villus two other types of specialization occur. The first, termed syncytial *knots* or *clumps*, are localized thickenings in which there is a close aggregation of a number of nuclei. Their significance has until recently remained obscure but in some cases appears to be related to the maintenance of a neighbouring delicate, non-nucleated, *epithelial plate* of syncytium which comes into particularly close apposition with a fetal capillary. A recent ultrastructural study of syncytial knots (Jones and Fox 1977) has shown that their nuclear aggregates exhibit marked degenerative changes, and it is suggested that they represent a sequestration phenomenon involving removal of senescent nuclear material from adjacent metabolically active areas of syncytium. Fusion of knots from adjacent villi appears to be the basis of *syncytial bridge* formation, and for the latter a mechanical role as an internal placental strut system has been advanced. The second specialization is termed a *syncytial sprout* which continues to be formed throughout pregnancy. Some sprouts are unquestionably initial stages in the development of a new branch villus. Many others, however, project into the maternal bloodstream and become detached, forming syncytial emboli which pass to the maternal lungs. It has been computed that there is a passage of some 100,000 of such sprouts daily into the maternal circulation. In the lungs they provoke little local reaction and apparently disappear by lysis, but they may, on occasion, form a locus for neoplastic growth.

MATURATION AND FUNCTIONS OF THE PLACENTA

In the early stages of placental development the blood in the fetal vessels is separated from the maternal blood in the intervillous space by: the fetal vascular endothelial cells and their basement membranes, the relatively abundant connective tissue of the villus, the subepithelial basement membrane, and its covering of cyto- and syncytial trophoblast. These layers constitute a *placental barrier* which is interposed between the two bloodstreams, but it is a permeable barrier and allows water, oxygen and other nutritive substances and hormones, to pass from the mother to the fetus, and some of the products of excretion to pass from the fetus to the mother.

During the first half of pregnancy the placenta not only increases its surface area, but reaches its maximum thickness. The growth in depth results from increases in the size and length of the villous stems, and is not accompanied by any further invasion of the uterine wall. In the latter half of pregnancy the placenta further increases its surface area, doubling its diameter, but it does not increase in thickness (Stieve 1948; Hamilton and Boyd 1951). (Placental weight has also been correlated with parity—Chakraborty *et al.* 1975.) It therefore tends to fail to keep pace with the functional demands of the growing fetus, but, in compensation, the placental barrier becomes reduced in thickness. After the fourth month the trophoblastic covering of the villi becomes reduced; as it ages the syncytium becomes directly related to the subepithelial basement membrane over an increasing area, and it also becomes thinner. The fetal capillaries approach the surface of the villus but are always separated from the basement membrane of the trophoblast by some delicate connective tissue.

The mechanism of transfer of substances across the placental barrier is complex. The surface area of the villi has been variously estimated; it may, however, be as large as 14 square metres (Wilkin and Bursztein 1958). The volume of maternal blood circulating through the intervillous space has been assessed at 500 ml per minute (Assali *et al.* 1960). Simple diffusion suffices to explain gaseous exchange and a transfer of many dissolved substances of low molecular weight (e.g. sodium, potassium, chloride, iodide, phosphate). In later pregnancy, water is interchanged between fetus and mother (in both directions) at about 3·5 litres per hour. The transfer of substances of high molecular weight such as proteins, lipids and antibodies is not so readily understood. Energy-dependent selective transport mechanisms, including micropinocytosis, are probably involved.

Lipids may be transported unchanged through and between the cells of the trophoblast to the core of the villus. The passage of maternal antibodies across the placental barrier confers some degree of passive immunity on the fetus. The whole problem of investigations into transplacental mechanisms is complicated by the fact that the trophoblast itself is the site of synthesis and storage of certain substances, e.g. glycogen. For a comprehensive

review of placental transfer mechanisms consult Boime and Boguslawski (1974).

The placenta is an important endocrine organ; the steroid hormones, various oestrogens and progesterone, and the proteinaceous placental lactogens, are synthesized by the syncytium, whilst chorionic gonadotrophin is probably secreted by both the syncytium and the cytotrophoblastic cells. It is of interest that steroid hormones are formed in isolated perfused placentae, and also by placental explants in tissue culture. The trophoblast is rich in birefringent lipids, and cytochemical methods show that it also contains enzyme systems which are associated with the synthesis of steroid hormones.

Leucocytes are more numerous in the blood of the umbilical vein than in that of the umbilical artery, suggesting that they may migrate from the maternal blood, through the placental barrier, into the fetal capillaries. It has also been shown that some fetal and maternal red blood cells may cross the barrier (Dancis 1959). The former may have important consequences, e.g. in Rhesus incompatibility (p. 68). The vitamins pass the placental barrier with different degrees of facility; vitamins B, C and D pass readily, whilst the remainder experience greater difficulty.

The majority of drugs pass the barrier and many are apparently tolerated by the fetus, but some may exert grave teratogenic effects on the developing embryo (e.g. thalidomide, *vide infra*).

Finally, a wide variety of bacteria, spirochaetes, protozoa and viruses are known to pass the placental barrier from mother to fetus, although the mechanism of transfer is uncertain. The presence of maternal rubella in the early months of pregnancy is of especial importance in relation to the production of congenital anomalies (*vide infra*).

Placental Variations

As a rule the placenta is attached to the posterior wall of the uterus near the fundus, with its centre in or near the median plane. The site of attachment is determined by the point where the blastocyst becomes embedded but the factors on which this depends are not yet fully understood. The placenta, however, may be attached at any point on the uterine wall, but these variations offer no complications to a normal labour unless it is attached so low down that it overlies the internal os uteri, when it may give rise to serious antepartum haemorrhage, especially if it is nearly central in position. This condition, which occurs in about 0·5 per cent of pregnancies, is known as *placenta praevia*. (*Extrauterine* sites of implantation are discussed on p. 110).

The umbilical cord, although usually attached near the centre of the organ, may reach it at any point between its centre and margin. In the latter event it is known as a *battledore* placenta. Occasionally the cord fails to reach the placenta itself and ends in the membranes in its vicinity. This is termed a *velamentous insertion* of the cord, and the larger branches of the umbilical vessels traverse the membranes before they reach and ramify on the surface of the placenta. A small accessory or *succenturiate* placental lobe is occasionally present connected to the main organ by membranes and blood vessels; it may be retained in the uterine cavity after delivery of the main placental mass and prolong postpartum haemorrhage. Occasionally other types of division of the placenta occur (*bipartite* or *tripartite* placentae). Other placental variations include *placenta membranacea*, in which villous stems and their branches persist over the whole chorion, and *placenta circumvallata*, in which its margin is undercut by a deep groove. Pathological forms of adherence or penetration include—*placenta accreta*, with exceptional adherence to the decidua basalis, *placenta incerta*, in which the myometrium is invaded, and *placenta perceta*, when the invasion by placental tissue has passed completely through the uterine wall.

At birth, when ligature of the umbilical cord is delayed, the blood volume of the child is, on the average, appreciably greater than it is when the ligature is applied at the earliest possible moment (de Marsh *et al.* 1942). It appears that in the former case most of the blood in the fetal placental vessels is transferred from the placenta to the fetus. The meaning of the phenomenon is far from clear, for in the first few days of life after late ligature of the cord the newly born suffers a loss both of plasma volume and of haemoglobin (Gotsev 1939).

Congenital Abnormalities—Teratology

The term teratology was at one time reserved for grosser examples of congenital abnormality—for the study of 'monsters'. Cleft-palate or thalassaemia could scarcely be regarded as monstrosities—something to be pointed at with surprise or aversion. But the Greek τέρας and the Latin *monstrum* both imply pointing of a different kind—a pointing to the future, a warning or portent. In primitive cultures the advent of abnormal offspring or prodigy, whether human or otherwise, was usually accepted as a portent of ill-omen. Hence records of human congenital malformations, in cave-paintings, sculptures, and ultimately in writings, extend backwards into prehistory, as do also theories and beliefs in regard to their causes. Talipes, achondroplasia, and conjoined twins were portrayed in most ancient times, together with centaurs, sirens, mermaids and other fanciful creatures (Barrow 1971). The Hippocratic School identified hydrocephalus. Aristotle described many major and minor malformations with accuracy, but unlike his contemporaries, and his successors through many subsequent centuries, he denied the magical and divinatory aspects of teratology, ascribing 'monsters' to natural causes, a view which was not reawakened until the times of Harvey, Wolff, von Haller, and the Hunters. They and their contemporaries of the seventeenth and eighteenth centuries, stimulated by the growing knowledge of embryology, initiated the *theory of embryonic arrest* to explain malformations. Saint-Hilaire experimented on developing chick embryos in the early nineteenth century, and with this approach the study of teratology was consolidated as a science. In parallel, however, superstition and prejudice persisted, producing for example the 'hybrid theory' which attributed monstrous births to unnatural hybridization, a groundless hypothesis which cost many innocent men and women their lives. Another old theory, which is scarcely dead even today, was the concept that the experiences of the pregnant mother, usually visual, could influence her unborn offspring in an adverse manner. That factors in the *maternal environment* may influence the embryo has, of course, proved true, but in a different sense, for Watson, as long ago as 1749, suggested that fetal disease, contracted by a transplacental route, might be a cause of congenital abnormality, citing variola as an example. This theory slowly dwindled, and was almost extinguished a century later by the authority of Virchow and His, whose views dominated teratological opinion through most of the second half of the nineteenth century. A contemporary, working in obscurity, was Mendel; and as his work became known and genetics flowered into the twentieth century, attention inevitably turned to the hereditary aspect of congenital defects (already foreshadowed by Paré and John Hunter, centuries earlier). In 1941 Gregg's observation that congenital cataract is associated with the infection of pregnant mothers by rubella revived interest in environmental factors. Subsequent to this, teratology has been largely concerned with *genetic* and *environmental factors*, particularly in attempts to explain the mechanisms of abnormal development.

The expansion of experimental embryology has revealed a wide array of *environmental agents* capable of affecting normal development, including temperature variations, mechanical insult, variation in substances such as lithium and magnesium in culture media, irradiation exposure, hypoxia, hypo- and hypervitaminosis, hormonal effects (especially with oestrogens and androgens), nutritional defects, and exposure to various drugs and other chemicals. These experiments have stimulated and illumined research into teratogenic agents. Though much of such work has been pursued on the embryos of fish (minnow), amphibians (frog), and birds (chick), experiments on mammals in producing cleft palate, anophthalmia and other abnormalities suggest that similar mechanisms must operate in human maldevelopment. The identification of human teratogens may be said to have commenced with Gregg's demonstration of the effects of rubella virus. Other viral and bacterial maternal infections have since been implicated. But with the multiplication of drugs, for such purposes as abortion (aminopterin) and sedation (thalidomide), some of which have proved tragically teratogenic, teratological research has been much concentrated

upon drugs. In parallel with this, however, has been the recognition of the genetic conditioning of a growing list of abnormalities (McKusick 1975), including metabolic aberrations (Garrod 1963). These remain the two major fields of current teratology, pharmacological and genetic.

While the great volume of recorded research has led to the identification of a large number of causal agents, the detailed mechanisms by which these produce abnormalities are for the most part obscure. In some cases it is clear that normal embryonic processes are delayed, arrested, or accelerated, leading to agenesis or to varying degrees of hypoplasia or hyperplasia. The recognition that cell death plays a normal role in prenatal growth and differentiation, leading to the disappearance, modelling, or reduction of structures (p. 79), has been extended to explanations of congenital defects. The available evidence (Henkes *et al.* 1970) suggests that cell death is a major factor in developmental aberrations associated with viruses, irradiation, nutritional defects and hypervitaminoses. Local hyper- or hypo-plasia and disturbed morphogenetic movements of cells may obviously produce distortions of normal development. It cannot be doubted that such factors as these are concerned, but in most cases the explanations are partial and missing links in the causal chain persist (Saxén 1970; Johnston and Platt 1975). This is not surprising, since the precise march of events in much of normal development is still imperfectly known.

A very large number of cytotoxic agents are now known, and many have been used as experimental teratogens, mostly on rodents. Some act as antimetabolites, amino-acid antagonists, anti-purines or spindle toxins, and most are highly selective in their effects, which are produced only by *controlled dosage* at *specific periods* during development. Connors (1975) has collated two decades of reports in this field, emphasizing the complex array of variable parameters which help to determine whether an agent acts as a teratogen or not. These include embryonic age, the amount, route and mode of administration of the agent, placental and embryonic permeability, maternal or embryonic ability to inactivate the agent, the state of differentiation of target cells and their ability to recover. Sullivan (1975) has reviewed the literature concerning teratogenic drugs taken by pregnant women, classifying them on their sites of action, whether directly on the embryo (thalidomide, tetracycline antibiotics), on embryonic endocrine balance (oestrogens and androgens), on the placenta, or on maternal tissues. These considerations are, of course, of intense clinical importance, but their contribution to *explanations* of teratogenic *mechanisms* is limited, except in so far as some drugs are known to be teratogenic at specific stages of development.

Genetic conditioning of congenital abnormalities, whether structural, metabolic, or behavioural, has been the subject of very widespread research and observation. A long list of inheritable defects has accumulated (McKusick 1975). According to Polani (1973) about a third of recognized defects in the newborn are due to single gene abnormalities, a further twelfth to chromosomal errors, and a further substantial, but unknown, fraction to polygenic interaction. About 2,000 birth defects occur in mankind which are either known to have, or are presumed to have, a genetic background. Of these 1,700 are probably autosomal and 150 sex-linked (McKusick 1975). Although much information is thus available which may prove of great value in genetic counselling, complete mechanisms from disturbed DNA coding to actual phenotypic expression of particular deformities or other aberrations are not likely to be definable. Such explanations are dependent upon a more complete knowledge of embryonic processes than is yet available. Presumably, different genetic errors may operate at different stages in the procession of events through multiplication, determination, aggregation, morphogenetic movement, differentiation, localized proliferation and cell death, each of which is itself a complex of biochemical activities. In some examples, however, it is possible to demonstrate or to hypothecate such events in detail, normal and abnormal metabolic processes in bacteria providing the most successful field. One of the earliest, if not the first of human abnormalities to be identified as genetic was alkaptonuria, now known to be due to deficiency of a single enzyme (homogentisic acid oxidase) and hence, presumably, to a single gene disturbance. Although the locus of the latter is not established as yet, the biochemical sequence during which 'alkapton' is produced is fully clarified. In sickle-cell anaemia, which is inherited as a Mendelian recessive characteristic, there is demonstrably a defect in the production of the protein moiety of the haemoglobin molecule (in fact an amino-acid substitution). The actual 'sickling' of erythrocytes only occurs in conditions of local oxygen concentration, an interaction between genetic effect and environmental factor which appears to be involved in the development of many basically genetic abnormalities. In the case of more elaborate structual deformities it is obvious that complete explanations are dependent upon adequate clarification of embryogenetic processes as noted above.

A relatively common example of an autosomal genetic abnormality often cited is the complex termed Down's Syndrome (mongolism), which occurs in 1 in 600 live births. It is due to a trisomy or tripling of chromosome No. 21. The incidence of Down's Syndrome increases with maternal age, suggesting that the aetiology is complicated and may not be simply genetic. The discovery that sex chromosomes can be identified has expedited the recognition of several sex-linked conditions, although, of course, familial history alone had indicated the sex-linked nature of haemophilia at a much. earlier date. In Klinefelter's Syndrome, which is characterized by testicular atrophy and hence sterility and eunuchoidism, associated with a variable depression of intelligence, there is a condition of X-polyploidy, such as XXY, XXXY and even higher states of X. Development of the gonad into a testis is ensured by the Y chromosome, and the additional X chromosomes presumably retard differentiation. In another congenital deviation, Turner's Syndrome, which features dwarfism, rudimentary ovaries, amenorrhoea and failure of the appearance of secondary sexual characteristics, the Y chromosome is absent (XO) or imperfect. A similar sex inversion (XX) occurs in males. As in the case of autosomal abnormalities, sex-linked chromosomal defects are common in spontaneously aborted individuals. (XO is said to be the commonest, at about 1 per cent of all conceptions.)

It is clear from the foregoing that although the exact causology of the great majority of human congenital malformations is uncertain, the role of genetic and environmental factors (including teratogenic drugs) cannot be doubted. Wherever adequate familial studies can be established there is frequently an indication of genetic mechanism. However, an increased frequency of certain abnormalities may be equally associated with depressed socio-economic status, climate, or geographical regions, and maternal age.

Epidemiological studies of congenital aberrations are of considerable interest and value, not only in genetic counselling, but also in attempts to unravel the complex problems of causation. The incidence of congenital abnormality may be as high as 6 per cent in surviving infants. With the decline in incidence of, and death from, infectious and nutritional diseases, congenital abnormality is assuming a proportionately greater importance in the medical care of many populations. Several large epidemiological surveys, carried out in many countries, are now available (Kennedy 1967; Stevenson 1966; WHO 1972). These show not only the overall incidence of abnormality, but also the comparative frequency of various malformations, and the regional and racial variations which some display. For example, neurulation defects such as anencephaly and spina bifida, while being relatively frequent abnormalities, also show much variation in frequency (particularly high incidences have been recorded in Belfast and Bombay). Galactokinase deficiency was identified about 15 times more often in a Canadian series (Manitoba) than in the U.S.A. (Massachusetts). Such variations are at present largely inexplicable; but the well-known coincidence of sickle-cell gene for haemoglobin S, and of the thalassaemia trait, with the distribution of malaria are interesting exceptions.

The prenatal identification of certain malformations and aberrations must be mentioned. Aminocentesis and examination of the amniotic fluid and its suspended cells permits the diagnosis of some metabolic disorders, and potentially all chromosomal aberrations. It is of particular value in conditions of high incidence and early lethal effect such as Tay-Sachs disease, which occurs about 100 times more often in Ashkenazi Jews than in other

races. Radiology alone may reveal anencephalic or hydrocephalic fetuses (Russell 1969); but the hazards of this technique have led to the substitution of ultrasonography, which is presumed to be safer and can discover similar conditions (Santos and Duenhoelter 1975; Taylor 1978). Amniography consists in radiological examination after the injection of a water-soluble radio-opaque substance into the amniotic fluid; fetography is a variant of this technique which employs an oily radio-opaque injectant (Wiesenhaan 1972). By absorption of the radio-opaque substance in the vernix caseosa, the latter technique is claimed to yield clearer delineation of surface features (For literature consult Persaud 1977).

Twinning

Twinning occurs once in about every eighty births. The twins may be *dizygotic* (binovular or fraternal) or *monozygotic* (uniovular or identical), of which the former occurs more frequently. Twin boys are most common, less common are a boy and a girl and least common two girls.

Dizygotic twins result from the discharge and fertilization of two ova, either from two separate or a single ovarian follicle. Each embryo develops in its own chorionic sac, but occasionally synchorial fusion occurs. The twins are of different genetic constitution and may be of the same or different sex. They bear no greater resemblance to one another than do other siblings of the same family. There is evidence that dizygotic twinning may be hereditary. The development of ovarian follicles, and the release of ova at ovulation, is under the hormonal control of circulating *gonadotrophins* produced by the β cells of the anterior lobe of the hypophysis cerebri. The control mechanisms are far from clear, but it has been demonstrated in a variety of mammals that raising the circulating gonadotrophic level by injections increases the number of ova discharged (Hammond 1961). Similar considerations apply to women who have had such treatment for long-standing amenorrhea (Gemzell and Roos 1966). In one series of about 100 cases so treated there were 43 pregnancies including 20 singletons, 14 twins, 2 triplets, 3 quadruplets, 1 quintuplet, 2 sextuplets and 1 septuplet.

Monozygotic twins arise from a single ovum fertilized by a single sperm. At some stage up to the establishment of the axis of the embryonic area and the development of the primitive streak the formative material separates into two parts, each of which gives rise to a complete embryo. The twins may share one or have independent chorionic sacs and possess an individual or a common amniotic sac. The twins are of the same sex, have the same blood groups and tissues of identical antigenic potencies. They resemble each other closely. Monozygotic twinning is a hereditary character.

Interestingly, a number of workers have suggested that in addition to the widely recognized two foregoing types, a *third type* of twin (with several variants) may exist. Essentially this type is *uniovular* but *dispermatic* following an irregular meiotic cycle during oögenesis. It is considered that either the ovum, or the secondary oöcyte, or the primary oöcyte may undergo an equal cytoplasmic division (instead of throwing off a diminutive polar cell). Evidently each of the three variants would have different degrees of genetic dissimilarity depending upon the stage at which such an equal division occurred.

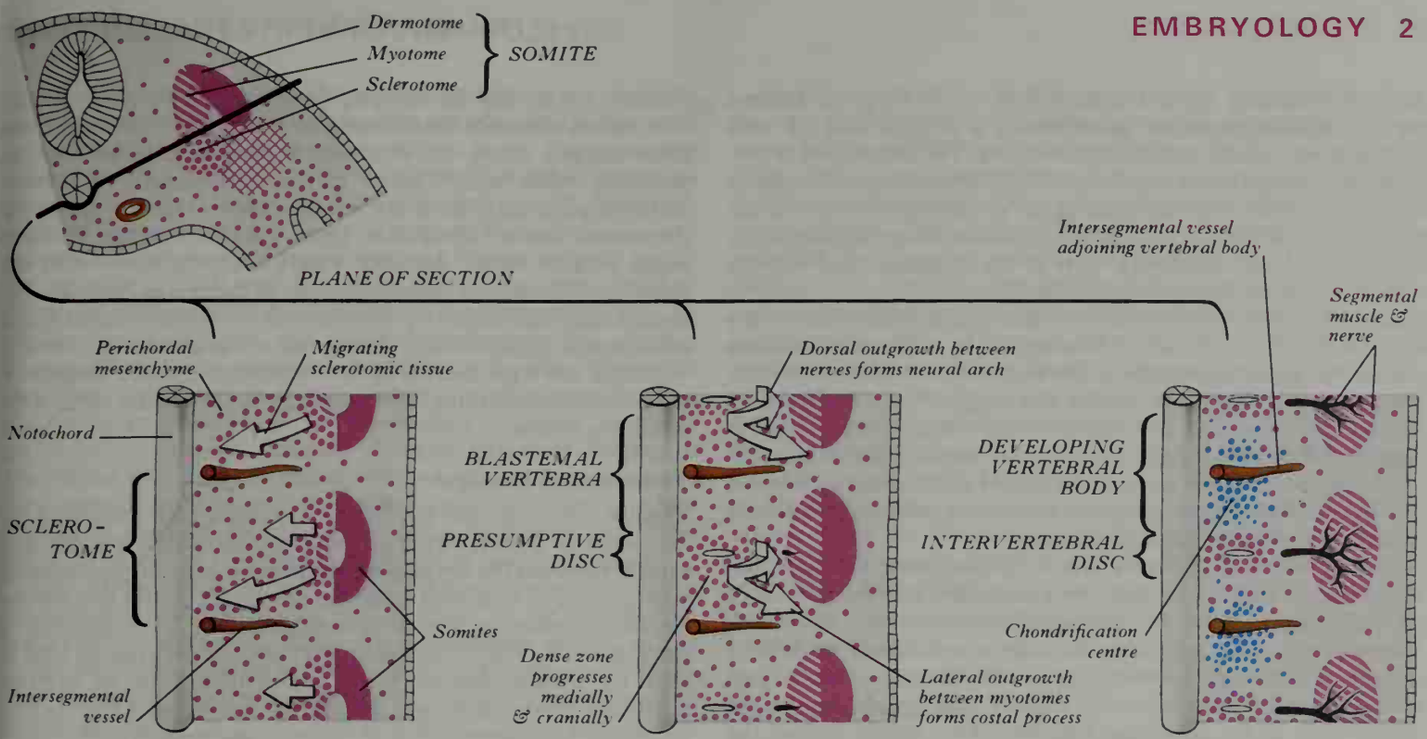
Multiple births greater than twinning, such as triplets or quadruplets, can arise from multiple ovulations or a single ovum, the formative material of which later separates into several parts, or from a combination of these mechanisms.

Conjoined twins or double monsters arise from the incomplete division of the formative material of a single early ovum. There is, however, no evidence that the condition is hereditary or that it occurs more frequently in families given to uniovular twinning. The conjoined twins are usually united by corresponding regions and the degree of duplication of parts varies.

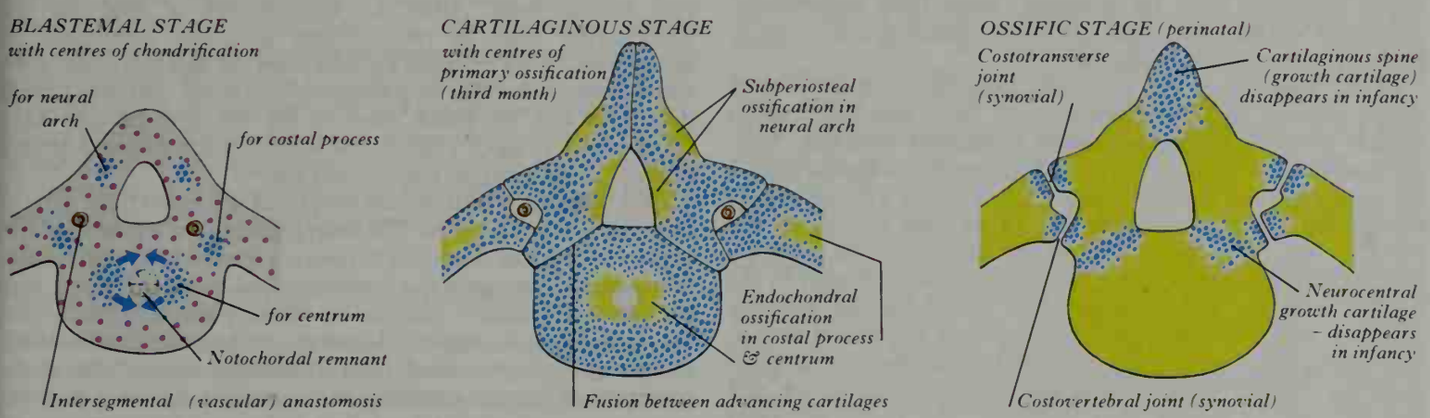
For an excellent review of the types, frequency, inheritance and embryology of twinning, the diagnosis of zygosity, the course and outcome of twin pregnancies, their possible evolutionary significance, and some post-natal characteristics of twins, the interested reader should consult Bulmer 1970.

DEVELOPMENT OF INDIVIDUAL SYSTEMS

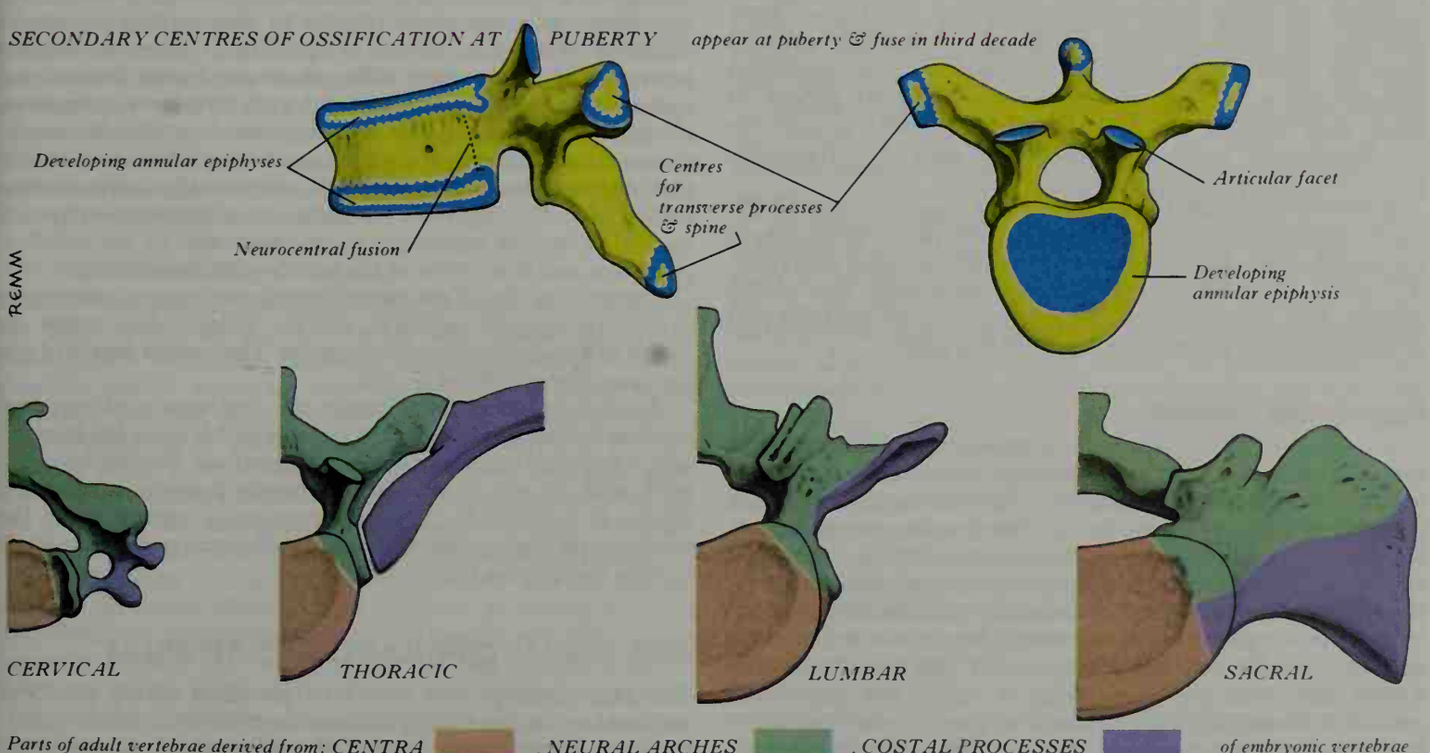
Development of the embryo has so far been considered as a whole, but, as the definition of its structures proceeds, overall description becomes so complicated as to be an actual impediment to clarity of appreciation of the events occurring. It is hence customary and convenient to limit attention to individual systems in their further development; but it must never be overlooked that the analysis of a whole organism into such divisions—however attractive on morphological and functional grounds—is largely a product of the sequential nature of human perception. Not only do the several systems into which we divide the organism develop simultaneously, they also interact and modify each other. This necessary interdependence is not only supported by the evidence of experimental embryology, but is also emphatically demonstrated by the phenomena of growth anomalies, which cut across the artificial boundaries of systems in most instances. For these reasons it is most desirable that the development of any one individual system should be frequently related to others, especially those most closely associated with it.



So far the development of the embryo has been taken to an age of between 3 and 4 weeks, the stage of early somite formation, equivalent to Horizons X or XI (*see* p. 222) on the scale established by the studies of Streeter and others (Streeter 1942–51). It is only partly constricted from the yolk sac, but the head and tail folds are well formed, with enclosure of the foregut and hindgut (proenteron and metenteron). The forebrain projection dominates the cranial end of the embryo, the oropharyngeal membrane and cardiac prominence being caudal and ventral to this. The intraembryonic mesoderm has begun to differentiate, and its paraxial region is undergoing segmentation into somites. The neural groove is in process of closure and is separated from the dorsal aspect of the gut by the notochord. The earliest blood vessels have appeared and a primitive tubular heart occupies the pericardium. The chorionic circulation is about to be established, after which event the embryo will be completely dependent for its requirements upon the maternal bloodstream. The intraembryonic part of the coelom consists of the pericardial cavity, leading dorsally into the caudally directed right and left pericardioperitoneal canals, and the peritoneal cavity, into which the two canals open caudal to the septum transversum, thus establishing free communication with the extraembryonic coelom (**2**.31).



Development of the Skeletal System



The skeleton is a derivative of mesoderm (and in some parts neural crest), including not only its axial and appendicular divisions but also all accessory ossicles such as sesamoid bones and the osseous and cartilaginous elements of the branchial arches. Most of these parts pass through a first, *blastemal stage* of mesenchymal condensation, and a second, *cartilaginous stage* before becoming ossified. In some bones, however, ossification follows immediately upon the blastemal stage, the intermediate phase of chondrification being omitted (p. 260). (For a review of embryonic cartilage *see* Glenister 1976. Noback and Böving, 1962 and Tanaka, 1976, have recorded extensive observations of the times of appearance of centres of chondrification in human embryos.)

THE SKELETAL AXIS

Before reaching its final condition the skeletal axis passes through three preliminary states (Präder 1947; Sensenig 1949; Peacock

2.50 Sequential diagrams of vertebral development from early somitic and perichordal stages through blastemal, cartilaginous, and pre- and post-natal ossificatory stages. For views concerning segmentation see text. Bottom row indicates principal morphological parts of adult vertebrae.

1951–2; Walmsley 1953; Tondury 1958; **2**.50). First it is formed by the **non-segmental notochord**, a flexible rod of cells enclosed by a thick, membranous sheath. The notochord is not, however, limited to the region in which the vertebrae will replace it, for it extends into the head as far as the caudal limit of the hypophysis cerebri, this cranial extension being subsequently incorporated into the basilar part of the occipital bone and the dorsal part of the body of the sphenoid (**2**.51).

In the second stage of the skeletal axis, the notochord serves as a framework around which a **blastemal** or **mesenchymatous vertebral column** is formed. On each side the fusiform cells of the sclerotomes multiply rapidly and migrate ventromedially to enclose the notochord in a mesenchymal sheath (**2**.29), which at first retains a semblance of its segmental origin. Sclerotomic cells later migrate dorsally around the spinal cord, passing between and lateral to the spinal ganglion rudiments, and ventrolaterally into the intervals between myotomes.

Around the notochord each sclerotomic segment is divided into equal cranial and caudal parts by a transitory transverse split or loosening between the two groups of cells to form a *sclerotomic fissure* (**2**.50). The adjoining mesoderm condenses to form a transverse plate, a *perichordal disc*, and the less dense, caudal part of one segment fuses with the slightly smaller and less dense cranial part of the adjoining segment. This fusion defines the centrum of a vertebra. In the dorsal extensions of the sclerotomes segmental condensations between the spinal ganglia define the neural arch and, later, its processes, while their ventrolateral extensions outline the costal processes, which are continuous medially with the perichordal disc.

In the third stage the vertebral components become more clearly defined, and chondrification of these mesenchymatous models produces a **cartilaginous vertebral column**. Each centrum is chondrified from a pair of centres which appear during the sixth week and quickly coalesce. Each half of a neural arch is chondrified from a centre starting in its base and extending ventrally into the pedicles, to meet and blend with the centrum, and dorsally into the laminae; but the latter do not meet in the midline until the fourth month. The transverse and articular processes are chondrified in continuity with the neural arches; intervening zones of mesenchyme which do not become cartilage mark the sites of intervertebral and costovertebral joints, and synovial cavities appear later in these. The costal processes chondrify separately, and in the thoracic region they extend ventrally, the more cranial members curving round in the body wall to reach the developing sternal plates. They are separated from the developing transverse processes by non-chondrified mesenchyme in which the costotransverse joints will appear. At other than thoracic levels the developing costal process (or pleurapophysis) becomes incorporated into the 'transverse process' of descriptive adult anatomy (**2**.50).

In both the blastemal and chondrifying stages, the cranial and caudal aspects of each perichordal disc proliferate, contributing to the growth of adjoining centra and eventually merging with them. The main, intermediate mass of each perichordal disc (which contains the sclerotomic fissure), together with the enclosed part of the notochord, becomes an *intervertebral disc*.

Hypochordal Elements

A structure which, though present during the blastemal stage, only becomes clearly recognizable as an entity during chondrification is the *hypochordal arch* or bow. This connects the vertebral ends of two costal processes to each other and spans the ventral surface of a centrum; it is associated only with the first three or four cervical vertebrae in man. Only in the case of the *atlas* does the hypochordal arch persist, chondrify, and become ossified during the first post-natal year; it forms the anterior arch and the ventral parts of the lateral masses of this vertebra. (The hypochordal arch may correspond to the paired intercentra, ventral elements in the development of vertebrae in many other animals. They may persist at any level, forming such arrangements as haemal or intercentral arches, which enclose the caudal vessels.) The homologies of the various elements which fuse to form vertebrae are still subject to disagreements (Jollie 1962). It does, however, now appear certain that the original concept of Gadow (1933), that all tetrapod vertebrae can be derived from four paired elements (basidorsals, basiventrals, interdorsals and interventrals) must be abandoned. Subsequent authorities, provided with much more extensive evidence, especially embryological data, have not substantiated Gadow's somewhat theoretical views (Mookerjee 1936; Devillers 1954; Williams 1959; Jenkins 1969). Another widely accepted view—that the centrum of the atlas is united with that of the axis as its dens—has been thrown into doubt by observations on developmental stages in mammals (Jenkins 1969). In the case of the axis and succeeding vertebrae the hypochordal arches degenerate, either disappearing entirely or becoming incorporated into the ventral parts of the adjoining centra.

Notochordal Vestiges

The notochord can still be identified for some time traversing the cartilaginous centra, but these parts of it ultimately atrophy and vanish. Between the developing vertebrae it expands as localizing aggregations of cells with intervening mucoid matrix to form the *nucleus pulposus* of the intervertebral disc. This nucleus is surrounded by the intermediate part of each perichordal disc to form the *annulus fibrosus*, which differentiates into an external laminated fibrous zone and an internal cuff around the nucleus pulposus. This inner zone contributes to the growth of the outer, and near the end of the second month of embryonic life it begins to merge with the notochordal tissue, being ultimately converted into fibrocartilage. After the sixth month of fetal life the notochordal cells in the nucleus pulposus commence to degenerate, being replaced by cells from the internal zone of the annulus fibrosus. This degeneration continues until the second decade of life, by which time all the notochordal cells have disappeared (p. 445). Thus, in the adult, notochordal vestiges are limited, at the most, to non-cellular matrix.

Each vertebra is thus usually described as formed from parts of two adjacent sclerotomes. The rearrangement of segmentation is said to result in an alteration in position of vertebrae with respect to myotomes, bringing the intersegmental vessels into line with the vertebral bodies, a relationship which persists in the lumbar and lower thoracic regions. However, an extensive study of the behaviour of the perichordal and sclerotomic mesenchyme in the embryos of sheep suggests that, in this species at least, 'resegmentation' of this kind does not occur, the primordia of vertebrae arising in their definitive positions, without any movement into new sites relative to surrounding structures (Verbout 1976). The essence of this view is that the vertebral *processes* and *centra* have different mesenchymal origins, the former from cells closely associated with myotomes (*sclerotomic tissue*), the latter from the non-segmented *perichordal mesenchyme*. The processes develop in a caudal condensation within their segment and are caudal to the numerically corresponding spinal nerve. It is suggested that a *gradient of segmentation* spreads medially from the myotomes to the precursors of the vertebral processes, and from these to the perichordal tissue (**2**.50).

Towards the end of the second month ossification commences in the cartilaginous vertebrae, and the column then enters the fourth and last stage in its development. The further details of this are described elsewhere (p. 282).

Applied Anatomy. Occasionally the coalescence of vertebral laminae is incomplete, a cleft of variable width being left through which dura and arachnoid mater may protrude. Part of the spinal cord, with its pia mater, also commonly projects, a condition known as *spina bifida*. The malformation is commonest in the lumbosacral region, but may occur at thoracic or cervical levels or even throughout the column.

RIBS, COSTAL CARTILAGES AND STERNUM

The ribs develop from the costal processes of the primitive vertebral arches, extending between the myotomic muscle plates. In the thoracic region (**2**.50C) of the vertebral column these processes grow laterally to form a series of *precartilaginous ribs*. The transverse processes grow laterally behind the vertebral ends of the costal processes, at first connected by mesenchyme, which later becomes differentiated into the ligaments and other tissues of

the costotransverse joints. The costocentral joints are similarly formed from mesenchyme between the proximal end of the costal processes and centra. In *cervical vertebra* (**2**.50) the transverse process is dorsal to the foramen transversarium, while the costal process, corresponding to the head and neck of a rib, limits the foramen ventrolaterally. The distal parts of these cervical costal processes do not develop, but occasionally they do so in the case of the seventh cervical vertebra, even developing costovertebral joints. Such *cervical ribs* may even reach the sternum (p. 283). In *lumbar vertebrae* (**2**.50) the costal processes do not develop distally, but their proximal parts become the 'transverse processes' of these vertebrae, whose morphologically *true* transverse processes may be represented by their accessory processes (p. 279). Occasionally movable ribs may develop in association with the first lumbar vertebra. Only the upper two or three *sacral costal processes* usually develop (**2**.50). They fuse into the lateral mass of the sacrum, forming its ventral part. The *coccygeal* vertebrae are apparently devoid of costal processes.

The sternum is formed from bilateral mesenchymatous condensations, sternal plates, which begin in the dorsolateral region of the body wall. They are immediately ventral to the rudiments of the clavicles and ribs, but are independent of them in their formation, in so far as experiments on their primordia in the mouse can testify to the human condition (Chen 1952). These plates chondrify, move ventrally towards each other from both sides as the costal processes lengthen, and they eventually fuse together across the midline in a craniocaudal direction. This forms a longitudinal cartilaginous bar, with which the clavicles and upper seven pairs of costal cartilages establish contact. The xiphoid process develops as a caudal extension of the sternal bar. Hypertrophy of the cartilage cells as a preliminary to ossification occurs opposite future intercostal spaces, as the first indication of segmentation of the sternum into manubrium, four sternebrae for the 'body', and xiphoid process. The ossification and further growth of the sternum and ribs is described later (pp. 287, 290).

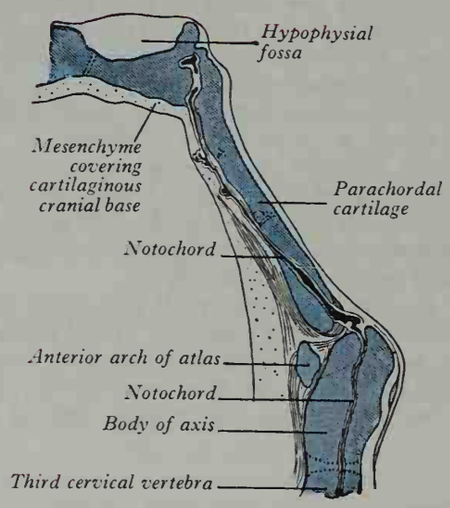
DEVELOPMENT OF THE CRANIUM (2.51)

The bones of the skull are developed in the mesenchyme which surrounds the cerebral vesicles; but, before the osseous state is reached, the cranium passes through blastemal and cartilaginous stages, like other parts of the skeleton. However, not all parts pass through a phase of chondrification; and hence the *chondrocranium*, which includes all those bones doing so, is incomplete. Most of the cranial vault and parts of its base are not preformed in cartilage. Though the mesenchymatous (membranous) and cartilaginous parts of the skull will be considered in sequence, they develop together and complement each other in forming the complete cranium, some of whose bones are composite structures derived from both sources. All elements, of course, pass first through a mesenchymatous phase.

The Desmocranium

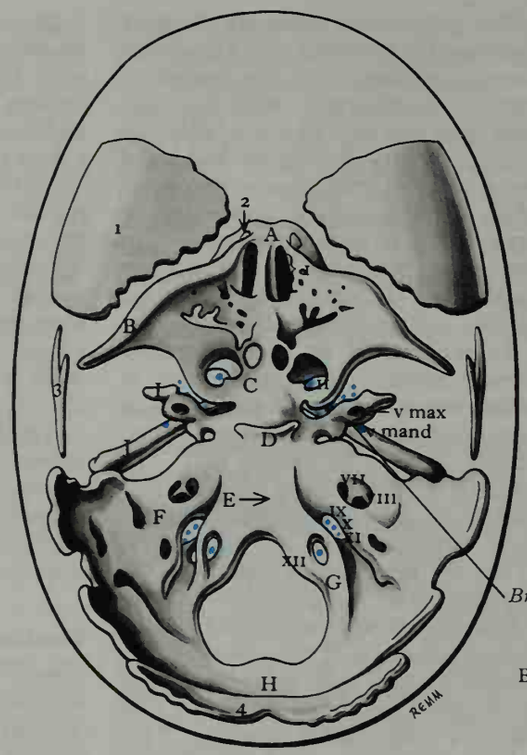
The blastemal skull (desmocranium) begins to appear at the end of the first month as a condensation and thickening of the mesenchyme which surrounds the developing brain, forming localized masses which are the earliest distinguishable cranial elements. The first masses evident are in the occipital region, outlining the basilar part of the occipital bone. These form an *occipital plate*, from which two extensions on each side grow laterally to complete a foramen around each hypoglossal nerve. At the same time the mesenchymal condensation extends forwards, dorsal to the pharnyx, to reach the primordium of the hypophysis, thus establishing the clivus of the cranial base and the dorsum sellae of the future sphenoid bone. Early in the second month it surrounds the developing stalk of the hypophysis and extends ventrally between the two halves of the nasal cavity, where it forms the anlage of the ethmoid bone and of the nasal septum. The notochord traverses the occipital plate obliquely, being at first near its dorsal surface and then lying ventrally, where it comes into close relationship to the epithelium of the dorsal wall of the pharynx, being for a time fused with it. It then re-enters the cranial base and runs ventrally to end just caudal to the hypophysis (**2**.51).

During the fifth week the two *otocysts* (auditory vesicles) become enclosed in their mesenchymal *otic capsules*, which are soon differentiated into dorsolateral *vestibular* and ventromedial *cochlear* parts, enveloping the primordia of the semicircular canals and the cochlea. Between these two regions the facial nerve lies in a deep groove. The otocysts fuse with the lateral processes of the occipital plate, leaving a wide hiatus through which the internal jugular vein and the glossopharyngeal, vagus, and accessory nerves pass. At this stage the mesenchyme around the developing hypophysial stalk, which is forming the rudiment of the postsphenoid part of the sphenoid bone, spreads out laterally to form the future greater wings of this element. Smaller processes ventral to this indicate the sites of the lesser wings of the sphenoid, while other condensations reach the sides of the nasal cavity and also blend with the still mesenchymatous septum.



The first signs of the vault or neurocranial part of the skull appear about the thirtieth day; they consist of curved plates of mesenchyme at the sides of the skull and gradually extend cranially to blend with each other; they also extend towards and reach the base of the skull, which will become part of the chondrocranium.

The Chondrocranium



Chondrocranium (**2**.51) is a term applied to the parts of any vertebrate skull which pass through, and sometimes remain in, a cartilaginous stage. (In *Chondrichthyes*, the cartilaginous fishes, such as sharks, all the cranium chondrifies and persists in this state—*see* p. 295.) The crania of all land animals, the tetrapods, contain variable regions which ossify directly from mesenchyme. Such *dermal* (membranous) elements form much of the cranial vault, and in mammals chondrification is limited to the basal regions of the skull (**2**.51). In mammals this change occurs primarily in three regions: (1) dorsally, in relation to the notochord; (2) intermediately, in relation to the hypophysis; and (3) ventrally, between the orbits and the nasal cavity. These may be named *parachordal*, *hypophysial*, and *interorbitonasal* regions. The parachordal cartilage is developed from the mesenchyme related to the cranial end of the notochord; caudally it exhibits traces of four primitive segments separated by the roots of the hypoglossal nerves. The hypophysial cartilage ossifies to form the postsphenoid part of the sphenoid bone, but its morphological status is uncertain. The interorbitonasal cartilage is perhaps to be equated with the trabeculae cranii of lower vertebrates and is usually known as the *trabecular cartilage*, which is a bilateral structure, developing from two centres of chondrification The trabeculae cranii may largely be derived from branchial arch (neural crest) mesoderm, i.e. from the **viscerocranium**, having been adapted into the cartilaginous or basal part of the **neurocranium**, or 'brainbox'. From the evidence in embryos of earlier vertebrates, most of the chondrocranium and the majority of the viscerocranium are derived from neural crest tissue, including almost all of the branchial skeleton. Only the caudal parts of the trabeculae, the parachordal parts of the trabeculae, the parachordal bars, the otic capsules and the second basibranchial appear to be derived from general head mesenchyme. For these and other details of development and morphology of the mammalian chondrocranium, see references (Fawcett 1911, 1917, 1918; de Beer 1937; Stone 1926; Hörstadius 1950; Stark 1965; Balinsky 1975).

In the human embryo chondrification of the cranium begins in the second month, the first cartilaginous foci appearing in the occipital plate, one on each side of the notochord (parachordal cartilages); these later fuse—at about the end of the seventh week—around the notochord, whose oblique transit through the region has already been mentioned above (**2**.51). The cartilage of the posterior part of the sphenoid is formed from two hypophysial centres, which flank the stalk of the hypophysis, uniting at first behind it and then in front, thus enclosing a *craniopharyngeal canal* containing the hypophysial diverticulum. The canal is usually obliterated by the third month; its association with the derivation of the anterior lobe of the hypophysis from the pharyngeal diverticulum of Rathke has been denied (p. 199).

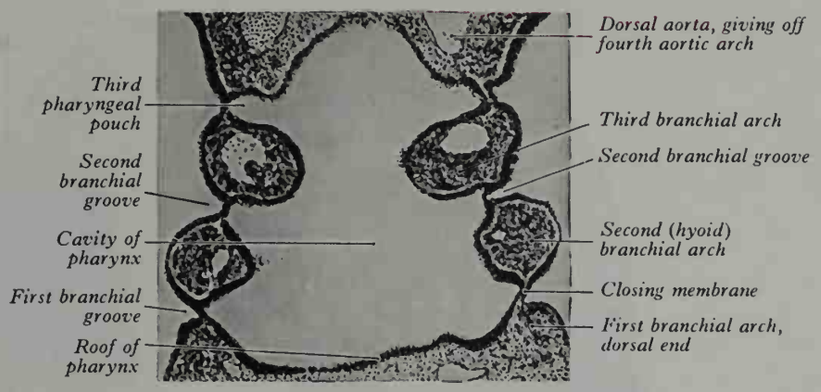
capsule, in turn become chondrified. The nasal capsule is well developed by the end of the third month, consisting of a medial septal part and two lateral regions. The free caudal border of each lateral part becomes incurved to form the inferior nasal concha, which ossifies during the fifth month and becomes a separate element. Posteriorly the lateral part of the nasal capsule becomes ossified as the ethmoidal labyrinth, bearing on its medial surface ridges which become the middle and superior conchae. Part of the rest of the capsule remains cartilaginous as the septal and alar cartilages of the nose, part is replaced by the mesenchymatous vomer and nasal bones.

The ventral surface of the chondrocranium is associated with the cartilages of the branchial arches, the *viscerocranium*, the development of which will be considered later (*vide infra*). The bones of the cranial base which are thus preformed in cartilage are the occipital (excepting the upper part of its squama), the petrous part of the temporal, the body, lesser wings, and roots of the greater wings of the sphenoid, and the ethmoid. These constitute the cartilaginous part of the neurocranium, the rest of which, the

2.53A Schema of developing branchial region showing (left) the pharyngeal floor and sectioned lateral walls, viewed from the dorsal aspect, and (right) details of generalized branchial constituents, including arches, endodermal pouches and ectodermal grooves. (Modified in part from *Basic Human Embryology*, by Williams, Wendell-Smith and Treadgold, 1969.)

mesenchymatous (membranous) neurocranium, corresponding to the cranial vault, is not preformed in cartilage. Its elements, frequently described as *dermal* bones because of their probable origin (p. 295), are the frontal bones, the parietals, the squamous parts of the temporal bones, and the upper (interparietal) part of the occipital squama. To summarize, therefore, the base of the skull—except for the orbital plates of the frontal and the lateral parts of the greater sphenoidal wings—is preformed in cartilage, while the whole of the vault is ossified directly in mesenchyme (**2**.51 B–F).

Ossification commences before the chondrocranium has fully developed, and as this change extends, bone overtakes cartilage until little of the chondrocranium remains. However, parts of it still exist at birth, and small regions remain cartilaginous in the adult skull. At birth unossified chondrocranium still persists at the following points: (1) the alae and septum of the nose; (2) in the sphenoid bone (p. 326); (3) the speno-occipital and spheno-petrous junctions (p. 330), (4) the apex of the petrous bone (foramen lacerum); and (5) the occipital bone. The further development of these areas and of the cranial bones in general is included with their individual descriptions (*see* Section 3, Osteology, p. 293).



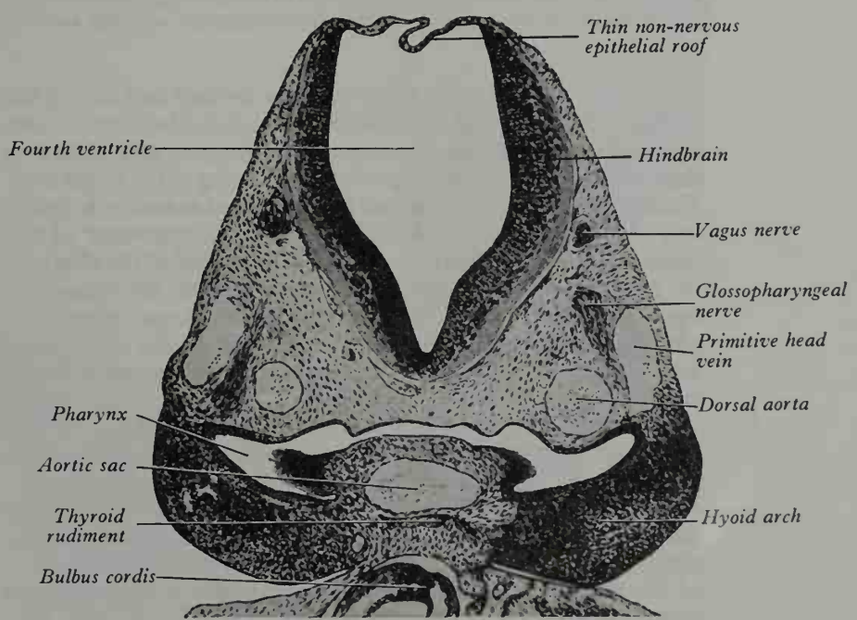
The Viscerocranium

Certain of the cranial components are derived from the branchial or visceral arches, the *viscerocranium*, and therefore this part of skeletal development will be considered next, before that of the appendicular skeleton (p. 153). It will also be convenient to include a general consideration of the branchial apparatus at this point.

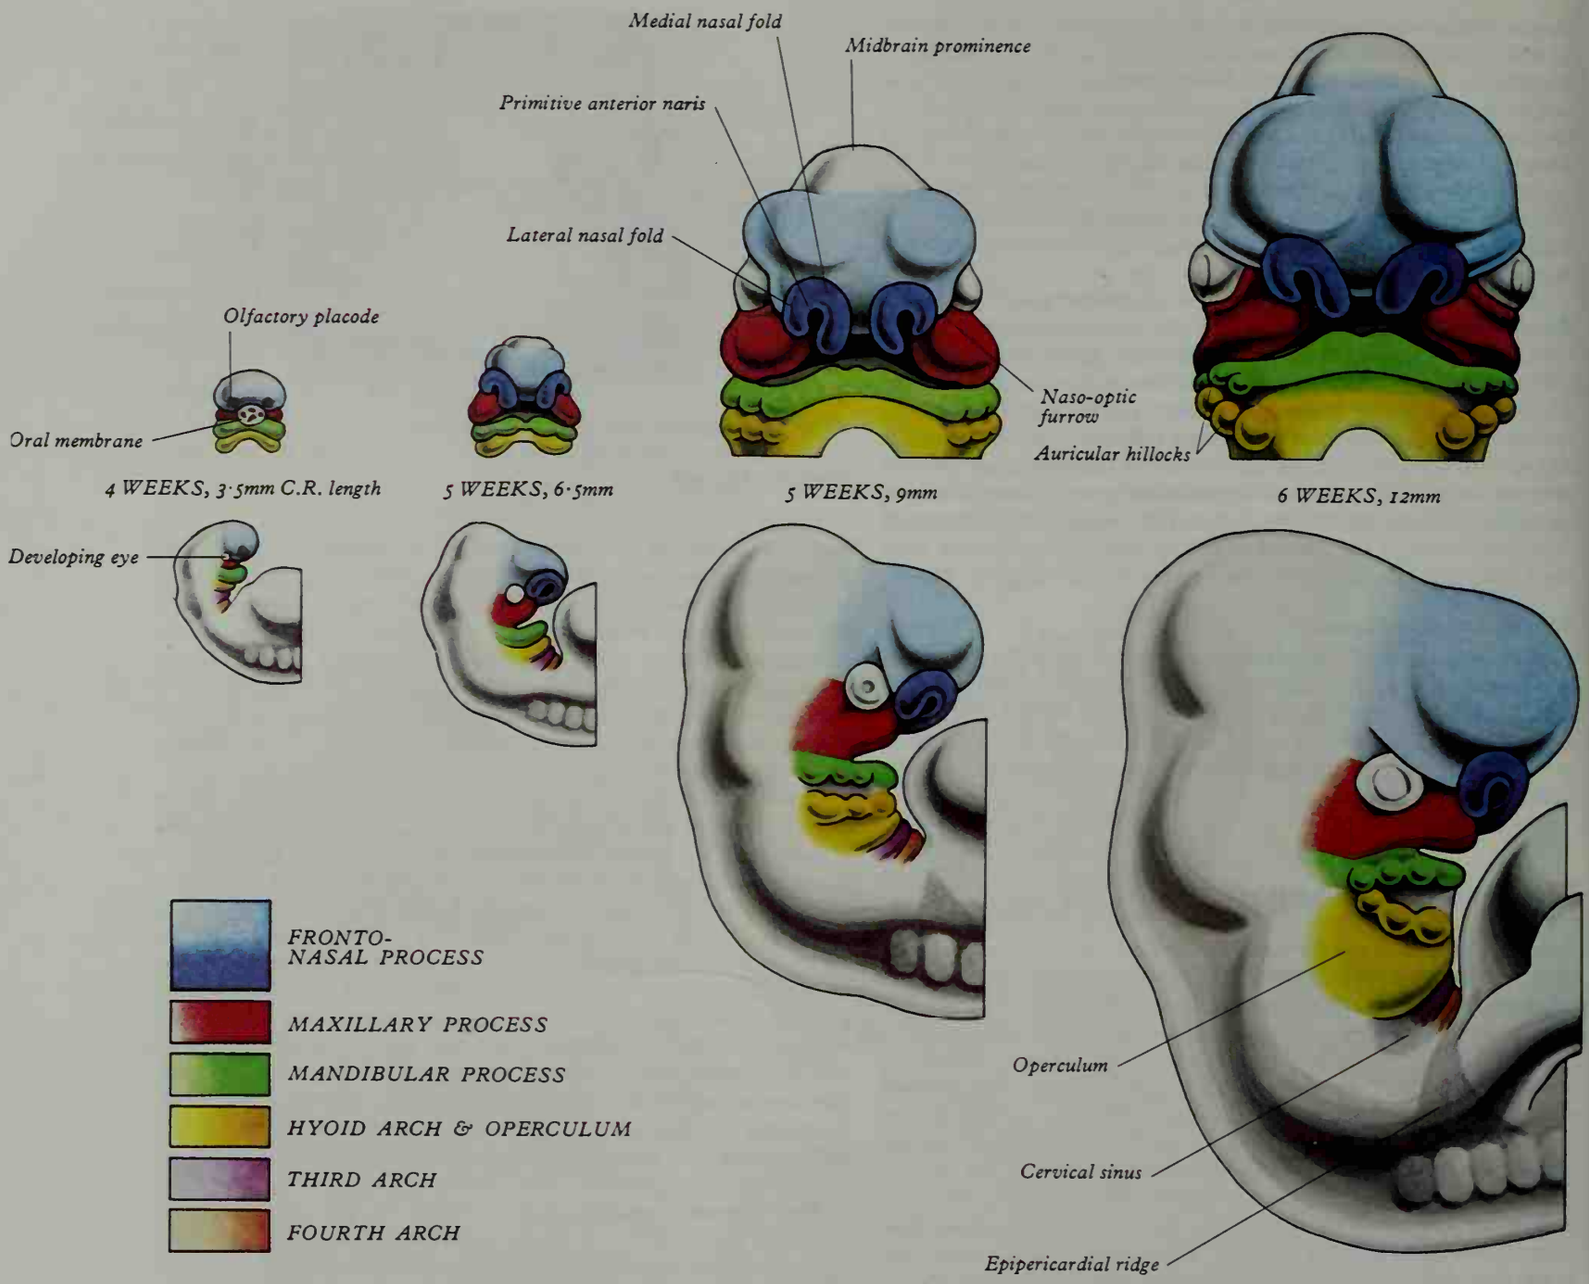
The Branchial Apparatus

After the head fold has formed, the *stomatodeum* or the primitive mouth, is bounded cranially by the projection of the forebrain and caudally by the cardiac prominence (**2**.52). The mandibular region and the whole of the neck, which will subsequently intervene between the mouth and developing thorax, are as yet absent, but will be formed by the appearance and modification of six paired **branchial arches**, which develop on the lateral aspects of the head in the vicinity of the hindbrain (**2**.53). In the earliest vertebrates (*Agnatha*), which were jawless, the arches were a uniform series of bars between the gill clefts; but long before the evolution of the terrestrial vertebrates, remarkable adaptations had occurred in them. What are commonly regarded as the first pair of arches became the jaws, upper and lower, of the *Gnathostomata*, the jaw-bearing vertebrates, including most fish; they are, therefore, usually named the *mandibular arches*. It should, however, be noted that since this early identification, strong evidence has accumulated that a pair of *pre-mandibular arches* existed and have become adapted as the *trabeculae cranii* of subsequent vertebrate embryos. These are probably represented by the interorbitonasal cartilage of the human embryo, as mentioned above (p. 141), forming the visceral, or branchial element in the chondrocranium. The next (post-mandibular) arch in the series is the hyoid arch, whose skeletal derivatives form the varied hyoid elements present in all vertebrates with jaws. The most dorsal of these elements, the *hyomandibula*, is already present in cartilaginous fish as a strut between the skull and the primitive jaw joint, thereby reducing the cleft between the mandibular and hyoid arches to a small opening, the *spiracle*. The interesting further evolution of this region in land animals in connection with the auditory apparatus will be considered later (p. 178). The hyoid arch also contributes to the formation of a gill cover, or operculum in bony fish, and the remaining arches persist as the supports of the gill apparatus.

The mesenchyme of the branchial region (p. 115) at first exists as a thin sheet between the ectoderm and endoderm; but, as growth proceeds, it proliferates to form a series of cylindrical processes which constitute the mesodermal core of the branchial arches, covered, of course, by the two epithelia mentioned. At first, the arches produce rounded ridge-like prominences both of the overlying ectoderm and of the endodermal floor of the pharynx. In the furrows between these prominences the ectoderm



2.53B A transverse section through the pharynx of a human embryo. C.R. length—2 mm. Magnification × *c.* 50. (E. H. Norris, *Contr. Embryol.*, **27**, 1938.)



and endoderm are in virtual contact. The thin membranes so formed break down in gill-breathing vertebrates but persist in the tetrapods, in which true clefts are not formed. However, the external *branchial grooves* which correspond to them are often, less appropriately, called *branchial clefts*, and their internal counterparts are the *pharyngeal sacs* or *pouches*. At this stage in the human embryo the pharynx is transversely wide at its cranial end but rapidly narrows in a caudal direction; it is also dorsoventrally compressed, so that there is little true lateral wall (**2**.54).

In gill-breathing vertebrates the exchange of respiratory gases is directly from solution in water to solution in blood. From the cranial (arterial) end of the heart emerge two *ventral aortae* which traverse the ventral aspect of the pharynx, sending branches dorsally into the branchial arches, where they feed blood into capillary plexuses. These are drained by corresponding arteries, which join two *dorsal aortae* supplying the general circulation. As water is taken in through the mouth and passed back through the gill clefts, its dissolved oxygen diffuses through the pharyngeal endoderm of the gills to reach the blood, carbon dioxide diffusing out of the latter into the water. The intimate relationship between the developing mouth, branchial apparatus, and heart in water-breathing vertebrates is repeated in the embryos of their tetrapod descendants, but with many modifications necessary to changed respiratory function.

The human mandibular arch (**2**.55, 56) grows ventro-medially in the floor of the pharynx to meet its fellow in the midline, being situated between the primitive mouth and the cardiac (pericardial) swelling. The *hyoid arches* are caudal to the

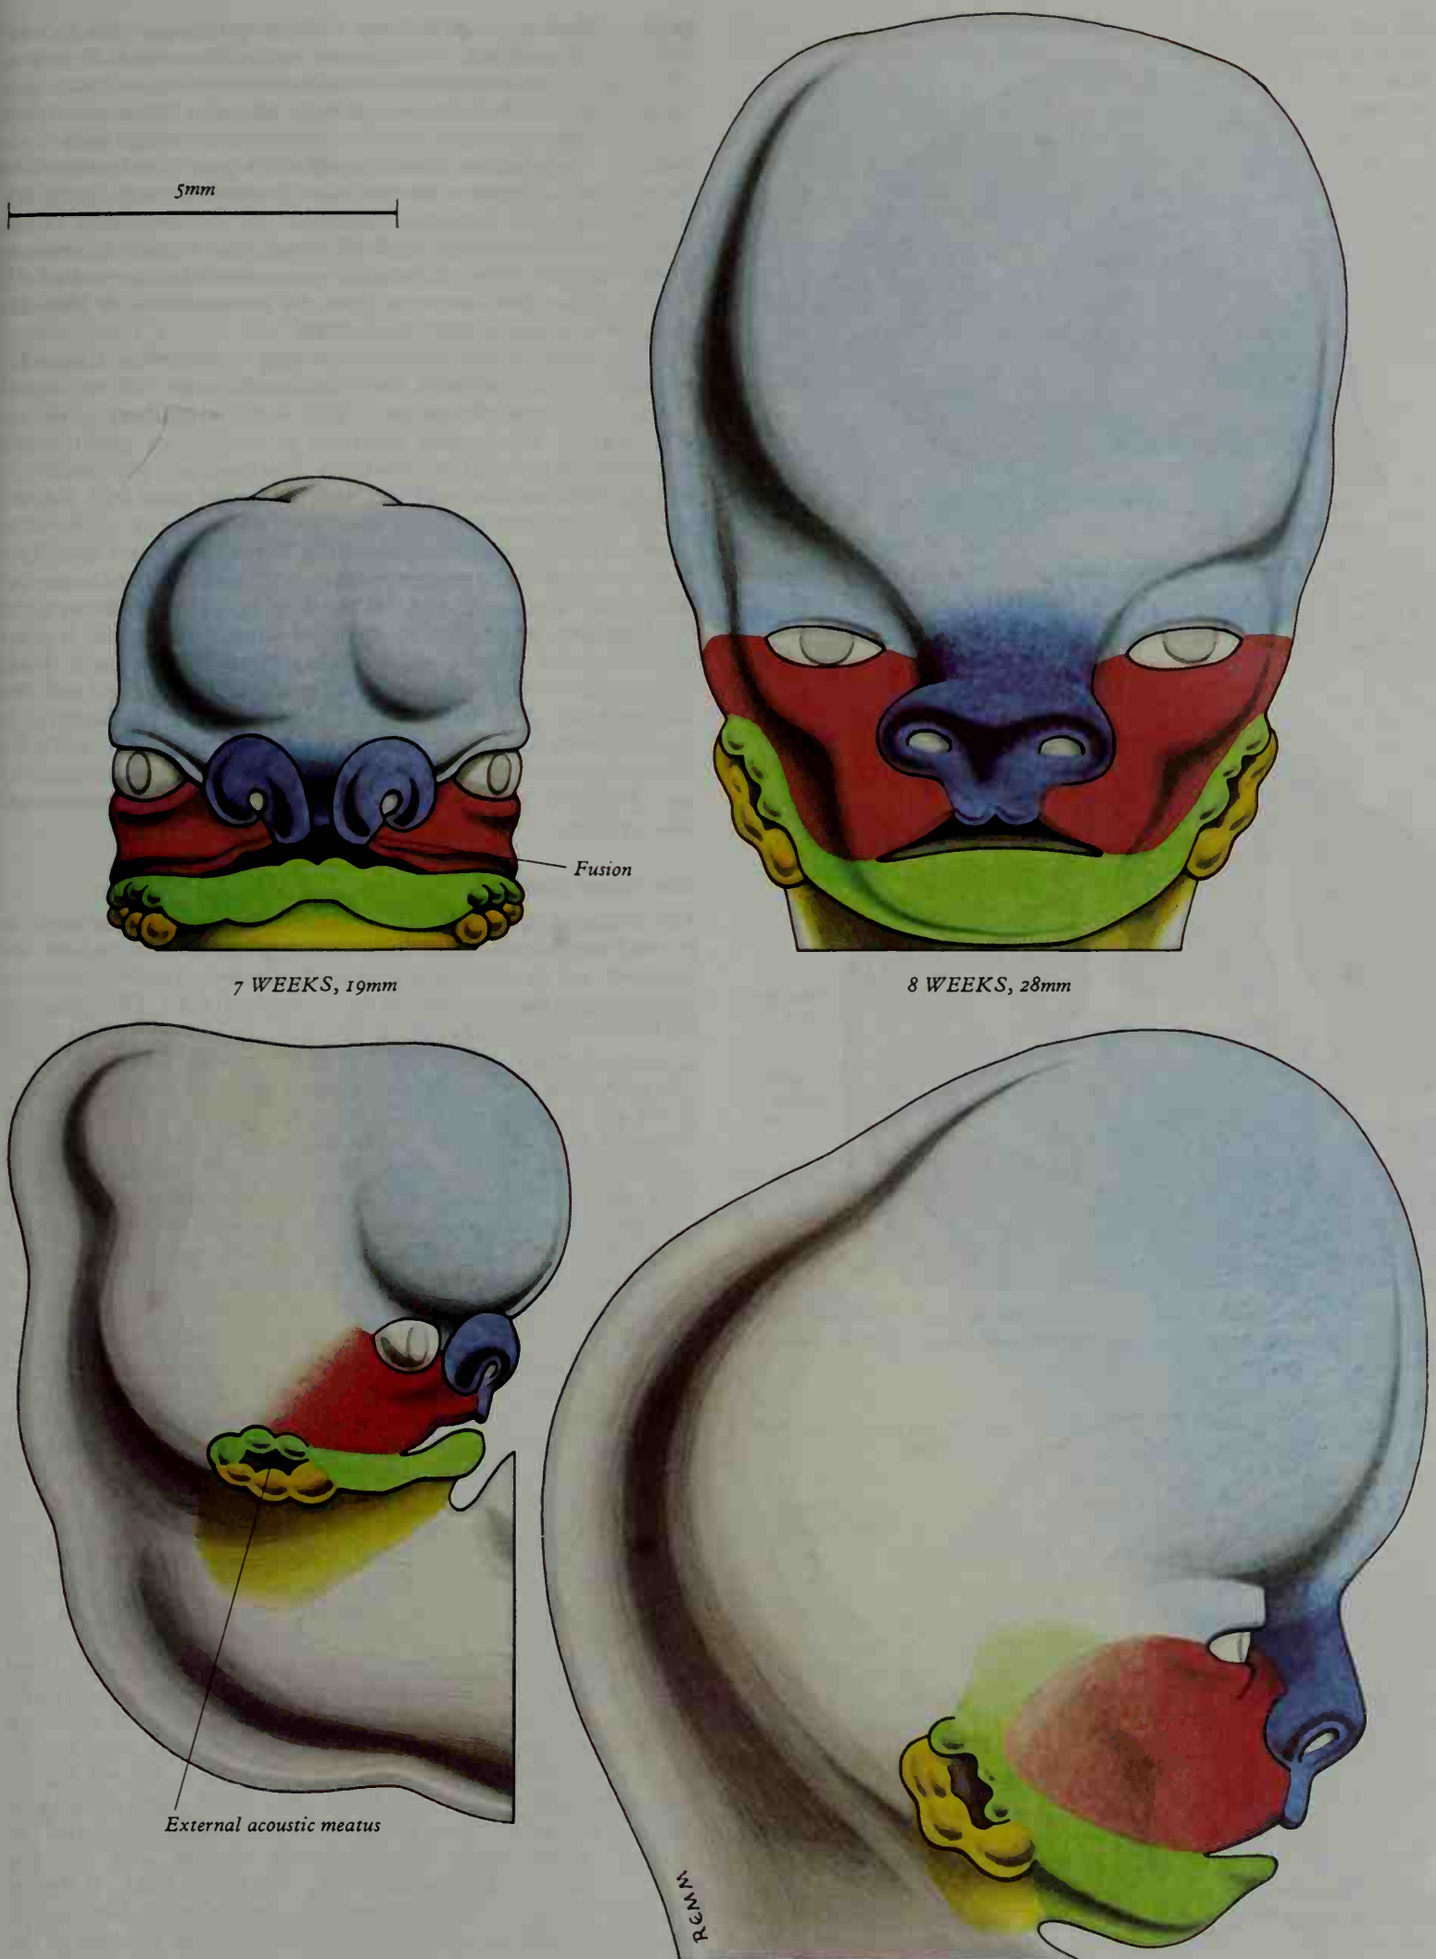
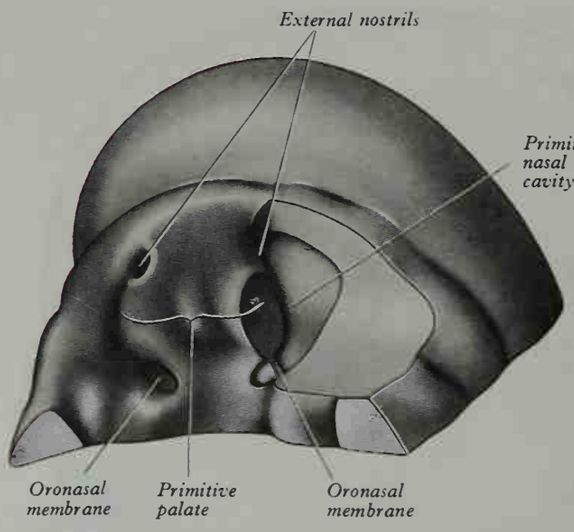
2.55 A sequence of diagrams showing the superficial contributions of the facial processes and branchial elements to the development of the face, including the external nose, circumorbital structures, external acoustic meatus and pinna, and neck. All diagrams are drawn to scale. Note changes in general proportions and relative positions.

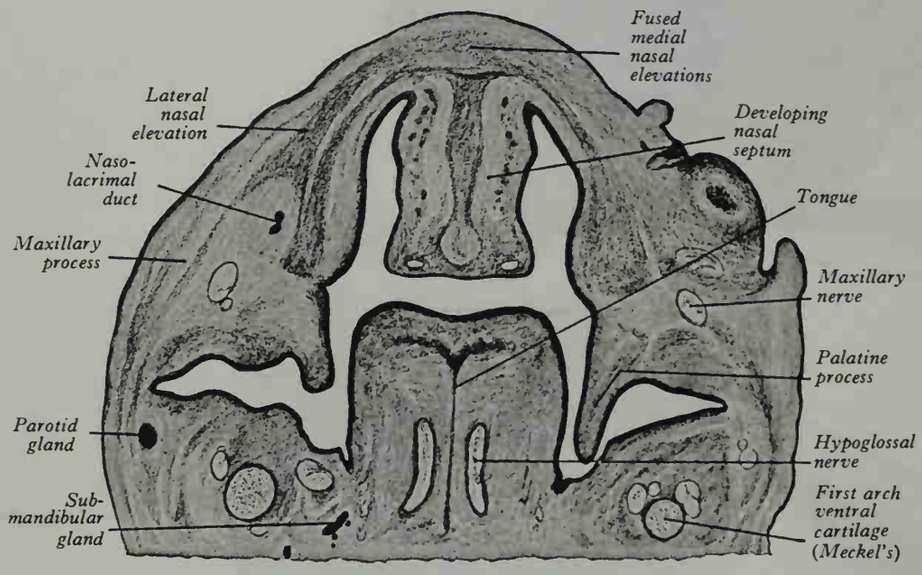


mandibular and similarly grow ventrally to meet and fuse in the midline. The *third* and *fourth arches*, especially the latter, do not attain any great degree of prominence, being largely sunk in a depression produced by the caudal overlapping of the hyoid arch. The *fifth* and *sixth arches* cannot be recognized as such externally, and they can only be identified by the arrangement of the mesenchyme and by slight projections in the wall of the pharynx. In their development the branchial structures are dependent upon the proximity of the pharyngeal endoderm, removal of which aborts branchial development. However, the mandibular arch is in part, at least, dependent upon the ectoderm of the stomatodeum.



Each branchial arch consists of an ectodermal exterior, a mesenchymal core, and an endodermal interior (**2**.53). The mesenchyme produces a *skeletal element*, which subsequently chondrifies either wholly or in part; and if this change is complete the element extends dorsally until it comes into contact with the mesenchymatous cranial base in the region of the hindbrain. Most of the remainder of the core of mesenchyme becomes *striated muscle*, which usually migrates and may lose all connexion with the skeletal elements in arches which cease to carry out their original respiratory function. The identities of these muscle masses, where they assume new functions, can nevertheless be traced by reference to their nerve supply. Motor nerves from the adjacent hindbrain (**2**.54) pass directly into the arches, which are ventral to it. However far muscle masses migrate from their sites of development, their original innervation almost always persists. The mandibular division of the trigeminal nerve innervates the musculature of the mandibular arch, the facial nerve supplies the hyoid arch, the glossopharyngeal the third arch, and the vagus and accessory nerves the rest of the arches. The recurrent laryngeal may be the nerve of the sixth arch and the superior laryngeal that of the fourth. The nerve of the fifth arch, itself difficult to identify in the human embryo, is uncertain.

The branchial arches play a large part in the formation of the face, oral cavity, neck, pharynx and larynx, but before the development and adaptations of each are detailed it is convenient to describe the events which lead to the construction of the face and nasal cavity.



THE FACE, NASAL CAVITY AND PALATE

While the **mandibular process** is invading the floor of the pharynx, the mesenchyme between the central aspect of the forebrain and the epithelial roof of the mouth proliferates and bulges under the ectoderm to form the *frontonasal elevation* or

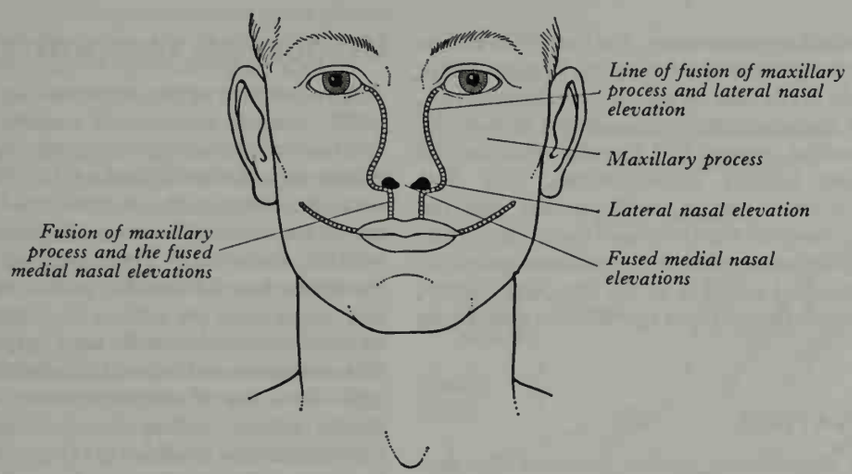
process. During the fifth week a thickened plaque of ectoderm develops on each side ventrolateral to the frontonasal elevation, dividing this into *medial* and *lateral nasal elevations* or folds; these thickenings are the *olfactory* or *nasal placodes*. They are at first widely separated, and, as the elevations develop, they soon become depressed to form the *olfactory pits* (nasal pits). The lateral nasal elevations are the more prominent (**2**.55, 56B), but the medial nasal elevations, separated by the remainder of the frontonasal field, project caudally beyond the former. Extensions of mesenchyme from the medial processes into the roof of the stomatodeum proliferate to form the *premaxillary* or globular fields—the globular processes of His.

While these changes are progressing a somewhat triangular elevation swells ventrally from the cranial aspect of the dorsal region of the mandibular arch. This is the **maxillary process**, and like the frontonasal elevation it consists of proliferating mesenchyme covered by ectoderm. The maxillary process grows in a ventral direction and fuses with the lateral nasal fold, the two being at first separated by a *nasomaxillary groove* (**2**.55, Streeter 1948). The opposed margins of the lateral nasal and maxillary elevations growing together thus establish continuity between the side of the future nose and the cheek (**2**.55). The ectoderm along the boundary between them does not entirely disappear; it gives rise to a solid cellular rod, which at first develops as a linear surface elevation, the *nasolacrimal ridge*, and then sinks into the mesenchyme (Polityer 1952). Its caudal end proliferates to connect with the caudal part of the lateral nasal wall, while its cranial extremity later connects with the developing conjunctival sac. The solid rod becomes canalized to form the *nasolacrimal duct* (**2**.56B).



The Nasal Cavity

The rounded apex of the triangular maxillary process extends beyond the lateral nasal fold, crossing the caudal end of the olfactory pit to meet and fuse with the *premaxillary elevation* developing at the extremity of the frontonasal field. This closes off the lower or caudal edge of the olfactory pit, the upper part of the opening of which is thus defined as the primitive *external naris*. The growth of the surrounding mesenchyme leads to a deepening of the pit to become a primitive nasal cavity, or *nasal sac*, the epithelial wall of which, in the dorsocaudal part of its extent, retains contiguity with the epithelium of the stomatodeal roof. This contact area becomes progressively greater as growth continues, forming a thin layer, the *oronasal membrane*, which disappears later. Thereafter the primitive nasal cavity communicates with the stomatodeum through a primitive *choana*, which is at this stage still well forward or ventrally situated in the stomatodeal roof (Warbrick 1960). By these changes a new cranial boundary is set for the oral opening, consisting of the fused premaxillary and maxillary regions. This is the future upper lip, but it has not yet become separated from the deeper tissues which will form the maxillary alveolus (**2**.59). At the same time the nasal cavity acquires a floor through the fusion of the nasal folds and the maxillary process. At this stage the two external nares are still widely separated by an area derived from the frontonasal field, but this separation becomes reduced by the fusion of the premaxillary mesenchyme from the two sides. According to some investigators the mesenchyme of the maxillary processes invades the premaxillary regions, the mesenchyme of which is said to become buried, to form later the premaxilla or os incisivum (p. 341) (Boyd 1933; Baxter 1953). The maxillary mesenchyme is considered by some to contribute substantially to the formation of the philtrum of the upper lip, thus accounting for its maxillary innervation. Others, however, maintain that the philtrum is derived wholly from premaxillary tissue (Warbrick 1960; Keith 1948; King 1954; Wood *et al.* 1967). The maxillary nerve primarily innervates the maxillary mesenchyme but apparently extends later into the territory of the frontonasal elevation. (See also p. 1084.) It should be added that some workers deny that sensory nerve distribution is a reliable guide to migration of mesenchyme in the case of the maxillary process.

The Palate

Once the primitive nasal cavities are defined the ventral part of the

roof of the oral cavity can be regarded as the *primitive palate* (**2**.56). It is formed by the premaxillary regions and maxillary processes, which become confluent and establish continuity with the thick median *primitive nasal septum*. As the head grows in size the region of mesenchyme between the forebrain and oral cavity increases greatly by proliferation, and the nasal cavities deepen, extending towards the forebrain. Simultaneously they also extend dorsally from the primitive choanae as two narrow and deep grooves in the oral roof (**2**.56) which are separated by a partition. The grooves and the partition deepen together, and the latter becomes the *nasal septum*, continuous ventrally with the *primitive* nasal septum (**2**.56B). The broad dorsocaudal border of the nasal septum is at first in contact with the dorsum of the developing tongue (**2**.56B), the right and left nasal cavities still communicating freely with the mouth except where the nasal floor is already established ventrally by the primitive palate.

2.57 A diagram to show the parts of the adult face which are derived from the nasal elevations, and the maxillary and mandibular processes.

During the sixth week the internal aspects of the maxillary processes produce *palatine processes*, which grow towards the midline but are for some time separated from each other by the tongue. At this stage the roof of the oral cavity projects ventrally beyond its floor, and the tip of the developing tongue actually lies in contact with the cranial (superior) surface of the primitive palate. A coronal section dorsal to this shows the maxillary palatine processes contiguous with the sides of the tongue and bent into a vertical position on each side of it (**2**.56B). With further growth, the mandibular region and the tongue are carried forwards (ventrally), and the lingual tip passes round to the caudal surface of the primitive palate. By some mechanism, still subject to much controversy (Kraus *et al.* 1966), the palatine processes assume a horizontal position which allows them to grow towards each other and thus to fuse (**2**.56C). The change of position occurs very rapidly in some experimental animals and may be due to a sudden increase in turgor in the processes (Ferguson 1977). Other views, such as active contraction of neighbouring striated and non-striated muscle, have been advanced (e.g. Wee, Wolfson and Zimmerman 1976). The change is also said to be rapid in the case of the human palate. These events obviously may have a direct bearing on maldevelopment of the palate (*vide infra*). Palatal elevation in mankind occurs during the eighth week; the development of the neck allowing some descent of the tongue and floor of the mouth, is then also occurring, and may be an additional factor in the elevation. This permits the palatine processes to grow medially along the inferior borders of the primitive choanae, uniting with them, except over a small area in the midline where a *nasopalatine canal* maintains connexion between the nasal and oral cavities for some time and marks the position of the incisive fossa. (The plates which form the primitive palate are sometimes known as *median* palatine processes, the maxillary contributions being then named the *lateral* palatine processes.) As the medial borders of the maxillary palatine processes fuse together, fusing also with the cranial free border of the nasal septum (**2**.62), the nasal and oral cavities are progressively separated and the tongue is excluded from the former. The nasal cavities are thus extended dorsally, and the choanae reach their final position, leaving the caudal edge of the nasal septum free in about its dorsal quarter as the partition between them. Slightly later the dorsal extremities of the palatine processes, which extend dorsally beyond the choanae, fuse together to form the soft palate (**2**.57). This fusion, as is the case with most of the processes and elevations which form these regions, is more apparent than real, the epithelial cleft between the two processes being pushed to the surface by mesenchymal growth (Burdi and Faist 1967). There is later an upgrowth of mesenchyme from the third branchial arches into the palate and around the caudal margins of the auditory tubes, along a line corresponding in the final state to the palatopharyngeal arches (Baxter 1953).

On each side of the nasal septum, in a ventral or anterior position just above the primitive palate, the ectoderm is invaginated to form a pair of small diverticula, which extend dorsally and cranially into the septum. These are vestiges of the *vomeronasal organs*, whose openings are close to the junction between the two premaxillae and the maxillae; they are always rudimentary in mankind, but are well-developed auxiliary olfactory organs in many vertebrates (pp. 1055, 1142, 1144). For recent bibliographies in the field of facial development consult Sperber (1976) and Latham (1973).

Anomalies

Congenital malformations consequent upon arrest of development and failure of fusion of components in the formation of the face and palate are not uncommon. At the simplest, one maxillary process may fail completely to fuse with the corresponding premaxillary region (globular process), leading to a persistent fissure between the philtrum and lateral part of the upper lip on that side—*cleft* or 'hare' *lip*. A similar but rare malformation follows failure of fusion between the maxillary process and the lateral nasal elevations—*facial cleft*, in which the nasolacrimal duct is an open furrow, a condition usually associated with a cleft lip on the same side. The palatine processes may fail to fuse with each other and the nasal septum to variable degrees. In its severest form fusion is wholly lacking, leaving a wide fissure between the palatine processes through which the nasal septum is visible. On each side the premaxillary (primitive) parts of the palate are separated from the maxillary palatine processes by clefts which are continuous ventrally with bilateral clefts in the upper lip. In such cases the philtrum is a separate entity, continuous cranially and dorsally with the nasal septum. The floor of the nasal cavity is deficient throughout its extent and the choanae are not completed. Many varieties of milder degrees of cleft palate have been observed; the commonest type is unilateral, only one side of the nasal cavity being in communication with the mouth, the extent of the cleft being variable. In the mildest forms only the soft palate is cleft, or even merely the uvula. Such examples of arrested development may be associated with disturbances in embryonic nutrition during the second and the third months of gestation

(p. 136), and the grosser varieties are usually coupled with malformations in other regions of the body. In such cases the premaxillary region protrudes, with associated extension forwards of the nasal septum. For a recent discussion of this aspect of cleft palate consult Latham (1973).

The further growth of the face during the fetal period has received little attention, although this period is by no means characterized entirely by incremental growth. It is during fetal life that human facial proportions develop. The facial and cranial parts display different patterns of growth, though each influences the other. For an interesting analysis of the data observed from 280 fetuses consult Lavelle (1974).

Further Branchial Development

As has already been described to some extent, the branchial arches contribute extensively to the growth of the face, neck, nasal cavity and mouth, as they also do in the case of the larynx and pharynx. Although there are never complete clefts between the arches, the external ectodermal *branchial grooves* and internal endodermal *pharyngeal pouches* make various contributions. The first branchial groove does to some extent persist as the external acoustic meatus, but it is closed by the tympanic membrane. The remaining grooves disappear, except insofar as such derivatives of their corresponding pharyngeal pouches as the tympanic cavity, auditory tube, tonsil, thymus, parathyroid and thyroid glands can be counted.

ECTODERMAL DERIVATIVES

The ectoderm over the mandibular arches becomes the skin of the mandibular region of the face (**2**.55), and it also takes part in forming the tragus of the auricle (p. 1191). The ectoderm on the cranial aspects of these arches thickens along a curve which later becomes the *labiogingival* (vestibular) *groove*. This epithelial proliferation invades the subjacent mesenchyme and subsequently breaks down to separate the lower lip from the developing gum. Before this, however, an epithelial lamina develops from its internal surface (**8**.63) from which the enamel organs of the teeth will eventually be derived (p. 1293).

The first branchial groove is obliterated ventrally, as in all but the most ancient vertebrates. In man its dorsal end deepens to form the epithelium of the external acoustic meatus and the external surface of the tympanic membrane.

At the dorsal ends of the first, second and fourth grooves thickened patches of ectoderm appear, called the *epibranchial placodes*. These are closely related to the developing ganglia of the facial glossopharyngeal, and vagus nerves, to which they contribute (p. 174): other placodal cells also contribute to the trigeminal and vestibulocochlear ganglia.

At the end of the fifth week the third and fourth arches are sunk in a retrohyoid depression, the *cervical sinus*. Cranially the sinus is bounded by the hyoid arch, dorsally by a ridge produced by ventral extensions from the occipital myotomes and by mesenchyme developing into sternocleidomastoid and trapezius. Caudally, the smaller *epipericardial ridge* separates the sinus from the pericardium and curves cranially near the midline, and then with its fellow reaches the mandibular arch. The muscle cells which are often held to migrate from the occipital myotomes to the tongue follow the epipericardial ridge together with the hypoglossal nerve (but *see* p. 198). The established view that the sinus is obliterated by caudal growth of the hyoid arches to fuse with the cardiac elevation, excluding the succeeding arches from any part in the formation of the skin of the neck, has been criticized; an alternative view is that the sinus is reduced by gradual approximation of its walls from within outwards. During these changes the epibranchial placodes sink inwards as small vesicles which ultimately lose connexion with the surface ectoderm, and are then more closely associated with the glossopharyngeal and vagus nerves. The vesicle derived from the fourth groove placode is also for some time associated with the rudiments of the thymus and parathyroid arising from the third endodermal pharyngeal pouch (pp. 197–98 (Garrett 1948)), but there is no evidence that the human thymus receives any contribution from this vesicle.

Experiment clearly shows that in lower vertebrates the facial, glossopharyngeal and vagus nerves derive elements from the overlying epibranchial placodes, or are dependent upon the associated placode for their full development. In man, the placodal vesicles associated with the glossopharyngeal and vagus nerves are believed to regress and disappear, abnormal persistence giving rise to *branchial cysts*, which are lined by stratified squamous epithelium and are situated between the carotid sheath and sternocleidomastoid (Wilson 1955). It is claimed that branchial cysts, lined by columnar epithelium, may be derived from persistent remnants of pharyngeal pouches, and that *branchial fistulae* may result from the second branchial cleft or possibly the cervical sinus (Martins 1961).

MESODERMAL DERIVATIVES

The mesoderm of the branchial arches (of mixed *unsplit lateral plate*, *neural crest*, and possibly *placodal* origin) is still 'pluripotential', as is demonstrated by the variety of its derivatives. These include the following: (1) An endothelial tube, an *aortic arch*, develops in the substance of each arch, connnecting the aortic sac, ventral to the pharynx (p. 182), to the dorsal aorta, which is dorsal to it. There are thus six pairs of aortic arches, but the appearance of the fifth pair in man is questioned; its position and connexions are subject to disagreement (Shaner 1921; Barry 1951). For further details *see* p. 187. (2) Some of the mesodermal cells condense to form a skeletal element in each arch; and this is typically a bar of cartilage connected by its dorsal end to the caudal region of the chondrocranium and meeting its fellow ventrally in the midline. (3) Other mesodermal cells differentiate into 'special visceral' striated muscle tissue; and partly associated with this developing *branchial musculature* is to be noted the invasion of the mesoderm by a nerve supply. The proportion of branchial mesoderm from each of its various sources noted above that contributes to the different types of derivative is unknown.

Typically each arch is invaded by two nerves, derived from the hindbrain. One runs along the rostral border of the arch and is hence described as *post-trematic*, because it is behind or caudal to the cleft or *trema* rostral to the arch. Similarly the other nerve, which is close to the caudal border, is *pre-trematic*—with respect to the cleft caudal to it. In the human embryo the pre- and post-trematic nerves can be identified only with certainty in the first, mandibular arch (*vide infra*).

The mesoderm of the branchial region also contributes to the fibro-areolar and other connective tissues of the lower face, tongue and neck. In the third arch it gives rise to some cellular elements of the *carotid glomus* or body (*see* p. 1462), which may also receive neuroblasts from the glossopharyngeal nerve and the developing superior cervical sympathetic ganglion (Boyd 1937; Adams 1958; Rogers 1965). Similarly *para-aortic* bodies are developed in association with the fourth and sixth arches, receiving accessions of neuroblasts from the ganglia of the vagus nerve (Hammond 1941). Kando (1975) has investigated the development of the carotid glomus in mice and has discussed the difficulties in identifying the sources of its neural elements (see also p. 1462).

Derivatives of the Branchial Skeleton (2.58A)

The first arch contains on each side a dorsal and ventral element. The former represents the *palatopterygoquadrate bar*, a prominent element in earlier vertebrates, forming part of the upper jaw, but much reduced in mammals. In human embryos it is transient in appearance, and its contribution to permanent cranial structures, such as the maxilla, is uncertain, (but *vide infra*). The *ventral cartilage* (of Meckel, **2**.58A) extends from the developing otic capsule into the mandibular arch, meeting its fellow at its ventral end. The dorsal end of Meckel's cartilage becomes separated, and is often held to form the rudiments of both *malleus* and *incus*. However, there is strong paleontological (Romer 1970) and comparative anatomical (Shute 1956) evidence that the incus is to be regarded as a homologue of the *quadrate bone* of reptiles, and it is therefore probably more correctly regarded as a

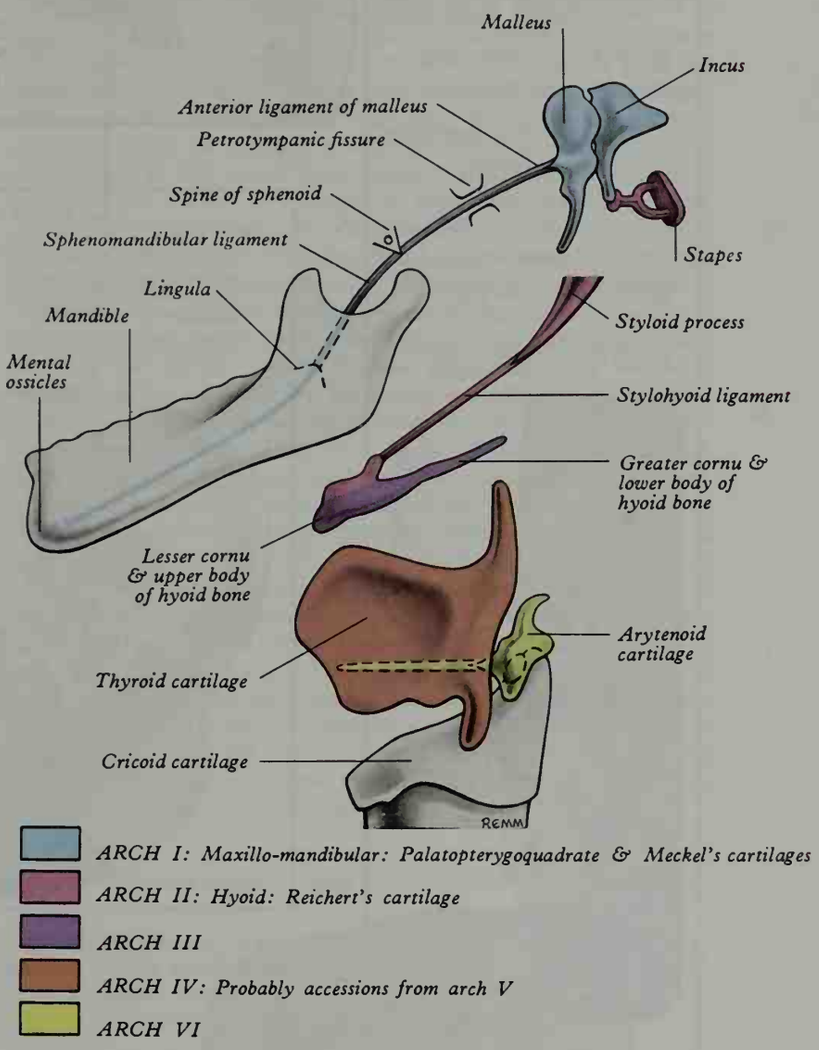
derivative of the palatopterygoquadrate cartilage. This cartilage may also contribute to the ala major of the sphenoid bone. A more precise developmental analysis of this region is needed. Beyond the rudiment of the malleus, the intermediate part of Meckel's cartilage disappears, but its sheath persists as the *anterior malleolar* and *sphenomandibular ligaments*. The ventral part, much the largest, is enveloped by the developing mesenchymatous mandible (p. 148); a small fraction of this, extending from the mental foramen almost to the site of the future symphysis, probably becomes ossified from invading mandibular tissue, into which it is incorporated, while the remainder of the cartilage is ultimately absorbed.

The cartilaginous element of the second arch (Reichert's cartilage) also extends from the otic capsule to the midline. Its dorsal end also separates and becomes enclosed in the developing tympanic cavity as the *stapes*. Thereafter the cartilage gives rise to the *styloid process*, *stylohyoid ligament*, the *lesser cornu* and probably the *cranial rim* of the body of the *hyoid bone* (2.58A).

Chondrification does not occur in the dorsal parts of the skeletal elements of the third to sixth arches. The ventral cartilage of the third arch becomes the *greater cornu* of the *hyoid bone* and the *caudal part* of its *body* (the whole of the body may be formed from the third arch cartilage). Alternatively, the hyoid body may be derived from cartilage formed in the base of the hypobranchial eminence (p. 197) and thus from third arch tissue alone (Frayer 1926), acquiring its connexion with the second arch cartilage secondarily.

The final adaptations of the cartilages of the skeletal elements in the fourth, fifth, and sixth arches are a source of much disagreement, but the following represents the general view. The thyroid cartilage develops from the fourth and fifth arches, which may also give rise to the arytenoid, corniculate, and cuneiform cartilages. The cricoid cartilage may be derived from the sixth arch cartilage, or it may be a modified tracheal ring. The epiglottis is developed in the substance of the hypobranchial eminence and probably not from 'true' branchial cartilage.

Derivatives of Branchial Musculature (2.58B)



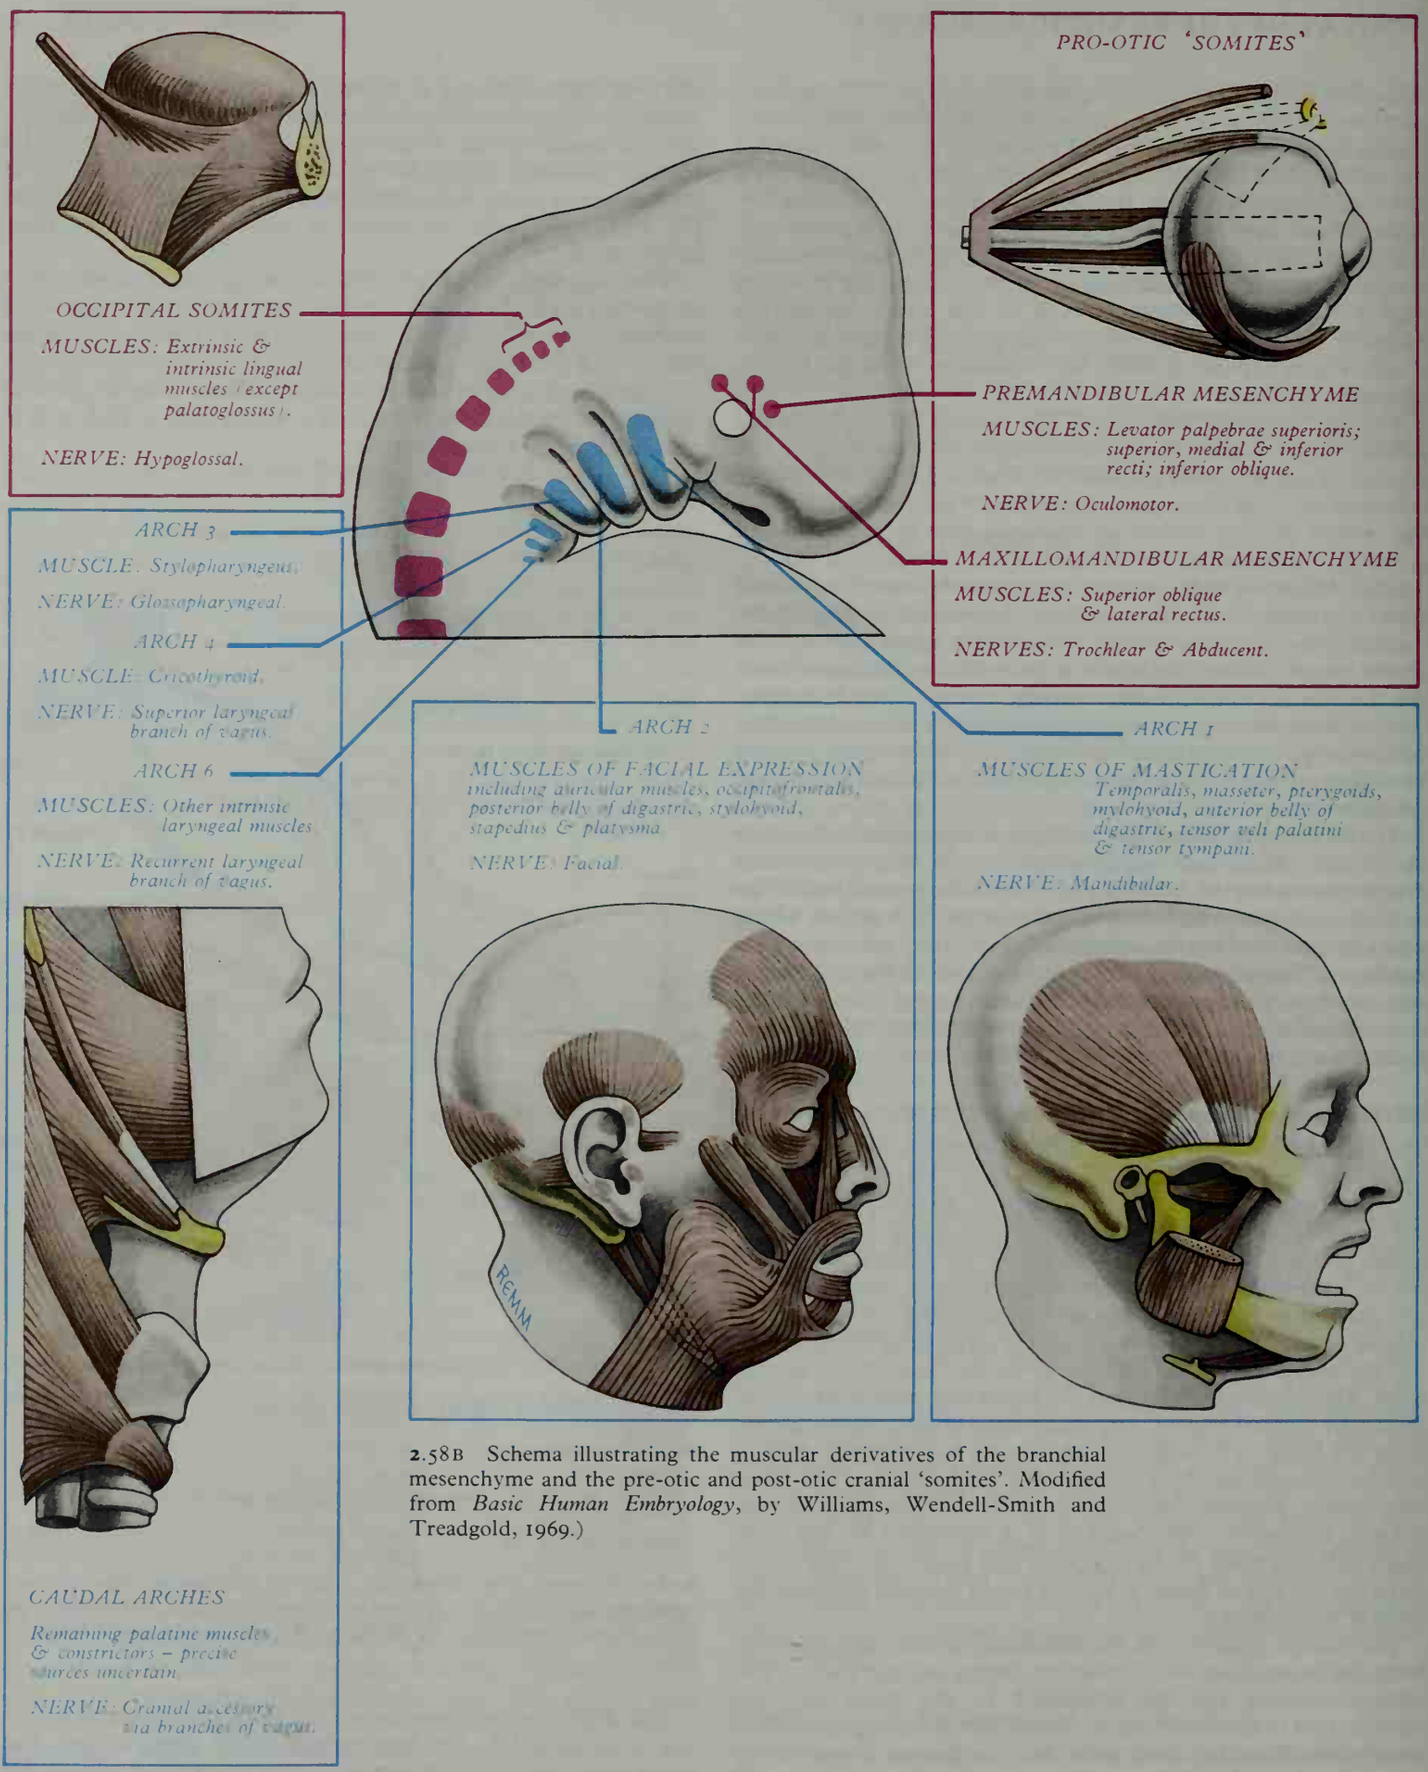
The muscle mass of the mandibular arch forms the *tensor tympani*, *tensor veli palatini*, and the *masticatory muscles*, including *mylohyoid* and the *anterior belly* of *digastric*, all being supplied by the mandibular nerve, the post-trematic nerve of the arch. The tensor tympani retains its connexion with the skeletal element of the arch through its attachments to the malleus, and the tensor veli palatini to the base of the medial pterygoid process, which may be derived from the dorsal cartilage cartilage of the first arch, but the masticatory muscles transfer to the mandible, a dermal bone. The muscles derived from the hyoid arch mesoderm for the most part migrate widely, but retain their original nerve supply from the facial. The *stapedius*, *stylohyoid*, and *posterior belly of digastric* remain attached to the hyoid skeleton, but the *facial musculature*, *platysma*, *auricular muscles*, and *epicranius* all lose connexion with it. Their migration is facilitated by the early obliteration of most of the first cleft and pouch (p. 178). (This cleft, the spiracle in fishes, is already much reduced in all but the earliest vertebrates.)

The muscle masses from the remaining arches are adapted to form the musculature of the *pharynx*, *larynx* and *soft palate*. The stylopharyngeus can be attributed to the third and the cricothyroid to the fourth arch; the rest of the laryngeal muscles are derived from the sixth arch, but the precise origin of the remaining palatal muscles and the pharyngeal constrictors is uncertain in man. A mixed origin, partly from branchial mesoderm, and partly from adjacent myotomes, has been attributed to sternocleidomastoideus and trapezius (McKenzie 1955).

Neural Elements of the Branchial Arches

The nerves of the branchial arches, derived from the hindbrain, immediately enter the dorsal ends of them (2.54). They are typically mixed, their motor component supplying the muscles of the arch and their sensory fibres innervating the skin and mucous membrane derived from the region. In fish the trunks of the branchial nerves and their ganglia are close to the dorsal ends of the true clefts existing in these forms, each sending a post-trematic branch into its own arch and a pretrematic branch into the arch cranial to this. In mammals both types of branch can be identified in the first arch, but only a single nerve can be identified with certainty in the second to sixth arches, with the exception of the fifth, the nerve of which is unknown and may have disappeared.

The trigeminal mandibular division is the post-trematic nerve of the first arch, the chorda tympani being generally regarded as its pretrematic nerve derived from the facial. The latter supplies the second arch, the glossopharyngeal the third, the superior laryngeal branch of the vagus the fourth, and the latter's recurrent laryngeal branch the sixth. In lower vertebrates the fifth arch is also supplied by a vagal branch.



2.58A Schema illustrating the skeletal derivatives (osseous and cartilaginous) of the branchial arches (viscerocranium). (Modified from *Basic Human Embryology*, by Williams, Wendell-Smith and Treadgold, 1969.)

The difference in the courses of the recurrent laryngeal nerves can be explained by the development of the aortic arches. The nerve enters its sixth arch caudal to the aortic arch, retaining this position on the left side and hence being caudal to and looping round the ligamentum arteriosum in its final disposition. However, on the right, owing to the disappearance of the dorsal part of the sixth aortic arch and the whole of the fifth, the nerve loops round the caudal aspect of the *fourth* aortic arch, i.e. the subclavian artery.

DERIVATIVES OF THE PHARYNGEAL POUCHES

The first four pharyngeal pouches appear in sequence cranio-caudally, and their endoderm approaches the ectoderm of the overlying branchial grooves to form thin *closing membranes* (2.53,

2.58B Schema illustrating the muscular derivatives of the branchial mesenchyme and the pre-otic and post-otic cranial 'somites'. Modified from *Basic Human Embryology*, by Williams, Wendell-Smith and Treadgold, 1969.)

2.58A, B). The blind recesses of the second, third and fourth pouches are prolonged dorsally and ventrally as angular, wing-like diverticula. From the fourth a diverticulum grows caudo-ventrally and is at first demarcated from the pouch by a groove in which may occur a transient fifth aortic arch artery. From this diverticulum a fifth pouch may develop and establish a connexion with ectoderm. The remainder of this diverticulum is the *ultimobranchial body*. This, together with the fourth pouch and the transitory fifth, when present, constitute the *caudal pharyngeal complex*. Its communication with the cavity of the pharynx is the *common pharyngobranchial duct*. The ultimobranchial body is almost a constant feature of vertebrate development (Watzka 1955). Its form in the *human* embryo, however, has been a matter of controversy. Apparently it is incorporated into the rest of the caudal pharyngeal complex and contributes to the development of the lateral thyroid rudiment (p. 198). Ultimobranchial bodies exist in the adults of many lower vertebrates, and *calcitonin* has been isolated from such tissue (Copp *et al.* 1967). There is thus a strong presumption that the parafollicular cells of the human thyroid gland which are a source of calcitonin, are derived from ultimobranchial tissue. (*See* Proceedings of a symposium on: *Thyrocalcitonin and the C cells*, Taylor 1968; and Bussolati and Pearse 1967: also pp. 262, 1449).

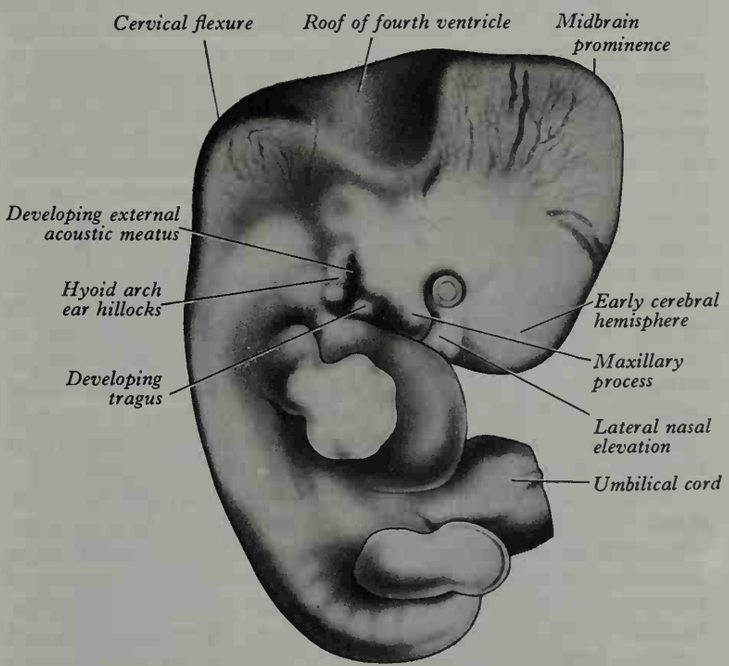
The further development of the endodermal derivatives of the

pharyngeal pouches is intimately associated with that of the mouth, pharynx and larynx, and will hence be considered with them later (pp. 197–200).

Development of Locomotor Structures

EARLY DEVELOPMENT OF THE LIMBS

Towards the end of the fourth week the limbs begin to appear as small elevations, the **limb buds**, from a slight lateral ridge extending along each side of the trunk (**2**.52, 59). The forelimb bud shows first, at the level of the more caudal cervical segments, the hind-limb bud being level with the lumbar and upper sacral segments. Each bud contains a small proliferating mass of mesenchyme derived from the somatopleure, covered by ectoderm. At this stage the limb bud is not more than a slight accentuation of the lateral ridge, or *crest of Wolff*, which—though not identified in all embryos—is considered to correspond to the *finfold of Gegenbaur*, the hypothetical origin of vertebrate limbs. From their initial appearance, the limb buds display an ectodermal crest at their developing apices, the *apical ectodermal ridge* or cap; and although there are some disagreements over details, there is general concurrence that the *interaction* between the mesenchymal core and the apical ectoderm is essential to the development of the limb. Most of the experimental evidence admittedly applies only to amphibian (Tschumi 1957), reptilian (Milaire 1957) and avian (Saunders 1948; Amprino and Camosso 1955; Amprino 1968; MacCabe *et al.* 1974) embryos, but some confirmation of similar behaviour in mammalian limb buds has been recorded, and observations on human embryos also (Horizons XII to XVII), have indicated the occurrence of ectodermal ridges (O'Rahilly *et al.* 1956). This evidence indicates that the ectoderm of the apical region of the limb bud, though itself relatively undifferentiated, is necessary to the development of successive accretions of mesenchyme as the bud grows. The potentiality of the initial mass of somatopleuric mesoderm is limited to the formation of the most proximal limb elements, i.e. the girdle region. The mesodermal development of the successive segments of the limb is induced, in a proximo-distal sequence by the ectodermal ridge, the cells of which apparently do not proliferate to add to the covering of the growing bud. The necessary increase in ectoderm for this appears to be derived by interstitial growth and from the body wall ectoderm. The apical ridge also appears to establish the polarity of the limb with respect to its pre- and post-axial borders and the arrangement of its basic vascular pattern. The evidence for these views has been surveyed by Zwilling (1961). Specific histochemical changes associated with morphogenetic events in the developing limb bud have been reviewed by Milaire (1962). Ultrastructural studies of the zone of epithelio-mesenchymal interaction at the apex of the bud have been reported (Kelly 1973). The evidence suggests that the sculpturing of the interdigital clefts is a process involving mesenchymal cell death with phagocytic removal (p. 79) accompanied by active epithelial invagination.



The mesenchyme of the limb buds is invaded by the ventral rami of adjoining spinal nerves—fourth cervical to second thoracic for the fore-limb, twelfth thoracic to fourth sacral for the hind-limb. The axial region of the mesenchyme proliferates and condenses to produce the skeleton of the limb, chondrification and ossification following as the limb grows. The musculature of the limbs is developed *in situ* from the mesenchyme surrounding the skeletal elements. It is important to emphasize that there is no migration of myotomic mesoderm into the limb bud, the so-called plurisegmental nature of the muscles in the limbs referring solely to their nerve supply. Such muscles as latissimus dorsi, with extensive attachments to the axial skeleton when fully developed, reach them secondarily by active migration.

The early stages of development of fore- and hind-limb buds are alike, except that the former precedes the latter in time by a few days in the human embryo (**2**.112). Differentiation in general proceeds in a proximo-distal direction. Flexion creases appear indicating the sites of elbow, wrist, knee and ankle; and the hands and feet are at first mere plate-like expansions (**2**.59, **2**.111). Towards the end of the sixth week there is still little difference in shape and posture between the arm and leg, the long axis of each being approximately orthogonal to the trunk with the prominences of elbow and knee both directed laterally (**2**.59, **2**.111). At this time the pre- and post-axial borders of the limbs are respectively cranial and caudal in orientation, as their names indicate.

Some preliminary observations on human limb buds, removed from embryos of 4 to 6 weeks and cultured for 4 to 18 days *in vitro*, have been reported (Yasuda 1973). There was a general retardation of development *in vitro*, but the effect was more marked in fore- than in hind-limb buds, and amongst tissues, cartilage was the least retarded.

Limb Rotation

During the seventh and eighth weeks differential growth rates are exhibited by the limbs which bring them into a position of adduction towards the ventral aspect of the trunk, and flexion at elbow and knee is increased. By the end of the eighth week the limbs have attained the *fetal position*, with the conspicuous differences that the elbow points caudally and the knee in a rostral direction. This divergence of final positioning is of the utmost importance in the future functioning of the limbs (p. 350); it is achieved by a kind of rotation in each limb around its axis, presumably in part due to growth changes, for it occurs before any joints are fully defined. The upper limb rotates laterally, so that its pre-axial border becomes lateral and its ventral surface rostral or anterior. The changes are the reverse of this in the hind-limb; medial rotation carries the pre-axial border into a medial position, turning the dorsal surface to face anteriorly. The same re-orientation is illustrated by the radius and tibia, both pre-axial primitively in their limbs, the former becoming the lateral fore-limb bone, the tibia taking up a medial position in the foreleg. Inevitably this affects the hand and foot, whose pre-axial digits, thumb and great toe, take up lateral and medial positions. It should be noted that reverse *forearm* rotation at a later stage in most mammals, and the retention of supination-pronation activity in the primate forearm, modify this arrangement (p. 350). The nerve supply follows these movements, and this explains the cutaneous innervation of the 'lateral' aspect (pre-axial border) of the human upper limb from the more cranial nerves of the brachial plexus (**7**.200), and the 'medial' border by its more caudal nerves. In the hind-limb the pattern is similar but less clear; but as a generalization, the upper spinal nerve elements in the lumbosacral plexus innervate the medial border, the lower ones the lateral (**7**.209, 213). (See also p. 1117.)

2.59 A human embryo, 15·5 mm long. Compare the upper and lower limb buds, concerning their stage of differentiation and degree of rotation. (G. L. Streeter, *Contr. Embryol.*, **32**, 1948.)

The foot and hand resemble each other closely at first, as flattened expansions at the terminations of the limb buds. The mesenchymal tissue in the periphery of these plates condenses to outline the pattern of the digits, and the thinner intervening regions break down from the circumference inwards. If this process is incomplete or becomes arrested varying degrees of webbing or *syndactyly* result. For a recent extended study of the phylogeny and development of the skeletal and muscular elements of hand and foot, with a full bibliography, consult Čihák (1972).

The further development and ossification of the skeletal elements of the limbs is described with the individual bones (*see* Section 3, Osteology). For a synopsis and bibliography concerning the chronology of appearance of ossific centres in human embryos consult O'Rahilly and Gardner (1972).

DEVELOPMENT OF JOINTS

Except in the vertebral column and the caudal part of the chondrocranium, which are derived from sclerotomes (pp. 118, 140), the mesenchyme from which other skeletal elements are derived at first shows no differentiation into primordia of individual bones. The skeletal mesenchyme appears as a continuous condensed mass which is not initially demarcated clearly from the surrounding myogenic tissue. Centres of chondrification and ossification develop in this mesenchymal core and rapidly extend to delineate individual skeletal elements, each of which contains its own centre or focus of change, the process of bone or cartilage formation spreading in an orderly and characteristic manner from it (Streeter 1949). Each element becomes limited by a compact layer of undifferentiated cells from surrounding tissues; this layer proliferates to produce cartilage cells and osteoblasts, which contribute to growth by surface accretion. This lamina gradually becomes more clearly demarcated from the underlying cartilage or bone as *perichondrium* or *periosteum*, continuing to generate chondroblasts and osteoblasts (p. 215). It appears to be an important factor in the determination of bone growth in the formation of individual elements (Fell 1939; Barnett *et al.* 1969). (For further details of development, *see* Section 3, Osteology.)

Connecting adjacent skeletal elements as they become defined from continuous mesenchyme masses are regions which do not undergo any change into cartilage or bone, but persist as plates of *interzonal mesenchyme*. These are the sites of future joints, and their development varies according to the type of joint formed. In fibrous joints the interzonal mesenchyme is converted into white fibrous tissue, as the definitive connecting medium between the bones involved. In the case of synchondroses it becomes cartilage of the hyaline type, whereas in symphyses the tissue formed is predominantly fibrocartilage. The interzonal mesenchyme of developing synovial joints becomes trilaminar, due to the appearance of a more tenuous intermediate zone between two dense strata next to the cartilaginous ends of the skeletal elements of the region. These latter are continuous peripherally with the adjoining perichondrium and, like it, are chondrogenic and thus concerned with growth of cartilaginous epiphyses (p. 241). In some synovial joints, however, this trilaminar interzone may be modified (Gardner and Gray 1953). The intermediate stratum merges with the general mesenchyme of the limb, which is vascularized. From this, a cuff condenses as the fibrous capsule of the joint, in continuity with the perichondrium of the bones concerned. A thinner layer of vascular mesenchyme is enclosed within this as the precursor of the synovial capsule (Haines 1947; Gardner and Gray 1950–1; Gardner and O'Rahilly 1968).

As the skeletal elements chondrify and in part ossify, the dense strata of the interzonal mesenchyme also become cartilaginous, and cavitation of the intermediate zone establishes the cavity or discontinuity of the joint. The synovial mesenchyme now forms the synovial membrane, and probably also gives rise to all other intra-articular structures, such as tendons, ligaments, discs and menisci. In joints containing discs or menisci and in compound articulations more than one cavity may appear initially, sometimes merging later into a single one. As development proceeds thickenings in the fibrous capsule can be recognized as the specializations peculiar to a particular joint. In some instances, however, such accessions to the fibrous capsule are derived from neighbouring tendons, muscles, or cartilaginous elements.

For a recent review of the literature concerning the chronology of developmental events in human embryonic limbs, consult O'Rahilly and Gardner (1975).

DEVELOPMENT OF SKELETAL MUSCULATURE

With the exception of certain muscles of the head and neck, which are developed from branchial mesenchyme (p. 152), and the limb muscles, which develop *in situ* from the mesenchyme of the limb buds (p. 153), all the somatic (striated or voluntary) muscles are derived from myotomes (p. 118). Typically, each myotome divides into dorsal (*epaxial*) and ventral (*hypaxial*) regions, the former sited dorsolateral to the vertebral column and innervated by the dorsal ramus of the corresponding spinal nerve, the latter migrating ventrally in the body wall or somatopleure and innervated by the corresponding ventral ramus. Primitively, in fishes, these two primary divisions of the myotomes are separated by vertebral transverse processes, and a fibrous septum extends from these to the lateral body line. The myogenic masses derived from the myotomes may divide longitudinally or tangentially, and the resultant parts may remain separate, e.g. intercostal muscles, or they may fuse with corresponding parts of adjacent myotomes to form sheets of muscle, such as the abdominal oblique and transverse layers. In mammals the derivatives of the ventral regions of the myotomes may subsequently migrate over the derivatives of their dorsal parts. Consequently, such muscles as the serrati posteriores, which reach the vertebral spines superficial to the erectores spinae, are nevertheless supplied by ventral rami of spinal nerves, indicating their origin from ventral myotomic mesoderm. It should be added that from experiments on chick embryos it is apparent that some parts of the intercostal and anterolateral abdominal musculature are not derived from myotomes but from the lateral plate of mesoderm (Straus and Rawles 1953). However, observations on amphibian (Detwiler 1955) and mammalian (Theiler 1957) embryos support their myotomic origin. Some muscles may also *migrate* in a rostral or caudal direction; the latter as in the case of latissimus dorsi, which is derived from lower cervical myotomes, and is innervated accordingly.

Although it is usually stated that the lingual muscles are derived from three or four occipital myotomes (Bates 1948; Deuchar 1958), with which the morphology of their supply from the hypoglossal nerve accords, the evidence for this in the human embryo is negligible, and earlier views that they arise *in situ* from mesenchyme associated with the developing tongue have not been controverted (Frazer 1926). The hypoglossal nerve is composite, representing the ventral roots of an uncertain number of segmental nerves cranial to the cervical series. It is considered to have acquired cranial status in the earliest land tetrapods, its exclusion from the modern amphibians being a secondary adaptation.

In lower vertebrates the extrinsic ocular muscles are developed from three paired head cavities which are considered to be three persistent pro-otic somites (Neal 1918). There is no direct evidence of this origin in man, although it is claimed that the most rostral of these cavities, in the *premandibular*, is derived from mesoderm originating in the prechordal plate, *see* p. 115 and Gilbert (1952). This condensation is held to give rise to the muscles innervated by the oculomotor nerve. The remaining extraocular musles are considered to develop from a mass of mesenchymal cells dorsal to the region of conjunction of the mandibular arch and maxillary processes (which may correspond to the mandibular and hyoid head cavities identifiable in sharks, and which has been termed *maxillo-mandibular mesenchyme* by some authors). The dual origin of this mass is at least in accord with the innervation of these muscles by the trochlear and abducent nerves. The same mesenchymal mass is said to contribute to the formation of the scleral tunic of the eye (Gilbert 1957).

In the differentiation of striated muscle the primitive muscle

cells, *myoblasts*, may arise from somite or non-somite (branchial or limb bud) mesenchyme. The myoblasts multiply by mitosis, but further recruitment from neighbouring mesenchyme also occurs. The cells elongate to form multinucleated *myocytes*, in which the nuclei move to the periphery as a myofibrillar structure and cross-striation begins to appear. Their maturation is described in more detail on p. 513. New fibres are said to form until mid-fetal stages of development, sometimes by splitting of pre-existing fibres. Thereafter growth of muscles is accomplished by enlargement of individual fibres (Cuajunco 1942). Muscle spindles can be identified as early as the twelfth week (Cuajunco 1940). The tendons of muscles develop independently in mesenchyme and their connexion with their muscles is secondary.

In man and other higher vertebrates some derivatives of myotomes degenerate and some disappear entirely. Others may persist as fibrous tissue vestiges; in some instances regions formed from myotomes which are muscular in ancestral forms may become aponeurotic or ligamentous, examples being the aponeuroses of the abdominal muscles and the sacrotuberous ligament (p. 474).

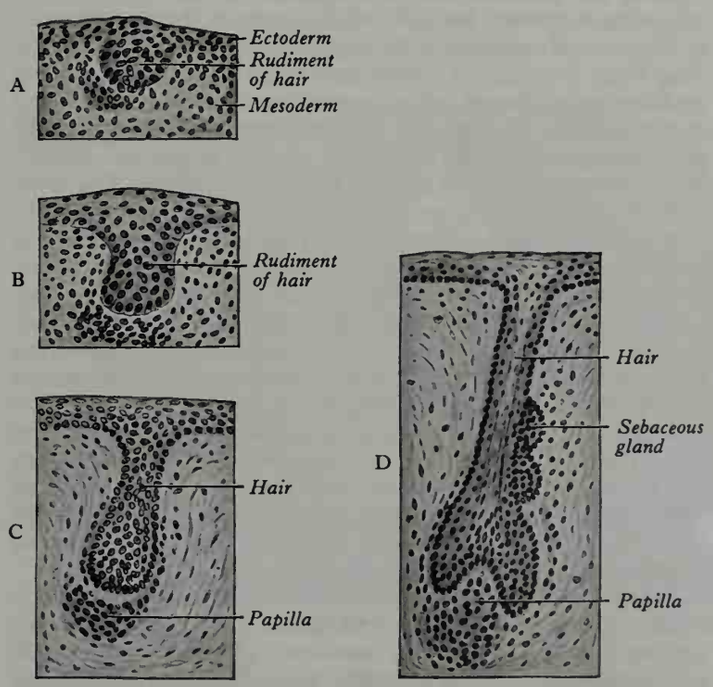
Non-striated and cardiac muscle are not obviously segmental in origin but arise from the mesoderm of the splanchnopleure and develop *in situ* (pp. 506, 515, 518).

Development of Skin and Appendages

The epidermis and its specialized appendages—hairs, nails, sudoriferous and sebaceous glands—are derivatives of the ectoderm, while the *dermis* (corium) is formed from the somatic layer of the mesoderm with some contribution from dorsolateral aspects of the mesodermal somites (p. 118). The ectoderm at first consists of a single stratum of cuboidal cells, but by the sixth week these have proliferated to form a double layer—a superficial *periderm*, or *epitrichium*, of flattened cells, and a subjacent *stratum germinativum*. The cells of the latter are at first cuboidal but become columnar. By multiplication and differentiation of these cells the characteristic layers of the epidermis are developed. The periderm is merely a temporary covering stratum. By the sixth month most of the periderm, which becomes keratinized, has disappeared, and the strata granulosum, lucidum, and corneum of the epidermis are established. The superficial cornified cells, together with sebaceous secretion and the remains of the periderm, form a cheesy or caseous material, the *vernix caseosa*, which may exercise the function of protecting the underlying epidermis from maceration by amniotic fluid. Vernix caseosa is characteristic of the surface of the fetus during its final three months of intrauterine existence, finally desquamating soon after birth. The developing epidermis has a high content of glycogen which, apart from its metabolic role, may aid in repelling the amniotic fluid, which also has a high concentration of glycogen.

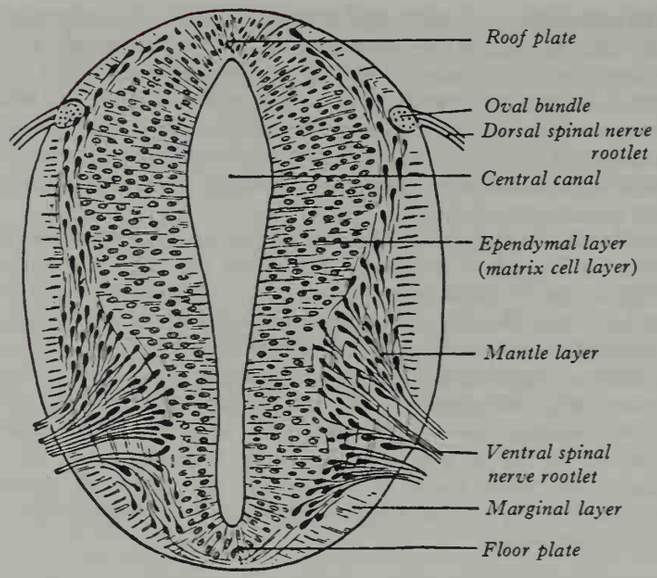
Ultrastructural studies of the human periderm in recent years have shown that its cells possess microvilli, which are in contact, of course, with the amniotic fluid (Breathmach and Wylie 1965; Whittaker and Adams 1971). The functional significance of this transient surface layer remains nevertheless obscure.

At an early, but still undetermined age, neural crest cells invade the developing skin, and these elements differentiate into both epithelial and connective tissue pigment cells, such as *melanoblasts*. These assume a branching form and are hence named *dendritic cells*. In negro fetuses these cells become truly melanoblastic by developing granules of melanin (Rawles 1948; Billingham and Silvers 1960; Boyd 1960), which can be transferred to other cells in post-natal life. In less pigmented races similar cells exist in the epidermis and deeper tissues which, though normally containing little or no pigment, retain a melanogenic potentiality by which, given appropriate stimulation, such as intense sunlight, they are able to form melanin granules.



Ectodermal areas in the head and branchial region develop special propensities, producing such structures as the ocular lens and the ganglia of certain cranial nerves. These *ectodermal placodes* are described elsewhere (pp. 148–150). For the olfactory and otic placodes refer to pp. 174, 178, 225.

The dermis is a mesodermal derivative, and it is usually stated that some, at least, of its cells develop from the lateral wall of the somites which are hence named *dermatomes*. It is also held that dermal tissue is partly derived from mesenchyme associated with the somatopleuric sheet of lateral plate mesoderm and also the neural crest. Perhaps all such regions contribute; at present available evidence is not sufficient to support positive quantitative statements.



Towards the end of the third month the mesoderm next to the epidermis begins to condense and define the dermis, deep to which areolar connective tissue appears. A month later dermal papillae can be identified, and the characteristic patterns of ridges on the ventral hairless skin of the extremities, best seen and most familiar as fingerprints, are quickly established and remain substantially unchanged in the individual apart from growth in size (Cummins and Midlo 1961; Hale 1952). The histological elements of the dermis differentiate at various times; thus, collagenous fibres begin to appear and to aggregate during the third month, whereas elastic fibres become identifiable two or three months later.

Hairs begin to appear in the third month as solid cylinders of epidermis which grow obliquely into the dermis (2.60), each *hair bud* having an external layer of columnar cells and a core of polygonal elements (Hale 1952). The deepest part of the bud expands into a *hair bulb*, which becomes invaginated by a mesodermal *hair papilla*. The central cells become keratinized to form the substance of the hair itself; and as further cells are added from the inner layer of the bulb, these also contribute to the shaft of hair, which lengthens and begins to project above the skin surface. Further growth is due to continued proliferation of the epidermal cells around the mesodermal papilla (see also p. 1212). Hairs appear first on the face, and by the end of the third month there is a general covering over the body of somewhat scattered fine hairs, the *lanugo*. These are shed before birth and are replaced by thicker hairs arising in a new set of follicles. Melanoblasts become associated with developing hairs at an early stage, and these produce melanin in dark-haired individuals during the later months of gestation (Boyd 1950).

Sudoriferous glands first begin to develop in the skin of the palms and soles during the fourth month, appearing like hairs as solid downgrowths of epidermis into the dermis. These elongate and their deeper parts coil to form the main secreting part of the sweat glands. A lumen develops and opens superficially at about the seventh month. Both the duct and the coiled 'body' of each gland is double-layered, the inner epithelium being surrounded by a layer of myoepithelial cells (pp. 39, 521), outside which is a

2.60 Successive stages in the development of hair.

2.61A A transverse section through the developing spinal cord of a human embryo four weeks old. (After His.)

basement membrane; the myoepithelial cells are contractile. Some glands arise from the superficial parts of hair follicles, acquiring a surface opening later. Specialized sudoriferous glands are formed in some sites, such as in the skin of the axillae, eyelids and external acoustic meatuses (Montagna and Ellis 1962).

Sebaceous glands develop as solid epidermal buds from the cuboidal cells of hair follicles during the fifth month. The buds extend into the mesenchyme, branching into several oval alveoli, the lining cells of which are derived from the stratum germinativum. These proliferate, the older cells being pushed centrally, where they degenerate to form sebum, this being extruded into the hair follicle. Sebaceous glands develop independently of such follicles in the nostrils, eyelids (where they form tarsal glands), and in the anal region. The arrectores pilorum develop near the sebaceous glands and hair follicles, but at some little distance from them, arising independently from the mesenchyme; their attachment to follicles is a secondary development (Pinkus 1958). Some of the independent sebaceous glands do not develop fully until after birth.

Nails are demonstrable as rudiments in the third month, appearing as *primary nail fields* of ectoderm on the dorsal aspects of the terminal segments of the digits. The thickened ectoderm of these fields is in fact for a short time at the *tips* of the digits; but proliferation of the nail fields in a proximal direction defines their dorsal position. Due to their relatively slow rate of growth the fields become somewhat depressed, and the epidermis overlaps their sides and proximal ends to form the *nail folds*. The distal ends of the nail fields are bounded by a shallow groove. The proximal part of each nail field proliferates to form the roots of the nail, which becomes the formative zone. From the stratum germinativum of the root the actual substance of the nail, consisting of modified stratum lucidum cells, is continuously formed. The stratum at first covers the nail as the *eponychium*, but this disappears for the most part, remaining only as a narrow proximal crescentric fold overlying the *lunule* of the nail. The *hyponychium* is an accumulation of epidermal cells beneath the free edge of the nail. (It is a much more massive development in claws and hooves.) Growth of the nails during fetal life is gradual, and their extremities have merely reached near to the tips of the digits by the time of birth, those of the fingers being rather more advanced than the nails of the toes.

Anomalous development of the epidermis and its derivatives is relatively common. Excessive or diminished growth, or even complete absence may affect sebaceous or sudoriferous glands and hair, either locally or generally. Similarly, the epidermis may be excessively pigmented (*melanism*), or lack melanocytes (*albinism*). Excessive keratinization leads to *ichthyosis*. A *naevus* or 'mole' is a locus of excessive pigmentation.

Mammary glands are considered to be much modified sudoriferous glands, and as such they are basically ingrowths from the ectoderm, which forms their ducts and alveoli, supported by vascularized connective tissue derived from the mesenchyme. In embryos at about the fifth or sixth week two ventral bands of somewhat thickened ectoderm, the *mammary ridges*, extend from axilla to inguinal region, and in many mammals paired mammary glands develop at intervals along these ridges. In the human embryo the ridges are not prominent features, and a single pair only develops in the pectoral region. The ridges disappear later in embryonic life, but before this the cranial third of each begins to show proliferation to form the two rudiments of the glands. Supernumerary rudiments may form anywhere along the path of the mammary ridges, and these may develop into actual mammae or merely accessory or supernumerary nipples.

As the mammary primordium develops, its ectodermal ingrowth branches into fifteen to twenty solid buds of ectoderm which will become the lactiferous ducts and their associated lobes of alveoli in the fully formed gland. These are surrounded by mesenchyme which forms the connective tissue and fat. By proliferation and elongation and further branching the alveoli are formed and the duct system defined. During the last two months of gestation the ducts become canalized, and the epidermis at the point of original development of the gland forms a small *mammary pit*, into which the lactiferous tubules open. Around the time of birth, or slightly after it, the nipple is formed by mesenchymal proliferation. Should this fail the ducts open into shallow pits, a malformation known as inverted nipple. At birth the mammary glands are alike in their stage of development in both sexes, and in both some transient secretory activity may be observed, due presumably to circulating prolactin in the mother (Smith 1959). In males thereafter the mammary glands remain undeveloped, but in females at puberty, in late pregnancy, and during the period of lactation they undergo further developmental changes (p. 1436). For reviews of the prenatal histogenesis and ultrastructural appearances of mammary tissues consult—Hughes (1950); Raynaud (1971); Tobon and Salazar (1974).

The enamel of the teeth is also an ectodermal derivative (*see* p. 1296).

The Nervous System and Special Sense Organs

The gross initial appearance of a neural plate, and the development within it of a median neural groove bounded on each side by neural folds, which meet dorsally and fuse during the fourth week to form a neural tube, have already been outlined (p. 111).

Reference has also been made to the wealth of comparative experimental data, largely from submammalian forms, which indicate the fundamental role of *primary embryonic induction* in these early stages of development of the nervous system (p. 111).

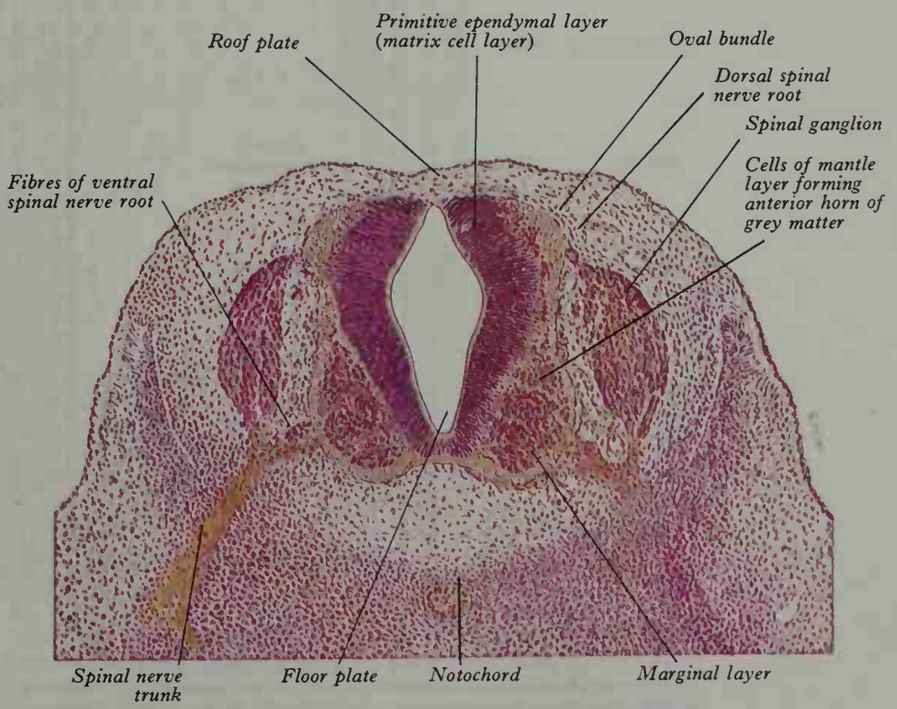
Briefly, during gastrulation, the chorda-mesoderm, which is invaginated through the dorsal lip of the blastopore, forms a midline strip in the roof of the archenteron which is continuous cranially with the endoderm of the prechordal plate (p. 112), and becomes closely applied to the superjacent ectoderm. For a period the latter is competent to react to the inductive influence of the chorda-mesoderm, and in this manner, neural plate formation is initiated. The early midline neural tube is thus co-extensive with the notochord, stretching from the dorsal lip of the blastopore (primitive knot) to the oropharyngeal membrane. Further analyses also demonstrated a regional specificity in the inductive capacity of the various rostro-caudal regions of the archenteric roof. The region first invaginated, i.e. the endoderm of the prechordal plate and rostral tip of the notochord, induces the formation of forebrain and eyes, etc. (the so-called *archencephalon*); the intermediate part of the chorda-mesoderm induces hindbrain and associated structures (the *deuterencephalon*), whilst the remaining (caudal) roof of the archenteron operates as a *spino-*

caudal inducer promoting the formation of spinal cord and neighbouring muscle masses.

Although the search for the chemical identity of inducing substances continues, as pointed out on pp. 83, 85, there has, in recent years, been a great change of emphasis on the part of developmental biologists. Nevertheless, despite the profound developmental modifications introduced by the secondary reduction of yolk in mammalian ova associated with viviparity (p. 74), it is widely assumed that similar primary mechanisms operate throughout the *Chordata*, including mankind. Thus, from the outset, the development of the nervous system is heavily dependent upon morphogenetic influences from neighbouring non-nervous structures.

(For excellent reviews of early neurogenesis consult Hughes 1968; Jacobson 1970; Gaze 1970; Bellairs 1971, 1974; Gottlieb 1974.)

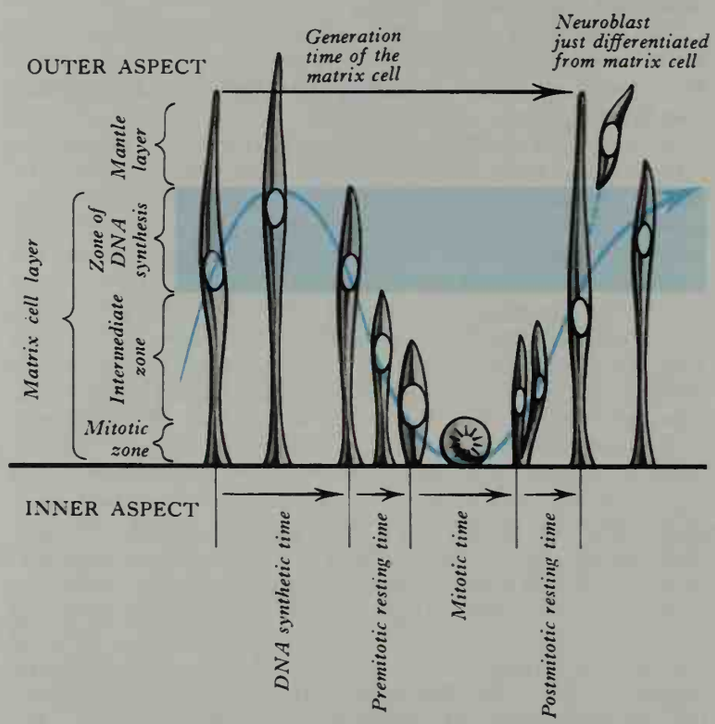
THE SPINAL CORD



When the neural tube is closing, its walls consist of a single layer of columnar *neural epithelial cells*, the extremities of which abut on internal and external limiting membranes. The mechanism of rounding up of the neural plate into a neural tube has been studied particularly closely in amphibia (Burnside 1971). The columnar cells increase in length and develop numerous longitudinally disposed microtubules, whilst the borders of their luminal ends are firmly attached to adjacent cells by junctional complexes, the cytoplasmic aspect of the complexes being associated with a dense paraluminal web of microfilaments (*see* p. 36; **1**.37; **2**.5, also Watterson 1965). It is proposed that this disposition of organelles imparts a slight wedge conformation on the cells resulting in neural groove, and eventually, neural tube formation. As the cells elongate their nuclei become clustered at varying depths in the deeper part of the wall (i.e. nearer the internal limiting membrane) and, for a period, the epithelium is *pseudostratified* with an inner nucleated zone, and an outer zone composed of the peripheral cytoplasmic processes of the cells. Soon, however, some of the peripheral cytoplasmic processes become detached from the (basal) external limiting membrane and rounded cells appear close to the inner membrane which by their repeated mitotic division, form descendants, which *migrate* outwards to take up an intermediate position in the wall of the tube. Histologically at this stage therefore, the wall of the tube presents three zones or layers (**2**.61–63). The internal **ventricular zone** (variously termed the *germinal, primitive ependymal* or *matrix layer*), consists of the nucleated parts of the columnar cells, and the round cells undergoing mitosis. The **intermediate zone** or *mantle layer* consists of the migrant cells from the divisions occurring in the deeper layer, just described. The outer **marginal zone** for a period consists of the external cytoplasmic processes of some of the original columnar cells, but they are soon invaded by tracts of axonal processes which grow from neuroblasts developing in the intermediate zone, together with other varieties of non-nervous cells (glioblasts, and later, vascular endothelium and perivascular mesenchyme).

HISTOGENESIS OF THE NEURAL TUBE

The classical view of neural tube histogenesis was first propounded by Wilhelm His in 1890 and soon, sometimes with minor modifications, gained quite wide acceptance (e.g. Kölliker 1896; Ramón y Cajal 1909). His proposed that almost from the first the wall of the tube was *stratified* and contained a *variety* of distinct cell types—primitive *spongioblasts, neuroblasts* and *germinal cells*. (Some contemporary cytologists even believed that the early neuroepithelium was syncytial, but this gained little acceptance.)



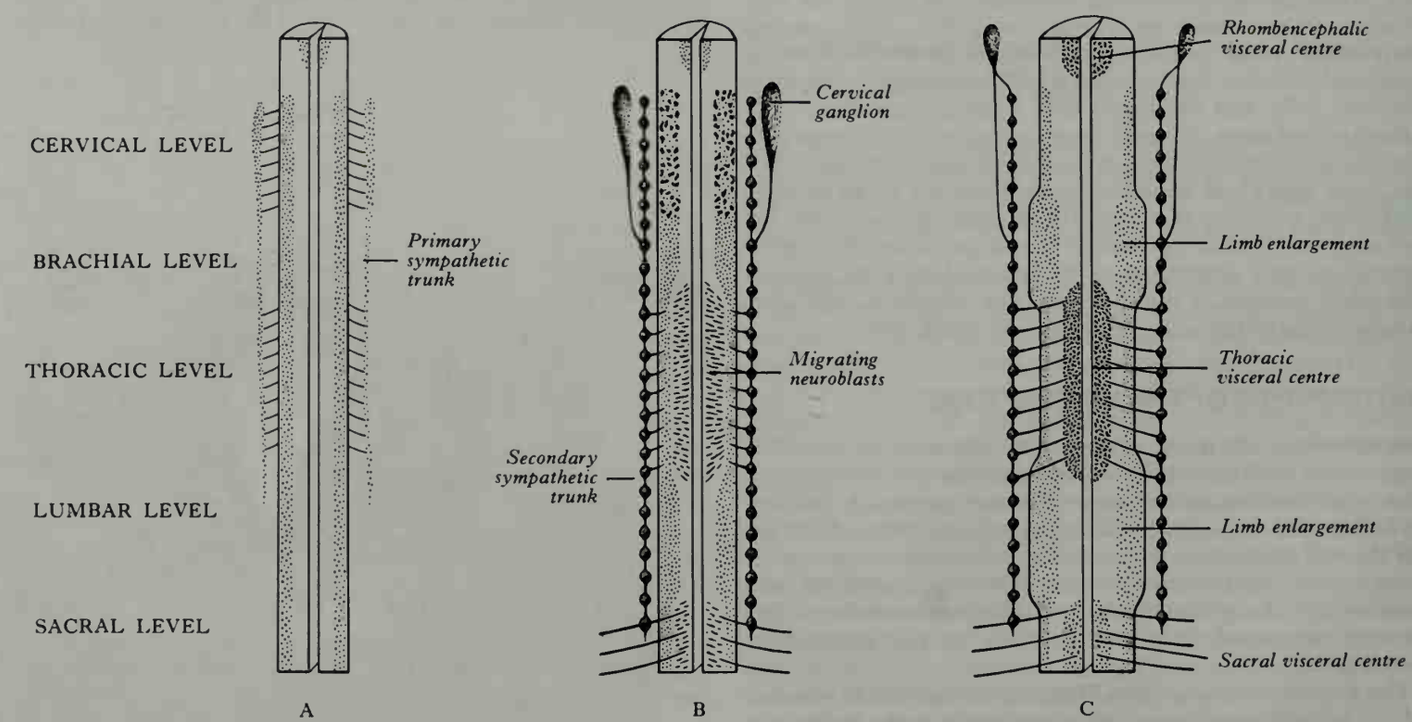
The primitve spongioblasts, originally elongate cells attached to both limiting membranes, with their nuclei in the ventricular zone, were considered to differentiate into a number of *sustentacular cell* varieties. By losing contact with one or both limiting membranes, they may differentiate into either astroblasts and astrocytes, oligodendroblasts and oligodendrocytes, or, retaining an internal attachment, into the definitive ependymal cells which line the central canal. The *neuroblasts*, one of the cell types found in the intermediate zone, differentiated into the wide array of neurons. The round deeply placed *germinal cells* or *medulloblasts* (Glees 1963) he regarded as undifferentiated stem cells, which by repeated division gave further generations of both spongioblasts (*glioblasts*) and neuroblasts. On this view, therefore, the early neural epithelium was regarded as a *heterogeneous* grouping of cells and their various derivatives developed *simultaneously*.

The meticulous cytological studies of Sauer (1935 a, b; 1936) led him to oppose the classical view, and he maintained that the early neural epithelium, including the deeply placed ventricular mitotic zone, consisted of a *homogeneous* population of pluripotent cells, the varying appearances merely reflecting different phases in a *proliferative cycle*, the sequence being termed by Sauer *inter-kinetic migration*. In the intervening years much experimental evidence based upon colchicine studies (e.g. Watterson *et al.* 1956), spectrophotometric nuclear analysis (e.g. Sauer and Chittenden 1959), and upon autoradiographic studies following the distribution of cells at varying times after nuclear labelling with tritiated thymidine (e.g. Sidman *et al.* 1959, 1970; Fujita 1963; Fujita and Fujita 1963), and more recently ultrastructural studies (e.g. Hinds 1971) has supported the latter proposition. The scheme amplified by Fujita in a series of subsequent publications is illustrated in **2**.62A. The ependymal layer of earlier workers (termed by Fujita the *matrix layer*) is considered to be populated by a single basic type of *matrix cell*, and to exhibit three '*zones*' (the M or mitotic, the I or intermediate, and the S or synthetic zones). As they pass through a complete inter-mitotic and mitotic cycle, the matrix cells show an 'elevator movement' progressively approaching and then receding from the internal limiting membrane. DNA replication occurs whilst the cells are extended and their nuclei occupy the S zone; they then enter a pre-mitotic resting period whilst the cells shorten and their nuclei pass through the I zone. The cells now become rounded close to the internal limiting membrane (in the M zone) and undergo mitosis; thereafter they elongate again, their nuclei passing through the I zone during the post-mitotic resting period, finally to enter the synthetic zone once again. The daughter cells may then start another *proliferative cycle*, but others, presumably after a 'critical' or 'quantal' mitosis (*see* p. 84), rapidly migrate outwards (i.e. radially) and differentiate into *neuroblasts* as they approach and enter the adjacent stratum; possibly this differentiation is initiated as they pass through the I zone during the post-mitotic resting

2.61B A transverse section of the developing spinal cord in the cervical region of a human embryo early in the sixth week. C. R. length = 8 mm.

period. The *proliferative cycle*, with the production of clones of vast numbers of neuroblasts, continues for a time; but eventually neuroblast formation wanes, and the mitotic activity of the remaining matrix cells then begins to decline as their progeny differentiate into ependymal cells and the various *macroglial cell* varieties.

2.62A A diagram showing the cytogenetic cycle in the matrix cell layer and mantle layer in the wall of the developing neural tube. Note the various zones and their associated time scales, through which the matrix cell nuclei pass during their postulated 'elevator movement' or 'interkinetic migration' which is described in greater detail in the text. (From S. Fujita, with the kind permission of the author and the *Journal of Comparative Neurology*.)



It should be emphasized here that differences of opinion persist concerning the precise details of the proliferative cycles, and differentiating mitoses in different species, sites in the central nervous system, and the possible mechanisms involved. Further, considerable confusion has obtained between different neuroembryologists in relation to the *terminology* to be adopted for the various '*layers*' or 'zones' at different times and places in the developing neural tube. An international group of neurocytologists (The Boulder Committee: *see Anatomical Record*, **166**, 1970) proposed an unambiguous nomenclature which is increasingly adopted. They termed the early pseudostratified neuroepithelium, in which the 'elevator movement' occurs, the *ventricular zone* (its further development is summarized below, on pp. 160, 161, and in **2**.63A, B). For an excellent review of the biological and terminological problems posed, and an extensive bibliography consult Berry (1974), and for further comments on the natural history of neurons—p. 860.)

Illustration **2**.63A summarizes the main stages of development of the neural tube and the nomenclature proposed by the Boulder Committee—the complete series of stages A–E applying to the cerebral neocortex: only stages A–C are relevant in the context of the spinal cord. As detailed in the caption, it will be seen that the early pseudostratified *ventricular* zone (V) is followed by the sequential appearance of *marginal* (M), *intermediate* (I), *subventricular* (S) zones and, concurrently with the latter, the early *cortical plate* (CP)—*see* p. 173. It is unfortunate that this use of the term *zone* for these *major ontogenetic strata* does *not* correspond in any way to the M, I and S zones of Fujita detailed above (and in **2**.62A), the latter applying to subdivisions of the early neural tube only.

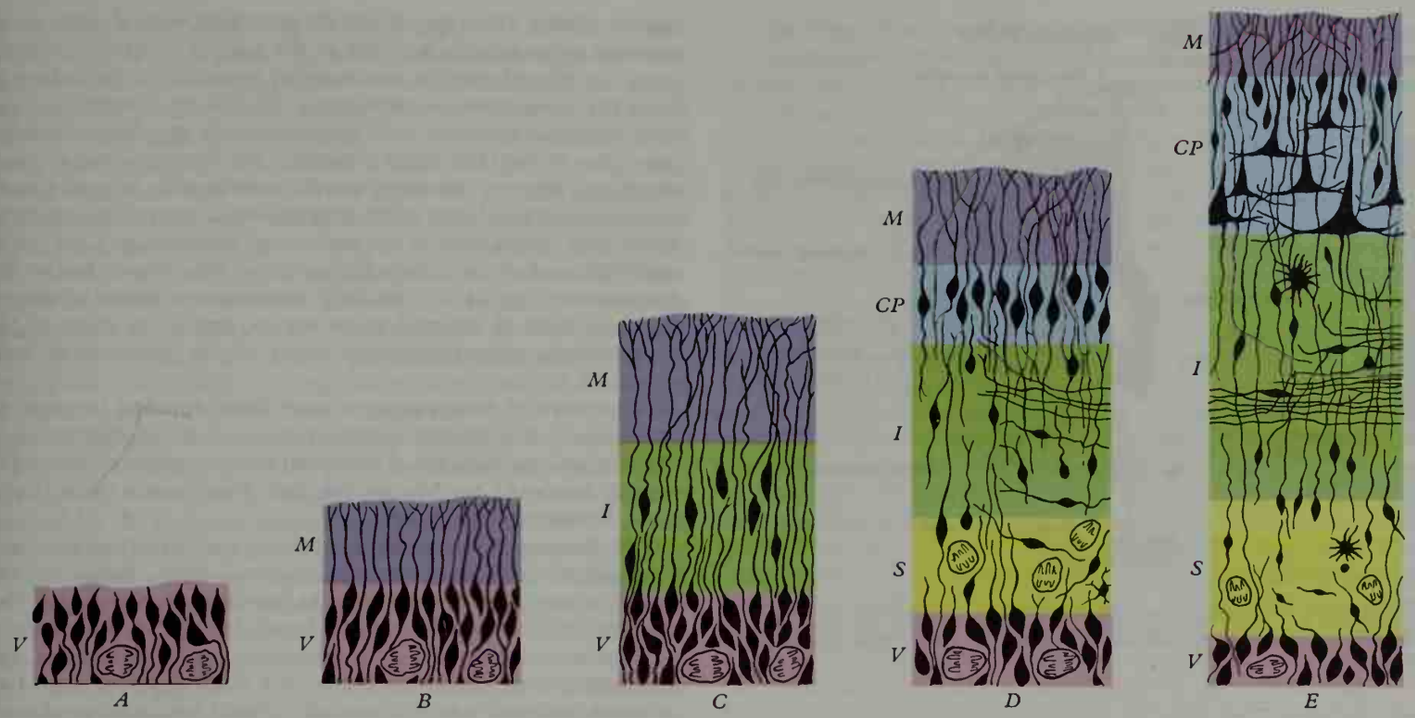


Illustration **2**.63B (which is based on the work of Berry and Rogers 1965, and Berry 1974) is included here for comparison with **2**.63A; it stems from labelling studies on the *patterns of migration* of neuroblasts in the developing neocortex of the rat and will be briefly mentioned later on p. 173.

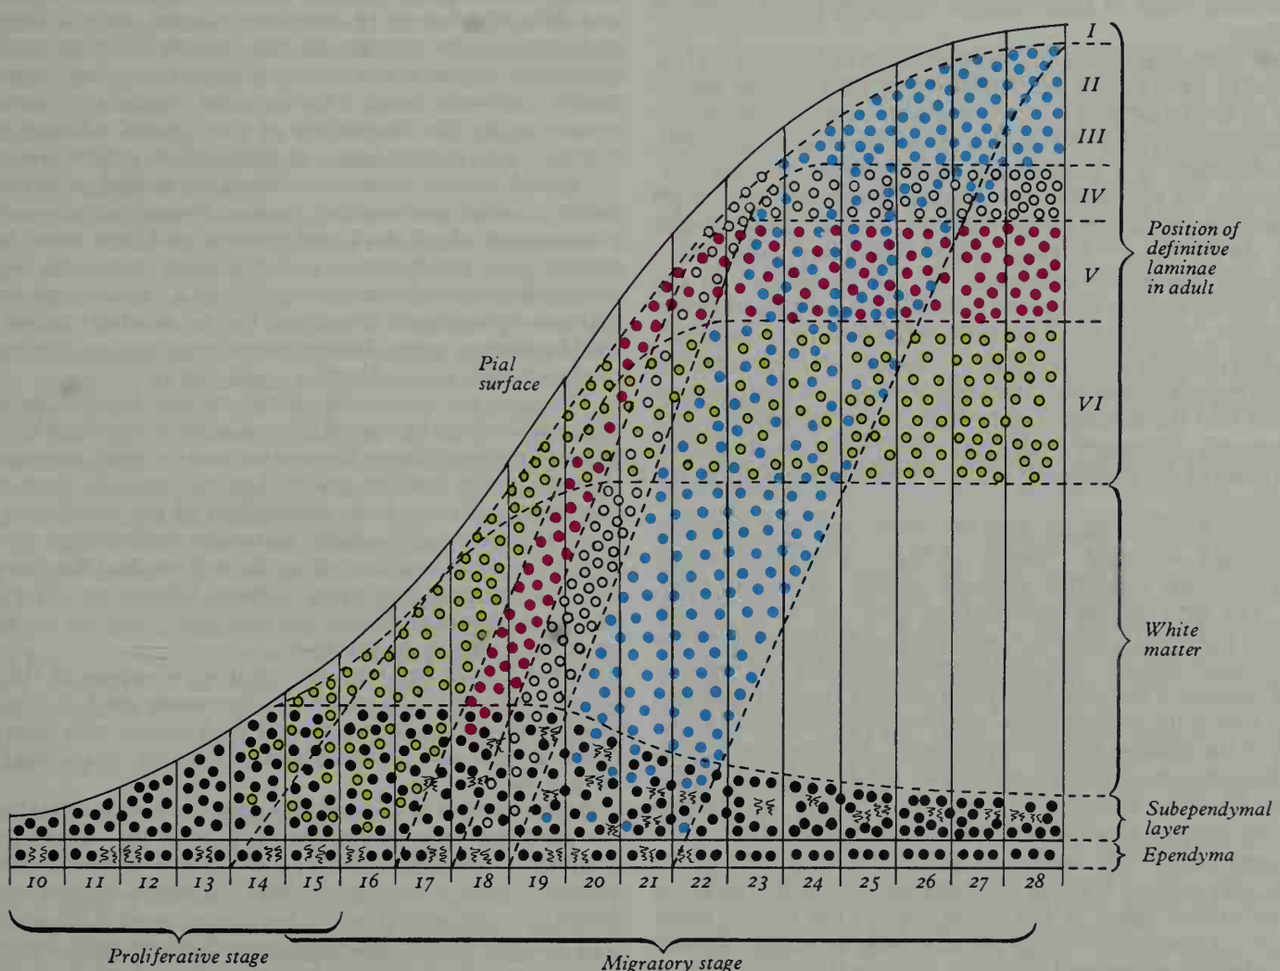
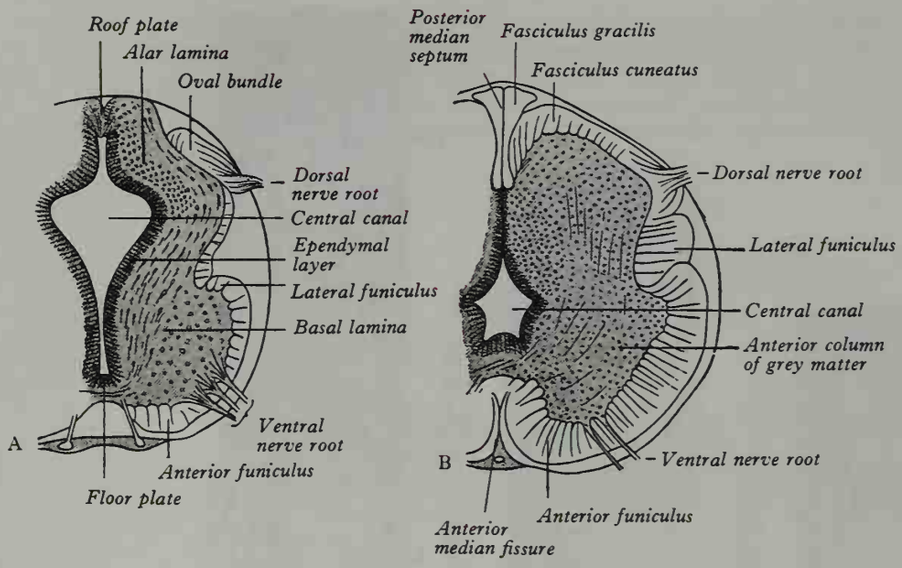
In the future spinal cord the *roof plate* and *floor plate* of the neural tube do not participate in the cellular proliferation affecting the lateral walls and hence remain thin. Their cells contribute largely to the formation of ependyma.

The neuroblasts of the lateral walls of the tube are large and at first round or oval. Soon they develop processes at opposite poles



2.62B A diagram illustrating the changing morphogenetic patterns in the developing neural tube of the *chick* seen in longitudinal section. Note the progression from A to C as the initial simple homogeneous columnar organization (A) is transformed into the definitive pattern (C). These changes follow variations in the turnover rate and differentiation rate of neuroblasts in different regions of the tube, combined with migration of neuroblasts in some regions. For further description see the text. (From V. Hamburger, with the kind permission of the author and the New York Academy of Science.)



2.63A Schema of five sequential stages (*A* to *E*) in the development of part of the neural tube's wall in section to form cerebral cortex. (Modified from: Boulder Committee recommendations, *Anat. Rec.*, **166**, 1970.)

Abbreviations: V—ventricular zone; M—marginal zone; I—intermediate zone: S—subventricular zone; CP—cortical plate. See accompanying text and also p. 860 for details.

2.63B Schematic representation of the dynamics of neuroblast migrations during transformation of the early cranial neural tube to form the cerebral neocortex of the rat through days 10 to 28. Note the successive waves of migration. Coding: symbolic metaphase chromosomes—mitotic cells; *full black* discs—ventricular and subventricular zone neuroblasts; *full yellow discs*—infragranular neuroblasts destined for lamina VI; full *magenta discs*—infragranular neuroblasts destined for lamina V; *open black circles*—granular neuroblasts destined for lamina IV; *full blue discs*—supragranular neuroblasts destined for laminae III and II. Redrawn and colour coded by kind permission from data provided by Dr. M. Berry (1974), of the Anatomy Department, Birmingham University.

2.64A and B Transverse sections through the developing spinal cord of human embryos. A About six weeks old. B About three months old. (After His.)

becoming *bipolar neuroblasts*. One process is, however, withdrawn and the neuroblast becomes *unipolar* although this is not invariably so in the case of the spinal cord. Further differentiation leads to the development of dendritic processes and they become typical *multipolar* nerve cells. In the developing cord the cells occur in small clusters which represent clones of neuroblasts.

At first the neural tube is oval in outline and its lumen is narrow and slit-like (**2.61A**). As the lateral walls thicken, the lumen widens in its dorsal part and is somewhat diamond-shaped on cross-section (**2.61B**). The widening of the canal is associated with the development of a longitudinal *sulcus limitans* on each side. This divides the ventricular and intermediate zones (ependymal and mantle layers) in each lateral wall into a *ventral (basal) lamina* and a *dorsal (alar) lamina*. This separation indicates a fundamental functional difference, for the neuroblasts in the ventral lamina include the motor cells of the anterior and lateral grey columns, while those of the alar lamina form 'interneurons', (both short and long axoned), some of which receive the terminals of primary sensory neurons. (It should, perhaps, be mentioned at this point that the scientific utility of the term 'interneuron' has been seriously challenged — *see* Gray 1974.) At its caudal end the central canal of the spinal cord exhibits a fusiform dilatation, the *terminal ventricle*.

The cells of the ventricular zone are closely packed at this stage and arranged in radial columns (**2.61B**). (For experimental studies of radial migration patterns consult Bergquist 1932, 1968.) The cells of the intermediate zone are more loosely scattered, and they increase in number at first in the region of the ventral (basal) lamina. This enlargement outlines the *anterior (ventral) column* of the grey matter and causes a ventral projection on each side of the median plane, the floor plate remaining at the bottom of the shallow groove so produced. As growth proceeds, these enlargements, further increased by the development of the anterior funiculi, encroach on the groove until it becomes converted into the slit-like anterior median fissure of the adult spinal cord (**2.64**). The axons of some of the nerve cells in the anterior grey column traverse the marginal zone and emerge on the anterolateral aspect of the spinal cord as the *ventral spinal nerve roots*. These constitute, eventually, both the alpha-efferents which establish motor end plates on extrafusal striated muscle fibres, and the gamma-efferents which innervate the contractile polar regions of the intrafusal muscle fibres of the muscle spindles (p. 847). (The histogenesis of beta-efferents is, of course, completely uncharted.)

In the thoracic and upper lumbar regions the intermediate zone neuroblasts in the dorsal part of the ventral lamina outline a *lateral column*. Their axons join the emerging ventral nerve roots and pass as preganglionic fibres, to the ganglia of the sympathetic trunk, or related ganglia, the majority eventually myelinating to form the *white rami communicantes*. The fibres constituting the rami establish synapses with the autonomic ganglionic neurons (pp. 174–75, and the axons of some of the latter proceed as post-ganglionic fibres to innervate smooth muscle cells, adipose tissue, or glandular cells. Some of the preganglionic sympathetic efferent axons pass to the cells of the suprarenal medulla (p. 1458). The innervation of other 'chromaffin' tissues is less certain (but *see* the carotid body—p. 1462). Similarly an autonomic lateral column is also laid down in the mid-sacral region, and gives origin to the preganglionic parasympathetic fibres of the pelvic splanchnic nerves (p. 1132).

A number of investigations have been directed towards an understanding of the cell dynamics involved in the elaboration of the distinctive groupings of cells seen in the mature spinal cord of various species (Levi-Montalcini 1950; Hamburger 1952; Harris 1965; Romanes 1951, 1964).

The changes in cell number, position and density as seen in a longitudinal section of the chick spinal cord, based on the investigations of Hamburger (1952), are illustrated in **2.62B**. The anterior region of each ventral (basal) lamina forms at first a continuous column of cells throughout the length of the developing cord. In many forms this soon develops into two columns (on each side)—a medially placed one concerned with the innervation of axial musculature, and a laterally placed one which innervates the limbs. At limb levels the latter enlarges enormously but retrogresses at other levels.

Involved in transformations such as the foregoing, there is an interplay between a number of fundamental processes which vary in their prominence at different times and at different levels—cell *proliferation, migration,* followed either by progressive cell *growth and differentiation* or, in complete contrast, by cell *degeneration and death*. In the example quoted, cell proliferation persists as a prominent feature at the levels concerned with limb innervation, whilst at thoracic levels a dorsomedial migration of neuroblasts occurs to lay the foundation of the visceral efferent column. Further, save at limb levels, massive cell degenerations occur in the lateral 'motor' columns, whereas the medial columns, which innervate axial musculature, persist throughout the cord. The phenomenon of cell death and removal on a large scale, balanced against local proliferation and migration rates, has only been recognized relatively recently (p. 79) as a fundamental feature in many morphogenetic situations. For an excellent review of this field in relation to the developing nervous system, the interested reader should consult Hughes (1968; 1974).

Thus, as we have seen, some ventral laminal neuroblasts differentiate into the ventral horn neurons from which both alpha, beta and gamma efferent fibres arise, and these are accompanied at thoracic, upper lumbar, and mid-sacral levels, by preganglionic autonomic efferents from neuroblasts of the developing lateral horn. However, additionally, numerous interneurons develop in both these situations (including the well-studied Renshaw cells), but it is uncertain how many of these differentiate directly from ventral lamina neuroblasts, and how many migrate to their final positions from the dorsal lamina.

In the human embryo, the definitive grouping of the ventral column cells which characterizes the mature cord (p. 869) occurs quite early, and by the fourteenth week (the 80 mm stage) all the major groups can be recognized (Romanes 1941, 1942, 1946, 1955, 1964).

As the anterior and lateral grey columns assume their final form the germinal cells in the ventral part of the ventricular zone gradually cease to proliferate, and the layer becomes reduced in thickness until it ultimately forms the single-layered ependyma which lines the ventral part of the central canal of the spinal cord. The *posterior (dorsal) column* is somewhat later in its development, and, as a result, its ventricular zone is for a time much thicker in the dorsal lamina than it is in the ventral (basal) lamina (**2.61B**).

While the columns of grey matter are being defined, the dorsal region of the central canal becomes narrow and slit-like, and its walls come into apposition and fuse with each other (**2.64**). In this way the central canal becomes, relatively, reduced in size and somewhat triangular in outline.

About the end of the fourth week advancing axonal sprouts invade the marginal zone. The first to develop are those destined to become short *intersegmental* fibres from the neuroblasts in the intermediate (mantle) zone, and also fibres of *dorsal roots* of spinal nerves which pass into the spinal cord from neuroblasts of the early spinal ganglia. The earlier dorsal root fibres invade the dorsal marginal zone stem from *small* dorsal root ganglionic neuroblasts. By the sixth week the latter form a well-defined *oval bundle* near the peripheral part of the dorsal lamina (**2**.61B); this bundle increases in size and, spreading towards the median plane, forms the *primitive posterior funiculus*; its constituent fibres are destined to be of fine calibre. Later, fibres derived from new populations of *large* dorsal root ganglionic neuroblasts join the dorsal root and invade the cord nearer the medial plane; they are destined to become fibres of much larger calibre. As the posterior funiculi increase in thickness, their medial surfaces come into contact separated only by the *posterior median septum*, which is ependymal in origin, neuroglial in nature. (A more detailed analysis of the temporal sequence of modifications of the dorsal root plate, posterior median septum, and the lateral displacement of the *primitive posterior funiculus* with the later development of the fasciculus cuneatus followed by the fasciculus gracilis, based on a study of sectioned human embryos of 6–10 weeks, and dissections of fetuses up to the end of the fourth month has been provided by Hughes (1976). He proposed that the displaced primitive posterior funiculus may form the basis of the dorsolateral tract or fasciculus (of Lissauer), and also correlated the sequence, siting and calibre of the entrant dorsal root fibres, with the changing size-distribution of the somata of the dorsal root ganglionic neuroblasts.)

Long intersegmental fibres begin to appear about the third month and *corticospinal* fibres about the fifth month. All nerve fibres are at first without myelin sheaths, and different groups commence to develop sheaths at different times, e.g. the ventral and dorsal nerve roots about the fifth month, the corticospinal fibres after the ninth month. In peripheral nerves the myelin is formed by Schwann cells; in the central nervous system oligodendrocytes are believed by the majority of workers to be concerned (p. 845). Myelination, of course, persists until overall growth of the central and peripheral nervous system has ceased.

The cervical and lumbar enlargements first appear simultaneously with the development of their respective limb buds.

In early embryonic life the spinal cord occupies the *entire length* of the vertebral canal, and the spinal nerves pass outwards at right angles. After the embryo has attained a length of 30 mm the vertebral column begins to grow more rapidly than the spinal cord, the caudal end of which gradually becomes more cranial in the vertebral canal. Most of this relative rostral migration occurs during the *first half of* intrauterine life. By the twenty-fifth week the terminal ventricle of the spinal cord (p. 869) has altered in level from the second coccygeal vertebra to the third lumbar, a distance of nine segments, and there remain but two segments before the adult position is reached (Streeter 1919). As the change in level begins rostrally, the caudal end of the terminal ventricle, which has become adherent to the overlying ectoderm, remains *in situ*, and the walls of the intermediate part of the ventricle and its covering pia mater become drawn out to form a delicate filament, the *filum terminale*. The separated portion of the terminal ventricle persists for a time but it disappears before birth as a rule. It does, however, occasionally give rise to congenital cysts in the neighbourhood of the coccyx.

THE SPINAL NERVES AND NEURAL CREST

Each spinal nerve is connected to the spinal cord by a ventral root and a dorsal root. The fibres of the ventral roots grow out from neuroblasts in the anterior and lateral parts of the intermediate zone; these pass through the overlying marginal zone and external limiting membrane, to enter the *myotomes* of the mesodermal somites and ultimately form the alpha-, beta- and gamma-efferents. At appropriate levels these are accompanied by the outgrowing axons of preganglionic sympathetic neuroblasts (segments T1–L2), or preganglionic parasympathetic neuroblasts (S2–4).

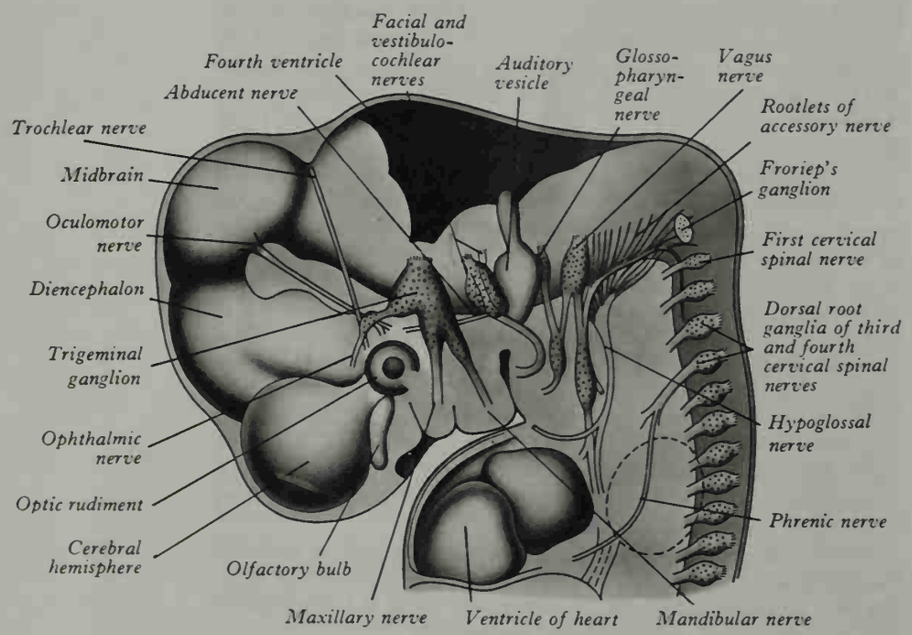
The fibres of the dorsal roots are developed from the cells of the spinal ganglia. Before the neural groove is closed to form the neural tube (p. 112) a ridge of neurectodermal cells, termed the *neural crest* (*ganglion ridge*), appears along the prominent margin of each neural fold (**2**.29). When the folds meet in the median plane the two neural crests fuse into a wedge-shaped mass along the line of closure of the tube. Opposite each primitive mesodermal segment the neural crest cells proliferate rapidly to form a bilateral series of oval-shaped *primordial spinal ganglia*, and these migrate for a short distance in a lateral and ventral direction. From the ventral *region* of each a small part separates to form *sympatho-chromaffin* cells (pp. 175, 1454), while the remainder becomes a *definitive* spinal ganglion. The spinal ganglia are arranged symmetrically at the sides of the neural tube and, except in the caudal region, are equal in number to the primitive segments. The cells of the ganglia, like the cells of the intermediate zone of the early neural tube, are glioblasts and neuroblasts. The glioblasts develop into the satellite cells, which become closely applied to the ganglionic nerve cell somata (perikarya), into Schwann cells, and possibly other cells. The neuroblasts, at first round or oval, soon become fusiform, with extremities gradually elongating into central and peripheral processes. The central processes grow into the neural tube, as the fibres of dorsal nerve roots, while the peripheral processes grow ventrolaterally to mingle with the fibres of the ventral root thus forming a mixed spinal nerve. As development proceeds the original bipolar form of the cells in the spinal ganglia changes; the two processes become approximated until they ultimately arise from a single stem in a T-shaped manner, to form a unipolar cell (sometimes, less appropriately, termed pseudo-unipolar). The biopolar form is, however, retained in the retina and in the ganglia of the vestibulocochlear nerve. Some observers hold that the T-form is derived from the branching of a single process which grows out from the cell.

It should be noted that the position of the early neural crest as a wedge-shaped mass along the line of tube closure noted above, and the identification of ganglionic cells in various positions in the wall of the early neural tube, and even within the central canal (Humphrey 1944; 1947), is strongly reminiscent of the developmental history of the *Rohon-Beard cells* in fish and amphibia (Rohon 1884; Beard 1896), which are thought to be important in the emergence of primitive locomotor patterns (Hughes 1968). In this regard, other investigators have claimed that in primitive chordates (Cyclostomes and Euselachians) the neural crest develops as an *evagination* of the dorsal region of the alar lamina of the late neural folds and early neural tube (Conel 1942). (For a review of the origin, widespread migration and differentiation of neural crest cells *see*, for example Weston 1970, Bellairs 1971, Leikola 1976, and p. 115.)

For more than a century there have been many attempts to plan investigations which would aid an understanding of the *causal morphogenetic mechanisms* which operate during the development of the nervous system, and to correlate the stage of development with emergent *behavioural patterns*. Whilst much has been established, the answers to many fundamental questions still remain in obscurity. A review of this important and interesting area of biology lies outside the scope of the present volume and the reader should consult the pioneering works which have appeared over the intervening years. Consult references (Bidder and Kupffer 1857; His 1879, 1883, 1887, 1890; Ramón y Cajal 1928, 1960; Waldeyer 1891; Harrison 1906, 1907, 1910, 1914, 1924; Coghill 1929; Detwiler 1936; Spemann 1938; Weiss 1950; Villier *et al.* 1955; Hughes 1968; Gottlieb 1974).

Briefly, the nervous system is closely interlocked, in terms of morphogenesis, with the 'periphery', i.e. surrounding non-nervous structures, and each is dependent upon the other for its effective structural and functional maturation.

Reference has already been made to the widely assumed initiating importance of a triggering system whereby the prechordal plate and chorda-mesoderm of the archenteron roof operate as a coordinated series of regional neural plate inducers—archencephalic, deuterencephalic, and spinocaudal. (However, *see* discussions on pp. 110, 112, 156 and consult Bellairs 1971.) Thereafter follows a period during which the main cell masses and subdivisions of the neural tube are established, and



transplantation experiments have indicated that some of the earlier patterning is an expression of self-differentiation of the tube. (For a descriptive and experimental review of pattern formation in these comparatively early stages of neurogenesis in the chick consult Watterson 1965.) However, the polarization of ventral lamina neuroblasts, and those of the neural crest, and the formation of segmentally arranged ventral nerve roots and spinal ganglion primordia, is closely related to, and dependent upon, the orderly segmentation of the neighbouring mesodermal somites. Experimental removal or intercalation of somites results in corresponding disturbances of pattern in these nervous structures.

There are many other examples of the influence of peripheral structures on the development of the nervous system. For example, if the normal peripheral innervation of the tetrapod limb is prevented experimentally, there follows a gross disturbance in the balance between neuroblast proliferation, degeneration, migration and maturation in the relevant part of the neural tube and primitive spinal ganglia. Conversely, the denervated limb rudiment itself fails to complete its development in the absence of nerve-mediated influences. Other extensively investigated situations include the inductive influence of the optic vesicle on adjacent ectoderm with the formation of a lens vesicle (p. 176), and the reciprocal influences of the developing lens and peri-optic mesenchyme on the differentiation of the optic cup (p. 176); the profound influence of peripheral innervation on the regeneration of limbs in amphibia; the 'trophic' maintenance of striated muscle structure by peripheral nerves (p. 862); the dependency of regenerating peripheral nerves on the establishment of normal peripheral connexions before a restoration of their structural and functional parameters ensues. Thus, whilst there are numerous experimentally demonstrable examples of the *interdependence* of the developing nervous system and the periphery, the precise causal mechanisms at work remain obscure. In this regard, however, mention should be made of a fairly recent proposal (Prestige 1965, 1967) concerning the operation of *maintenance factors* thought to be produced by the tissues of developing tetrapod limbs, and which may enter the nervous system, perhaps to be stored in the cytoplasm of neurons, where their concentration influences the turnover of neuroblasts, i.e. the balance between the rate of proliferation and degeneration. Similarly, other workers (Levi-Montalcini 1942, 1943, 1951, 1952, 1956, 1960, 1963; Cohen 1958, 1959, 1960; Cohen and Levi-Montalcini 1956, 1957) have isolated various proteinaceous *nerve growth factors* from tissue and tumour extracts, and snake venom, which influence the *in vitro* form and extent of nerve cell growth. Although the operation of such factors in normal ontogeny has not been claimed by these workers, others have demonstrated the presence of similar substances in homogenates of the axial structures of chick embryos during the period of early neurogenesis.

One problem which has attracted neuroembryologists for many years concerns the manner in which growing nerve fibres reach and make functional contact with their appropriate end organs (neuromuscular endings, secreto-motor terminals, or synapses with other neurons), during which they often pursue complex courses between the parent cell body and the sites of termination. If the cells concerned had been in contact from the first, the problem would have reduced to one concerning mechanisms of relative displacement and migration of both, with simple elongation of the nerve cell process between them. However, during the outgrowth of axonal processes from, for example, neuroblasts within the basal lamina to reach presumptive myoblasts in the limb buds, the earliest nerve fibres are known to cross appreciable distances occupied solely by loose general mesenchyme.

The growing tips of the neurites have been studied in tissue culture (Harrison 1910; Lewis 1945; Spiedel 1932, 1933, 1935; Nakai 1960; Nakai and Kawasaki 1959; Pomerat *et al.* 1967; and *vide infra*) and in the tail of larval amphibia (Spiedel 1932, 1933, 1935). Classically, the tip has been described as expanded into a *growth cone* which is constantly active, changing shape, extending and withdrawing processes which apparently 'explore' the local environment for a suitable surface along which extension may occur (*see* 'cell motility' p. 35). One process then enlarges at the expense of others and expands into a new growth cone, the exploratory behaviour recommencing. However, it has been suggested that the very rapid surface activity of growth cones is associated more with the micropinocytotic imbibition of water and solutes (perhaps in relation to a peripheral undulating cytoplasmic veil, or ruffled border, as in macrophages), forming cytoplasmic vacuoles which migrate centrally along the neurite. On this view the tip of the main body of the neurite moves in a series of discontinuous directional thrusts. Earlier ultrastructural studies also emphasized the presence within growth cones of microvesicles in the general cytoplasm (Estable *et al.* 1957) and vacuoles within the cisternae of the endoplasmic reticulum (Bellairs 1959), (but see also below). In this context it is also widely held that products important in the growth mechanisms, and synthesized within the cell bodies, are passed outwards by some form of proximodistal *axoplasmic flow* along the neurites. Bulk axoplasmic flow was first postulated following the experimental constriction of nerves in 1948 (Weiss and Hiscoe 1948), and since that time many intricate analyses of rapid and slow components of *bidirectional flow systems* within axons have been made (Lubinska 1964; and *see: Neurosciences Research Programme Bulletin* **4**, vol 5, 1968; also p. 826).

However, in a series of ultrastructural studies on the *in vitro* outgrowth of neurites from explants of chick *spinal cord*, a number of established views concerning their form, structure and surface contacts have been challenged (Grainger *et al.* 1968; James and Tresman 1969; Grainger and James 1970). In addition to describing the formation of neuromuscular junctions and varieties of synapse under these experimental conditions, the authors have shown that the neurites usually grow out in bundles rather than as single processes. The neurites contain arrays of longitudinal microtubules which are probably interconnected, microfilaments, mitochondria, linear densities in the cytoplasm, and populations of vesicles. The expanded tip of the neurite bundle is not an aggregation of simple 'growth cones', but usually the neurite terminals end in association with a 'glial' cell. The latter has a relatively dense cytoplasm containing an array of organelles enabling it to be distinguished from the neighbouring neurites. Further, the glial cell is complex in form. It sends a major cytoplasmic process back towards the parent explant; it presents

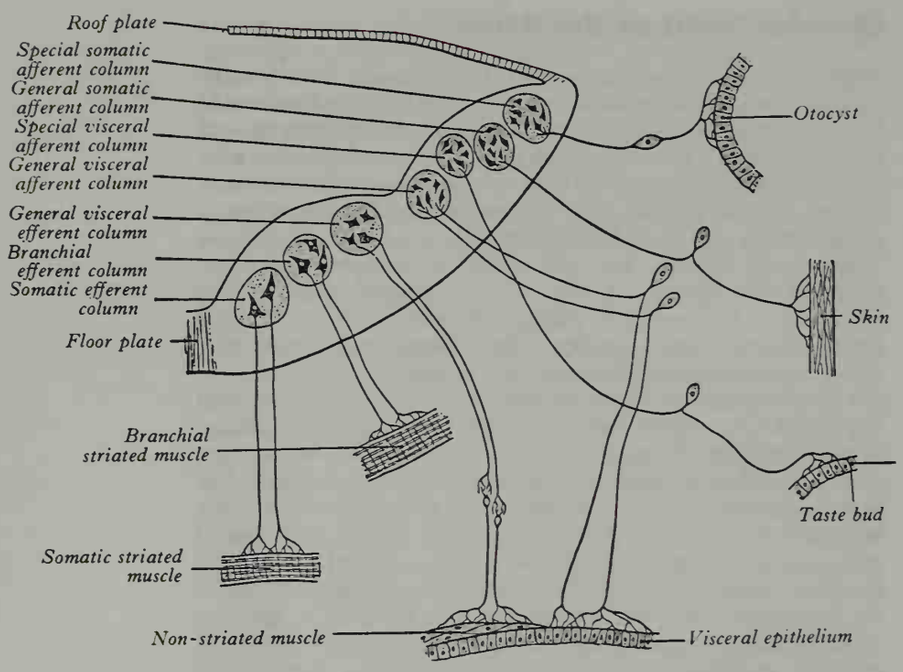
2.65 The brain and cranial nerves of a human embryo, 10·2 mm long. note the midbrain, cervical and pontine flexures, and the expanding fourth ventricle. Note also the ganglia (stippled) associated with the trigeminal, facial, vestibulocochlear, glossopharyngeal, vagus and spinal accessory nerves. Froriep's ganglion, an occipital dorsal root ganglion, is inconstant and soon disappears. (After His.)

surface projections which partly enfold the terminal neurites, and distally, beyond the neurites, cytoplasmic sheets or finger-like processes extend to come into intimate relationship with the culture substrate. Thus, the essential contacts appear to be between glial cell membrane and substrate, and between neurite membrane and glial cell membrane, posing the question whether the glial cell, rather than the tip of the neurite, is basically involved in determining the direction of outgrowth. Further investigations will be necessary to determine how far these appearances are reflected in the growth of both central and peripheral neurites in normal ontogeny, although some supporting evidence has been adduced concerning the growth of *central* neuroblasts (Rakic 1971). Further details cannot be pursued here, but recently an excellent review has appeared concerning the morphology, motility and directional growth of axons and their growth cones, including the *in vitro* establishment of synaptic contacts—for this consult James (1974). It may be pointed out that some authors (e.g. Rakic 1971) have suggested that within the central nervous system, the direction followed by advancing neurites may stem from contact guidance (*see* pp. 91, 862, and below) with previously established glioblast processes. On the other hand, in recent studies of the growth cones of neurites from explanted dorsal root ganglia of the rat (including their endocytotic uptake and transport of horseradish peroxidase), using light, transmission and scanning electron microscopy, many surface features and ultrastructural details of the cones were provided; no 'leading' glial or Schwann cells were identified. (For further discussion and bibliography consult Fischer 1977; and for a literature review concerning *dendritic* growth—Berry 1974.)

Over the years two principal theories emerged concerning the directional growth of nerve fibres—the *neurotropism* of Ramón y Cajal (1919), and the principle of *contact-guidance* of Weiss (1941). The former, based upon observations on the innervation of epithelia, proposed that growing fibres were guided by some form of attraction, presumably chemical, which emanated from the area to be innervated. The second view denied the existence of such attractive forces and, based upon many series of tissue culture experiments, held that pioneer neurites were guided to their destination by preferential growth along pathways provided by an orientation of the micellar substructure of the intercellular matrix in the intervening spaces. Despite the forceful arguments brought to bear on this question, it should be noted that in a more recent critical review of this field (Hughes 1968), it was stated—'Both contact guidance and neurotropism, however associated or combined, are inadequate to explain the pattern of the peripheral nervous system and, *a fortiori*, of the enormously more intricate plan of the fully differentiated neural tube. No imaginable hypothesis is at present adequate to explain the phenomena of the regeneration of the optic nerve, which is the only central pathway which has so far been studied by experimental means. At present the only possible way of regarding the whole question is in terms of a succession of influences which operate in turn upon a growing nerve fibre, from its first emergence to its final link with an end organ. Such a sequence of controlling factors was postulated as far back as 1911.' Nevertheless, whilst few would disagree with the general tenets of these remarks, hypotheses abound, and there is currently a great upsurge of interest in neuroembryology. As an introduction to the extensive literature, the interested reader should consult, for example, Sperry (1958, 1963, 1965); Schmitt (1970); Jacobson (1970); Gaze (1970); Gottlieb (1973, 1974); Mark (1974). In addition to questions concerning the growth, guidance, and patterning of neurites and somata, the following kinds of problem confront neuroembryologists. What are the basic ontogenetic factors providing positional information (p. 87, controlling proliferative cycles, differentiating mitoses, and the initial polarization and migration of neuroblasts? How much of the initial patterning is preprogrammed in the genome, and how much environmentally and functionally dependent? To what extent do regeneration experiments reflect ontogeny? Do neurons bear individually unique chemical markers? What are the structural bases of neuronal plasticity, and the behavioural phenomena of instinct, learning, and memory? Answers still elude us and we remain at the stage of attempting to plan meaningful experiments.

Development of the Brain

Prior to the closure of the neural tube the neural folds become expanded considerably in the head region as a first indication of a brain. Subsequent to the closure of the anterior neuropore (p. 112) these expansions form the three *primary cerebral vesicles* (**2**.65, 68). The customary use of the term 'vesicle' though followed here, suggests an exaggerated view of these localized accelerations of growth in the wall of the brain (O'Rahilly and Gardner 1971). In 'higher' vertebrates, and especially in primates, including mankind, the bulging is not initially marked, nor are the constrictions between them particularly narrow. The vesicles are more like gently fusiform tubes. The three regions are named the *rhombencephalon* or *hindbrain*, the *mesencephalon* or *midbrain*, and the *prosencephalon* or *forebrain*—the first being continuous with the spinal cord. As the result of unequal growth of its different parts three flexures appear in the brain; two of these are concave ventrally and there are corresponding flexures of the head. The first is associated with the formation of the head fold and is a *midbrain flexure*; as a result the forebrain bends in a ventral direction around the cephalic end of the notochord and foregut and thus progresses until its floor lies almost parallel with that of the hindbrain (**2**.65, 68). The midbrain is thus, for a time, the most prominent part of the brain, and underlies the marked *midbrain prominence* of the overlying ectoderm, seen to best advantage when the embryo is viewed from the side. The second bend appears at the junction of the hindbrain and spinal cord and is termed the *cervical* or *neck flexure* (**2**.65, 68). This increases from the fifth to the end of the seventh week, by which the hindbrain forms nearly a right angle with the spinal cord; after the seventh week, however, extension of the head takes place and the cervical flexure diminishes and eventually disappears. These bends are important factors in determining the shape of the cranial end of the embryo. The third bend is named the *pontine flexure*, because it is at the level of the future pons. It differs from the other two in that its convexity is directed ventrally, and it does not substantially affect the outline of the head. (For more recent accounts of the early development of the brain consult Bartlemez and Dekaban (1962); Jacobson (1970); Gaze (1970); Eccles (1972); Gottlieb (1972, 1974); Mark (1974).)



The lateral walls of the hindbrain and midbrain, like those of the spinal cord, are divided into *dorsal* (*alar*) and *ventral* or (*basal*) *laminae* by the upward continuation of the limiting sulci of the spinal cord.

THE RHOMBENCEPHALON

By the time the midbrain flexure appears, the hindbrain exceeds in length the combined extent of the other two brain vesicles. Cranially it exhibits a constriction, the *isthmus rhombencephali* (**2**.68B), best viewed from the dorsal aspect. Ventrally the hindbrain is separated from the dorsal wall of the primitive pharynx only by the notochord, the two dorsal aortae, and a small amount of mesenchyme; on each side it is closely related to the dorsal ends of the visceral arches (**2**.54).

The formation of the pontine flexure appears to 'stretch' the thin, epithelial roof plate, which becomes widened, the greatest increase in width corresponding to the region of maximum convexity, so that the outline of the roof plate becomes rhomboidal. By the same change the lateral walls become separated, particularly dorsally, and the cavity of the hindbrain, subsequently the fourth ventricle, becomes flattened and somewhat triangular on cross-section. The pontine flexure becomes increasingly acute until, at the end of the second month, the laminae of its cranial (metencephalic) and caudal (myelencephalic) slopes are opposed to each other (**2**.67C) and, at the same time, the lateral angles of the cavity extend to form the lateral recesses of the fourth ventricle.

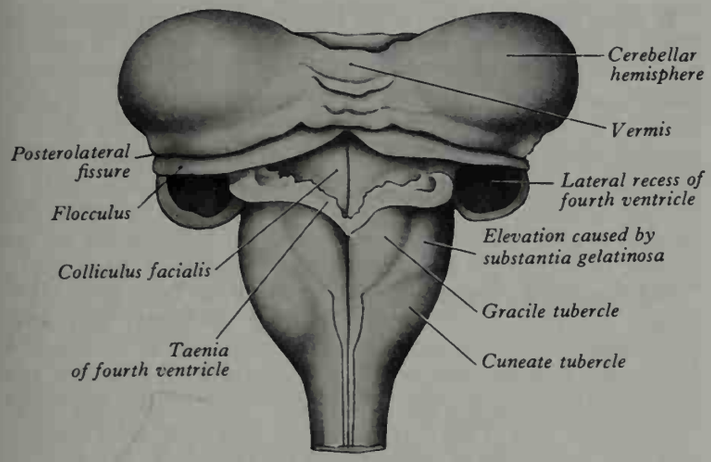
About the end of the fourth week, when the pontine flexure is first discernible, a series of six transverse *rhombic grooves* appears in the ventral lamina of the hindbrain. Between the grooves, the intervening masses of neural tissue have, at this stage, been termed *rhombomeres* (*neuromeres*). These are closely associated with the pattern of the underlying motor nuclei of certain of the

2.66 Diagram of a transverse section through the developing hindbrain of a human embryo, *c.* 10·5 mm long, to show the relative positions of the columns of grey matter from which the nuclei associated with the different varieties of nerve components are derived. Note the postganglionic neurons associated with the general visceral efferent column, the bipolar neurons associated with the otocyst and the unipolar afferent neurons associated with the other alar lamina columns.

cranial nerves. The first two overlie the trigeminal nucleus, the third the facial nucleus, the fourth that of the abducent nerve, the fifth that of the glossopharyngeal, and the sixth that of the vagus. These grooves, though transient, are constant in appearance, but their significance is uncertain. Some authorities regard them as evidence in support of a primitive segmental (neuromeric) origin for the brain and spinal cord (Berquist 1952).

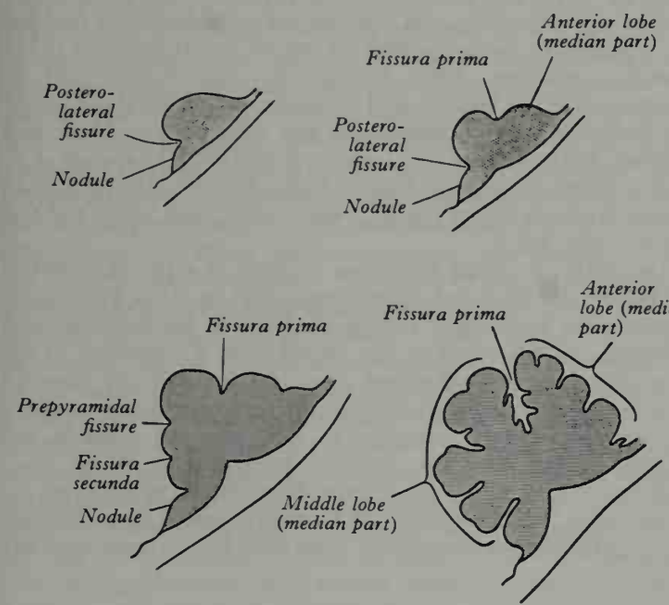
The differentiation of the lateral walls of the hindbrain into ventral and dorsal laminae has a similar significance to the corresponding differentiation in the lateral wall of the spinal cord (p. 160), and ventricular, intermediate and marginal zones are formed in the same way.

The cells of the ventral lamina are often, in elementary accounts, simply termed 'motor' (but *vide infra*), and they form three elongated, but interrupted, columns. The most ventral column is continuous with the anterior grey column of the spinal cord and will supply muscles considered 'myotomic' in origin. It is represented in the caudal part of the hindbrain, as the hypoglossal nucleus, and it reappears at a higher level as the nuclei of the abducent, trochlear and oculomotor nerves, which are *somatic efferent nuclei*. The intermediate column, which is only represented in the upper part of the spinal cord, is for the supply of branchial musculature. It is interrupted also, but the caudal part, which gives fibres to the ninth, tenth and eleventh cranial nerves, forms the elongated *nucleus ambiguus*. At higher levels this column gives origin to the motor nuclei of the facial and trigeminal nerves. These three nuclei are termed *branchial (special visceral) efferent nuclei*. The most dorsal column of the ventral lamina (represented in the spinal cord by the lateral grey column) innervates viscera. It is interrupted also, its large caudual part forming a portion of the *dorsal nucleus of the vagus* and its cranial part the *salivatory nucleus*. These are termed *general visceral (general splanchnic) efferent nuclei* and their neurons give rise to preganglionic, parasympathetic nerve fibres.



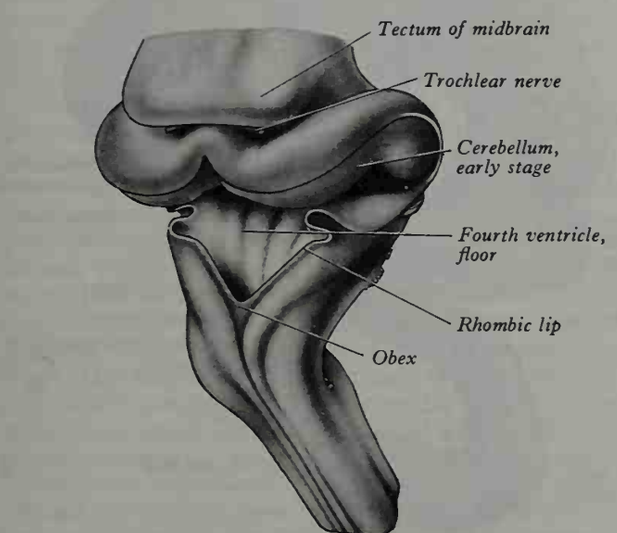
It should be noted here that the neuroblasts of the ventral (basal) lamina and their three columnar derivatives are only 'motor' in the sense that *some* of their number, form either α, β or γ motor neurons, or preganglionic parasympathetic neurons. The remainder, which almost certainly greatly outnumber the former differentiate into functionally related interneurons.

The cell columns of the dorsal lamina are also interrupted and give rise to *general visceral (general splanchnic) afferent, special visceral (special splanchnic) afferent, general somatic afferent* and *special somatic afferent* nuclei (their relative positions are shown in (2.66). The general visceral afferent column is represented by a portion of the dorsal nucleus of the vagus (see also p. 1076), the special visceral afferent column by the nucleus of the tractus solitarius, the general somatic afferent column by the afferent nuclei of the trigeminal nerve (Brown 1974), and the special somatic afferent column by the nuclei of the vestibulocochlear nerve (Verbitskaja 1973). (Again it should be noted here that the relatively simple functional independence of these afferent columns implied by the foregoing classification is, in the main, an aid to elementary learning. The emergent neurobiological mechanisms are in fact much more complex, and less well understood—*see* p. 1084.) Although they tend to retain their primitive positions some of these nuclei are later displaced by differential growth patterns and by the appearance and growth of neighbouring fibre tracts, and possibly by active migration. It has been suggested that a nerve cell tends to remain as near as possible to its predominant source of stimulation and that when the danger of separation arises, owing to the development of neighbouring structures, it will migrate in the direction from which the greatest density of stimuli come. This phenomenon was termed neurobiotaxis (Kappers 1921, 1934). Cells can migrate in this way only by lengthening of their axons, which therefore trace the route taken by the cells on their transit. The curious courses of the fibres arising from the facial nucleus (p. 910) and nucleus ambiguus (pp. 900, 905) have been held to illustrate this. In the 10 mm embryo the facial nucleus lies in the floor of the fourth ventricle, occupying the position of the special visceral efferent column and at this stage it is placed at a higher level than the abducent nucleus. As growth proceeds the facial nucleus migrates at first caudally and dorsal to the sixth nerve nucleus and then ventrally to reach its adult position. As it migrates, the axons to which its cells give rise elongate and their subsequent course maps out the pathway along which the facial nucleus has travelled. Similarly the nucleus ambiguus arises initially, immediately deep to the ventricular floor but in the adult it is more deeply placed and its efferent fibres first pass dorsally and medially before curving laterally to emerge at the surface of the medulla oblongata. Attractive as the concept of neurobiotaxis may have seemed, it must be added that it is supported by little direct evidence.



The Myelencephalon

The caudal slope of the hindbrain constitutes the *myelencephalon*, which develops into the medulla oblongata. The nuclei of the ninth, tenth, eleventh and twelfth cranial nerves develop in the situations already indicated, and afferent fibres from the ganglia of the ninth and tenth nerves form an oval marginal bundle in the region overlying the dorsal (alar) lamina. The dorsal edge of this lamina throughout the rhombencephalon gives attachment to the thin expanded roof plate and is termed the *inferior rhombic lip*. As the walls of the rhombencephalon spreads outwards, the rhombic lip protrudes as a lateral edge which becomes folded over the adjoining area. According to this widely accepted view it later becomes adherent to this area, and the cells of the rhombic lip migrate actively into the marginal zone of the ventral *lamina*. In this way the oval bundle which forms the *tractus solitarius* becomes buried beneath the surface. Dorsal lamina cells which migrate from the rhombic lip are believed to give origin to the olivary and arcuate nuclei and the scattered grey matter of the nuclei pontis. While this migration is in progress the thin floor plate is invaded by fibres which cross the median plane (accompanied by neuroblasts which cluster in and near this plane), and it becomes thickened to form the *median raphe*. Some of the migrating cells from the rhombic lip in this region fail to reach the ventral lamina and form an oblique ridge across the dorsolateral aspect of the inferior cerebellar peduncle; this ridge constitutes the *corpus pontobulbare (nucleus of the circumolivary bundle)*.



The lower part of the myelencephalon takes no part in the formation of the fourth ventricle, and, in its development, it

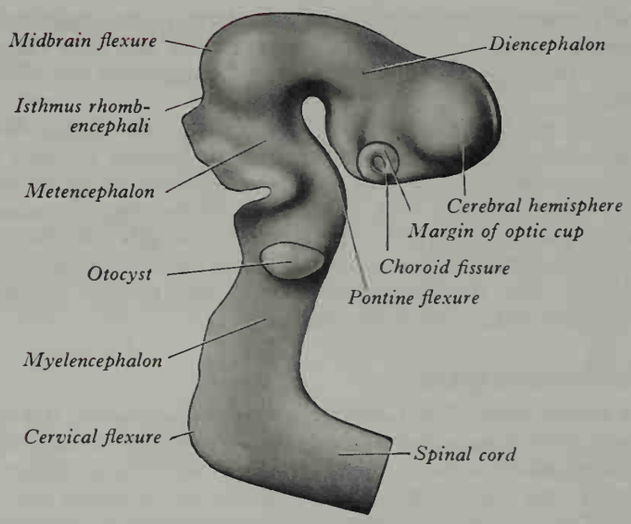
2.67C The dorsal aspect of the hindbrain of a human fetus about three months old. Viewed from behind and partly from the right side. (From a model by His.)

closely resembles the spinal cord. The large nuclei, gracilis and cuneatus, are derived from the dorsal lamina, and their efferent arcuate fibres play a large part in the formation of the median raphe.

About the fourth month the descending *corticospinal* fibres invade the ventral part of the medulla oblongata to form the pyramids, whilst dorsally, ascending fibres from the spinal cord, with olivocerebellar and parolivocerebellar fibres, external arcuate fibres, together with two-way reticulocerebellar and vestibulocerebellar interconnexions, form the inferior cerebellar peduncle. The reticular nuclei of the lower medulla probably have a dual origin from both laminae.

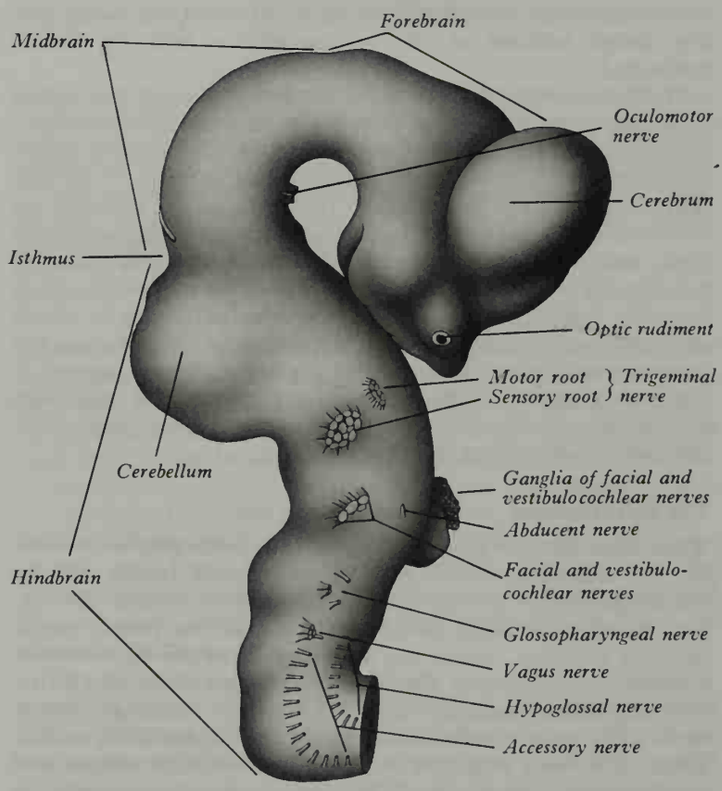
The Metencephalon

The rostral slope of the hindbrain is the *metencephalon*, and from it both cerebellum and pons are developed. Prior to the formation of the pontine flexure the dorsal laminae of the metencephalon are parallel with one another. Subsequent to its formation the roof plate of the hindbrain becomes rhomboidal and the dorsal laminae of the metencephalon lie obliquely, being close together at the cranial end of the fourth ventricle, but widely separated in the region of its lateral angles. The accentuation of the pontine flexure approximates the cranial angle of the ventricle to the caudal, and the dorsal laminae of the metencephalon now lie almost horizontally.



It should be noted that caudal to the developing cerebellum (*vide infra*), the roof of the fourth ventricle remains epithelial, covering an approximately triangular zone, from the lateral angles of the rhomboid fossa to the median obex (p. 933). Over this region the nervous tissue fails to develop and the vascular pia mater is closely applied to the subjacent ependyma. At each lateral angle, and in the midline caudally the membranes break through forming the lateral and median apertures of the roof of the fourth ventricle. Subsequently, these are the principal routes by which cerebrospinal fluid, produced in the ventricles, escapes into the subarachnoid space. The vascular pia mater, in an inverted V formation, cranial to the apertures invaginates the ependyma to form vascular fringes—the vertical and horizontal parts of the choroid plexuses of the fourth ventricle (p. 933).

The Cerebellum



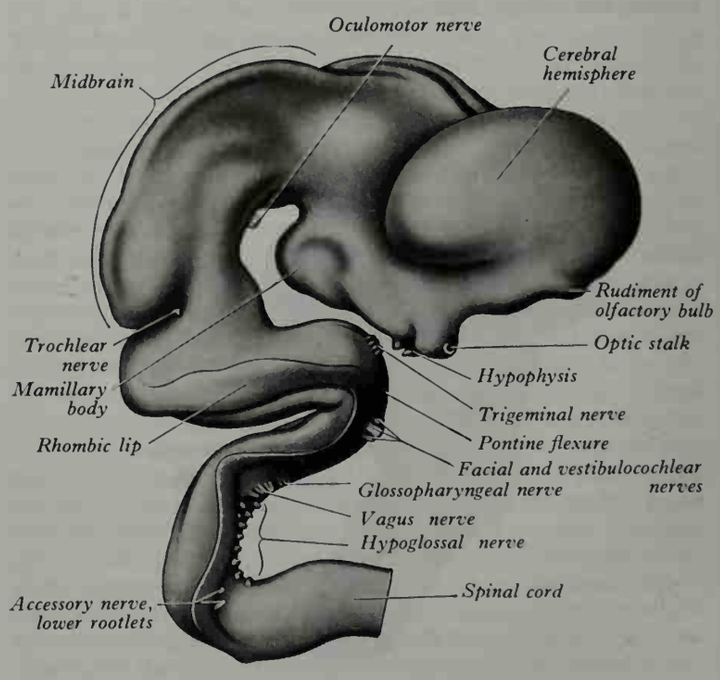
While these changes are occurring the cells in the *superior rhombic lip* and adjacent dorsal part of the dorsal lamina of the metencephalon proliferate to form the *rudiment of the cerebellum*. Two rounded swellings are formed which, at first, project partly into the ventricle (**2**.67B, C), and they form the rudimentary cerebellar hemispheres. The most cranial part of the roof of the metencephalon originally separates the two swellings, but it becomes invaded by cells, which form the rudiment of the vermis. These cells were regarded as derivatives of both ventral and dorsal laminae (Baxter 1953). At a later stage, *extroversion of the cerebellum* occurs, with reduction of its intraventricular projection and increasing prominence of a dorsal extraventricular projection. The cerebellum now consists of a bilobar (dumb-bell shaped) swelling stretched across the rostral part of the fourth ventricle (**2**.67A), continuous rostrally with the anterior medullary velum, which has formed from the isthmus, and caudally with the epithelial roof of the myelencephalon. As growth proceeds a number of transverse grooves appear on the dorsal aspects of the cerebellar rudiment, as the precursors of the numerous fissures which characterize the surface of the mature cerebellum **2**.67B, also p. 912).

The *posterolateral fissure*, in its lateral parts, appears first, demarcating the most caudal part from the rest of the cerebellar rudiment, enabling the *flocculi* to be identified. The lateral parts of this fissure extend medially and meet in the median plane, where they demarcate the nodule. The *flocculonodular lobes* can now be recognized and constitute the most caudal part of the cerebellum at this stage, but, owing to the growth of the adjoining areas, they progressively come to occupy the *anterior part* of the inferior surface in the adult. They are formed in close proximity to the line of attachment of the epithelial roof, i.e. to the rhombic lip (p. 933 and **2**.67C).

At the end of the third month a transverse sulcus appears on the

2.68A The right side of the brain of a human embryo, 9 mm long. (Drawn from a model by His.)

2.68B The brain of a human embryo about 10·2 mm long. Right lateral surface. (From a model by His.)



rostral slope of the cerebellar rudiment, and deepens to form the *fissura prima*, which cuts into the vermis and both hemispheres, separating off the most cranial region of the rudiment to form the anterior lobe.

About the same period two short transverse grooves appear on the inferior vermis; the first of these is the *fissura secunda*, which demarcates the uvula, and the second is the *prepyramidal fissure*, which demarcates the pyramid (their positions are indicated in 2.67B). The whole cerebellum now grows in a dorsal direction, and the caudal, or inferior, aspects of the hemispheres undergo much greater enlargement than the inferior vermis, which therefore becomes buried at the bottom of a deep hollow—the *vallecula*. While these changes are taking place numerous additional fissures develop, which are approximately parallel to, and intervene between, the foregoing. They are an expression of the relatively vast increase in surface area of the cerebellum which is occurring but their precise positions and systematic names have limited functional or morphological significance. The most extensive of these develops into the *horizontal fissure*.

In many mammals a part of the hemisphere immediately rostral to the floccular fissure becomes defined as an entity; in some it forms a very prominent part of the cerebellum; it is termed the *paraflocculus*, but the relationship is purely topographical, and, in contrast to the flocculus, the paraflocculus derives its afferent connexions mainly, but not entirely, from the cerebral cortex. It is uncertain whether any homologue of the paraflocculus exists in the human cerebellum, or whether it is represented by some small patches of grey matter which are found not infrequently on the inferior surface of the middle cerebellar peduncle (Larsell 1947).

Mammalian cerebellar histogenesis has been more completely described, both during normal ontogeny, and after experimental intervention, than in any other part of the nervous system, due in large measure to its precisely ordered geometry, and highly distinctive cell types. The connectivity, synaptology, and electrophysiology of the latter have also been intensively studied, and some knowledge of these aspects are a necessary prerequisite of any account of histogenesis (for this consult pp. 157–161). Particularly valuable in histogenetic investigations have been nuclear labelling with tritiated thymidine, the analysis of genetic variants, and the changes following surgical deafferentation, X-irradiation, and virus diseases. Most studies have been confined to mice and rats, and whilst it seems probable that *qualitatively* similar cell migrations and contacts occur, *quantitative* findings and ontogenetic *timings* cannot, of course, be extrapolated to the human cerebellum. Only the briefest introduction can be entertained in this volume, and the interested reader should enter the literature by consulting such key references as Miale and Sidman (1961), Fujita (1963), Fujita *et al* (1966), Kornguth *et al.* (1967), Mugnaini (1970), Eccles (1970), Hamori (1972), Altman (1972a, b and c), Eccles (1973), Swarz (1976), and Swarz and Del Cevro (1975, 1977).

The early cerebellar rudiment consists of a pseudostratified epithelium showing interkinetic migration (p. 157) which soon develops the three basic zones—ventricular, intermediate, and marginal—as elsewhere in the neural tube. Originating in the ventricular zone, *proliferation* of as yet *uncommitted germinal* (matrix) *cells* proceeds, however, in *two* quite distinct sites, which become increasingly separated as the rudiment expands and thickens. Germinal cells continue proliferating in the deep (subventricular) part of the intermediate zone forming what, for convenience, may be termed the *internal germinal layer*. Slightly later, spreading latero-medially from each side to meet centrally

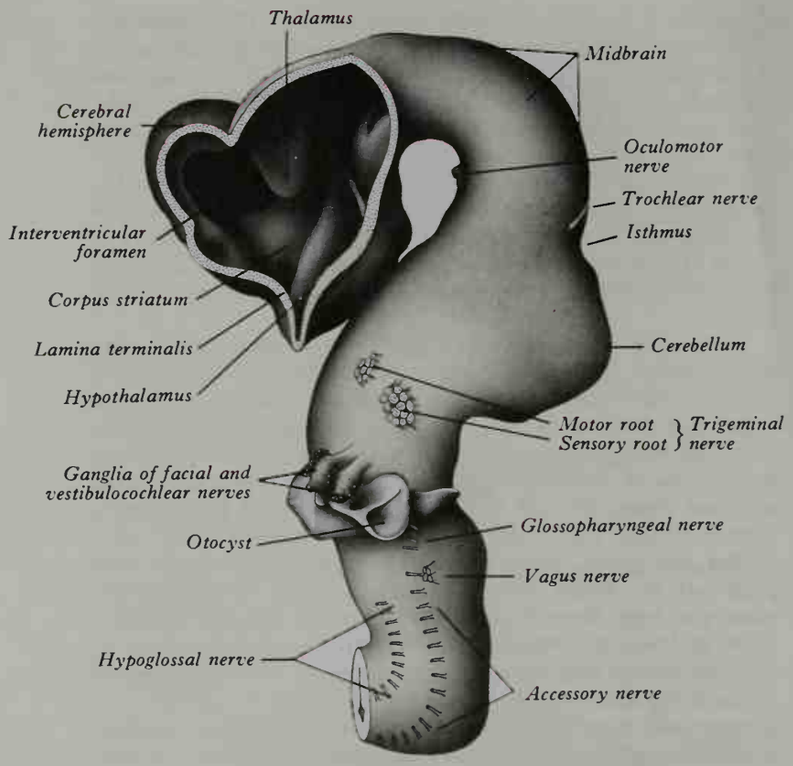
2.68C The right side of the brain of a human embryo, 13·6 mm long. The roof of the hindbrain has been removed. Compare with 2.69B. (From a model by His.)

in a subpial position (i.e. the most superficial part of the marginal zone), similarly uncommitted germinal cells proliferate forming an *external germinal layer* (sometimes, less appropriately, called the external granular layer). Both germinal layers continue *proliferative mitoses*, giving clonal progeny, until they are several cells thick. This *proliferative phase* gradually diminishes with the onset of the *phase of neurogenesis*, and this, in its turn, is gradually followed by a *phase of gliogenesis*. Following a precisely ordered time sequence, sets of *critical (quantal) mitoses* occur (p. 84), the progeny becoming *committed neuroblasts* which do not divide again. Each set is destined to become one of the specific neuronal varieties that characterize the deep cerebellar nuclei and cortex, and they *migrate* to their definitive positions, develop their neurites and synaptic contacts, and mature, again in finely patterned spatio-temporal *sequences*, the latter often exhibiting some degree of overlap. Similarly as neurogenesis wanes sets of quantal mitoses of some remaining germinal cells continue to give generations of *committed glioblasts* which, although less well documented than the neuroblasts, also migrate to, and mature in their definitive positions. The fate of each germinal layer will now briefly be reviewed.

Quantal mitoses of the uncommitted cells of the *internal germinal layer* result in the emergence of two types, followed somewhat later by a third type, of definitive neuroblasts. Initially, primitive Purkinje neuroblasts and primitive nuclear neuroblasts in approximately equal numbers, but whether this follows a series of symmetrical or asymmetrical mitoses (p. 84) is unknown. The *nuclear neuroblasts* remain embedded in the developing future white matter adjacent to the roof of the rostral part of the fourth ventricle. The main mass of nuclear neuroblasts then slowly subdivides into the primordial fastigial, emboliform, globose and dentate deep cerebellar nuclei, and the individual neuroblasts differentiate into either small intranuclear interneurons, or into the larger projection neurons. The axons of the latter invade the early cerebellar peduncles and pursue complex paths to their multiple destinations (*see* pp. 916–917). The *Purkinje neuroblasts*, in contrast, *migrate* superficially towards their definitive position in the expanding cortex, where they slowly mature into their highly characteristic form of somata and dendritic trees. As they migrate, the terminals of one neurite—the future axon—remain adjacent to, and ultimately in synaptic contact with, the nuclear neuroblasts, the remainder of the axon elongating as it 'trails' behind the advancing soma. The mature and developing Purkinje cell has been a favourite object for *quantitative* cytological and ultrastructural studies, both during normal ontogeny, and after such experimental manipulations as suppression of granule cell (and therefore parallel fibre) development, or after prevention of climbing fibre growth (*see*, for example, Hamori 1972, and p. 924). Excellent illustrative examples of the maturation of normal rat cerebellar cortex are to be found in the writings of Altman (1972b). When the formation of nuclear and Purkinje neuroblasts has proceeded for some time, a number of the remaining internal germinal cells give rise to generations of *Golgi neuroblasts* which also migrate superficially to gradually occupy, and mature in, their definitive position and morphology.

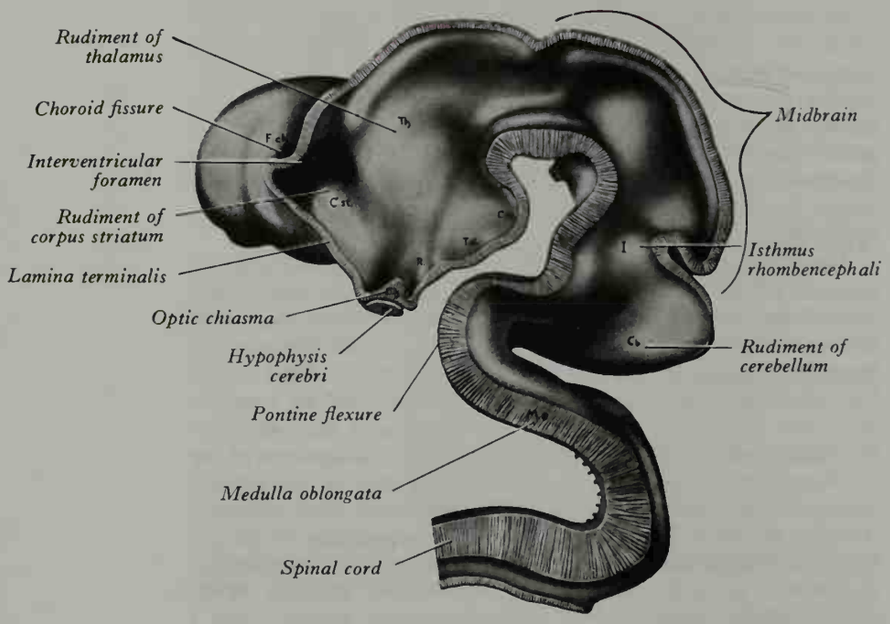
The first set of quantal mitoses in the *external germinal layer* gives generations of *basket neuroblasts* which migrate deeply to meet, and ultimately synapse with, the somata and preaxons of the ascending Purkinje neuroblasts, their axons passing transversely in the primordial cerebellar folia. Secondly, following intense proliferation of the external germinal cells, a second set of quantal mitoses results in vast numbers of *granule cell neuroblasts*. A widely held view is that these microneurons are at first bipolar, each presumptive axon growing in opposite directions along the long axis of the folium: bundles of such axons form the parallel fibres of the mature cortex (p. 922), and the more recently formed granule cell neuroblasts (with their parallel fibre axons) are placed in successive layers approaching the pial surface. The soma of the granule cell does not, however, remain bipolar and external to the Purkinje neuroblast layer. A neurite develops and grows deeply *through* the Purkinje layer, its tip ultimately dividing, meeting, and synapsing with the ingrowing mossy afferent terminals (p. 924), thus forming the primordial cerebellar glomeruli. As this centripetal neurite develops, the granule cell nucleus migrates along it to reach, and helps to form, the definitive granular layer of somata of the mature cortex. Rakic (1971a and b), however, reached a different conclusion from studies of migrating granule cell neuroblasts in the rhesus monkey, holding that they migrated deeply by contact guidance along the surface of the long radial processes of the Bergmann glial cells (Mugnaini and Forstrønen 1967). He considered that the migrating soma 'trailed' behind it an elongating neurite which subsequently bifurcated to form the parallel fibre axons, whilst dividing neurites passing in advance of the soma met the mossy afferents to form cerebellar glomeruli.

The final generations of neuroblasts from the external germinal layer merely migrate locally and differentiate into outer stellate cells.



The origin of the cerebellar glial cells remains much more problematical and has been the subject of dispute for almost a century. The view advanced by Obersteiner (1883) and Schaper (1897) was that the various macroglial cell varieties (Bergmann cells, astrocytes and oligodendrocytes) stemmed from final generations of germinal cells of *both* the internal and external germinal layers; this has received the more recent experimental support of such authorities as Fujita *et al.* (1966), Fujita (1967), Meller and Glees (1969) and Privat (1975). The second view proposed by Athias (1897) and Cajal (1911) held that the macroglia were formed exclusively from the internal germinal layer, and that the progeny of the external layer were solely the three varieties of neuroblast: this suggestion has been supported by the labelling studies of Swarz and Del Cerro (1977). Clearly such diametrically opposed views must await further critical evaluation using alternative methods, sites and species. All authorities seem agreed that the microglial elements are exogenous, invading the cerebellar rudiment from the surrounding mesenchyme.

The remainder of the metencephalon becomes the pons, but little is known of the individual stages in the transformation. Ventricular, intermediate and marginal zones are formed in the usual way, and the nuclei of the trigeminal, abducent and facial nerves develop in the mantle layer. It is probable that the grey matter of the formatio reticularis is derived from the ventral lamina and that of the nuclei pontis from the dorsal lamina by the active migration of cells from the rhombic lip. About the fourth month the pons is invaded by corticopontine and corticospinal fibres, becomes proportionately thicker, and takes on its adult appearance.



The region of the *isthmus rhombencephali* undergoes a series of changes which are difficult to interpret. As a result, the greater part of the region apparently becomes absorbed into the caudal end of the midbrain, only the roof plate, in which the anterior medullary velum is formed, and the dorsal parts of the dorsal laminae, which become invaded by the fibres of the superior cerebellar peduncles, remaining as recognizable derivatives in the adult. It should be noted that originally the decussation of the trochlear nerves is caudal to the isthmus, but as the growth changes occur it is displaced in a cranial direction until it reaches its adult position. These changes are also responsible (1) for the movement in the same direction of the trochlear nucleus, whereby it comes to lie in the midbrain, and (2) for the position of the mesencephalic nucleus of the trigeminal nerve, which is also a derivative of the isthmus rhombencephali (Frazer 1928).

THE MESENCEPHALON

The mesencephalon or midbrain is derived from the intermediate primary cerebral vesicle, which persists for a time as a thin-walled tube enclosing a cavity of some size, separated from that of the prosencephalon by a slight constriction and from the rhombencephalon by the isthmus rhombencephali. Later, its cavity becomes relatively reduced in diameter, and in the adult brain it forms the *cerebral aqueduct*. The ventral laminae of the midbrain increase in thickness to form the *cerebral peduncles*, which are at first of small size, but enlarge rapidly after the fourth month, when their fibre tracts begin to appear in the marginal zone. The neuroblasts of the ventral lamina give origin to the nuclei of the oculomotor nerve and grey matter of the tegmentum, while the nucleus of the trochlear nerve, and also the mesencephalic nucleus of the trigeminal nerve, migrate cranially into the midbrain owing to the developmental changes which occur in the isthmus

rhombencephali. It has been claimed (Chu-wu and Wen-kuei 1965) that some of the migrating neuroblasts of the mesencephalic nucleus reach the posterior commissure and its nucleus, and also the interstitial nucleus. The cells of the dorsal part of the dorsal laminae proliferate and invade the roof plate, which therefore becomes thickened and is later divided into corpora bigemina by a median groove. At its caudal end this groove becomes a median ridge, which persists in the adult as the frenulum veli. The corpora bigemina are later subdivided into the *superior* and *inferior colliculi* by a transverse furrow. The *red nucleus* is clearly defined at the end of the third month. Its origin, whether from neuroblasts of the ventral or dorsal lamina, is uncertain.

The detailed histogenesis of the tectum, and its main derivatives, the colliculi, will not be followed here, but in general the principles outlined for the cerebellar cortex (p. 166) and the paleopallium and neopallium (p. 173) also apply to this region. It may be noted, however, that there exists a high degree of geometric order in the developing retinotectal projection (p. 941), and also a precise somatotopy in tectospinal projection. These facts coupled with the ability of the piscine and amphibian central nervous tracts to *regenerate* after severance, have led the retinotectal pathways to become classical sites for experimentation. A review of this field is beyond the scope of the present volume, but typical experiments included the electrophysiological and neuroanatomical mapping of the patterns of retinotectal connexions that were established after, for example, mere cutting of an optic nerve, or following nerve severance, the rotation of one or both eyes through 180°. Other experiments included bilateral optic nerve section together with median section of the optic chiasma; additionally the regeneration pattern was followed after deletion of different retinal sectors, or following various recombinations of half eye-cups. In general the results of such experiments led to the elaboration of a powerful theory of the *chemospecificity of neuroblasts*, the main proposition being that every neuroblast possessed a unique surface molecular configuration. It was further postulated that the growth pattern of a neurite followed a chemically coded path which led to a precise group of target cells bearing complementary surface configurations (*see* Sperry, 1951a and b, 1958, 1963, 1965, 1971). While the *overall* results have received much subsequent experimental support, more detailed analyses of the re-established connectivity patterns, and in particular the *changing* patterns that occur with tectal growth, and the modulation that occurs with altered environments, behaviour, experience and the phenomena of learning and memory, has cast doubt on the validity of a *rigid* theory of chemospecificity applying to *all* neuroblasts and neurons (e.g. *see* Székely 1974; Hunt and Jacobson 1974).

It may be pertinent at this point to mention the interesting suggestion put forward by Jacobson (1969, 1970a and b, 1974) that there exist two principal classes of neuron (an elegant modern refinement of the old, Golgi type I and type II varieties—*see* p. 821). Jacobson's class I neurons are phylogenetically ancient, develop early in ontogeny, possess prominent somata, long axons, specific target cells, and have invariant and unmodifiable connexions and functions from their first establishment. It is

2.69C Medial surface of the right half of the brain of a human fetus, about three months old.

presumed that their final form and activities are almost wholly encoded in the genome. In contrast, class II neurons are small, possessing a short (or no) axon (microneurons); they are phylogenetically recent and develop relatively late in ontogeny. They are considered to possess, initially, *multiple* functional potentialities that may persist for considerable intervals, and only become progressively restricted during subsequent fetal or postnatal growth, the microneuron *ultimately* becoming 'unipotential and unmodifiable'. It is also proposed that this restriction of functional potential occurs at varying times and rates in different locations in the developing nervous system. Such microneurons are, on this view, therefore regarded as one of the main structural bases of *plasticity* in nervous systems whereby structural/functional modifications result from environmental changes, and the assessment of results of exploratory behaviour; they may thus be one of the sites where the elusive structural correlates of memory patterns should be sought (*see* essays by Young 1964; Gray 1974; Jacobson 1974).

THE PROSENCEPHALON

At an early stage, a transverse section through the forebrain shows the same parts as are displayed in similar sections of the spinal cord and medulla oblongata—thick lateral walls connected by thin floor and roof plates. Moreover, each lateral wall is divided into a dorsal area and a ventral area separated internally by the *hypothalamic sulcus*. This sulcus ends anteriorly at the medial end of the optic stalk, and in the fully developed brain, persists as a slight groove extending backwards from the interventricular foramen to the cerebral aqueduct. It is analogous to, if not the homologue of, the sulcus limitans.

At a very early period, before the closure of the anterior neuropore (p. 112), two lateral diverticula, the *optic vesicles*, appear, one on each side of the forebrain; for a time they communicate with its cavity by relatively wide openings. The distal parts of the optic vesicles expand, while the proximal parts become the tubular *optic stalks*; their further development is given on pp. 176–78. The forebrain next grows ventrally, and two diverticula rapidly expand from it to form two large pouches, one on each side. These diverticula subsequently form the *cerebral hemispheres*, and their cavities are the rudiments of the lateral ventricles; they communicate with the median part of the forebrain cavity by relatively wide openings which ultimately become the interventricular foramina. The anterior part of the roof plate of the forebrain consists of a thin sheet, the *lamina terminalis* (**2**.69A, B, C), which stretches from the interventricular foramina to the recess at the base of the optic stalks. The anterior part of the forebrain, including the rudiments of the cerebral hemispheres, is the *telencephalon*, and the posterior part the *diencephalon*; both contribute to the formation of the third ventricle, although the latter plays the predominant part.

The diencephalon develops into the (dorsal) thalamus and metathalamus along the dorsal area of its lateral wall. The *thalamus* (**2**.69–70) begins as a thickening which involves the anterior part of the dorsal area (Cooper 1950). Caudal to the thalamus the lateral and medial geniculate bodies, which constitute the *metathalamus*, are recognizable at first as surface depressions on the internal aspect and as elevations on the external aspect of the lateral wall (Cooper 1945). As the thalami enlarge, they gradually narrow the wide interval between them into a vertically compressed cavity which forms the greater part of the third ventricle. After a time these medial surfaces may come into contact and become adherent to each other over a variable area, the connexion (which may be single or multiple) constituting the *interthalamic adhesion*. The caudal growth of the thalamus excludes the geniculate bodies from the lateral wall of the third ventricle.

At first the lateral aspect of the developing thalamus is separated from the medial aspect of the cerebral hemisphere by a cleft, but as growth proceeds the cleft becomes obliterated (**2**.70) as the thalamus fuses with the part of the hemisphere in which the corpus striatum is developing. Later, with the development of the projection fibres of the neopallium (p. 173), the thalamus becomes related to the internal capsule, which intervenes between it and the lateral part of the corpus striatum (lentiform nucleus). Ventral to the hypothalamic sulcus the lateral wall of the diencephalon forms a large part of the hypothalamus.

The *epithalamus*, which includes the pineal gland, the posterior commissure and the trigonum habenulae, develops in association with the caudal part of the roof plate and the adjoining portions of the lateral walls of the diencephalon. The *pineal gland* arises as a hollow outgrowth from the roof plate, immediately adjoining the mesencephalon. Its distal portion becomes solid by cellular proliferation, but its proximal stalk remains hollow, containing the pineal recess of the third ventricle. In many reptiles the pineal outgrowth is double. The anterior outgrowth (*parapineal organ*) develops into the pineal or parietal eye (p. 1445) while the posterior outgrowth is glandular in character. It is the *posterior* outgrowth which is homologous with the pineal gland in man. The anterior outgrowth also develops in the human embryo, but soon disappears entirely.

The *posterior commissure* is formed by fibres which invade the caudal wall of the pineal recess from both sides.

The *nucleus habenulae*, which is the most important constituent of the *trigonum habenulae*, is developed in the lateral wall of the diencephalon and is at first in close relationship with the geniculate bodies, from which it becomes separated by the dorsal growth of the thalamus. The habenular commissure develops in the cranial wall of the pineal recess.

The roof plate of the diencephalon, rostral to the pineal gland, remains thin and epithelial in character, and is subsequently invaginated by the choroid plexuses of the third ventricle. Before the development of the corpus callosum and the fornix it lies at the bottom of the longitudinal fissure, between the two cerebral hemispheres. Here, and elsewhere, choroid plexuses develop by the close apposition of vascular pia mater and ependyma with no nervous tissue intervening. With development, the vascular layer is infolded into the ventricular cavity and develops a series of small villous (finger-like) projections, each covered by a cuboidal epithelium derived from the ependyma. The cuboidal cells carry numerous microvilli on their ventricular surfaces whilst basally their plasma membrane becomes complexly folded into the cell. The *early* choroid plexuses secrete a protein-rich cerebrospinal fluid into the ventricular system which may provide a nutritive medium for the primitive epithelial neural tissues. With increasing vascularity of the latter, however, the histochemical reactions of the cuboidal cells and the character of the fluid change to the adult type (Klosovskii 1963). It should also be noted that in addition to choroid plexus formation, the remaining lining of the third ventricle does not simply form generalized ependymal cells.

Many regions become highly specialized, developing concentrations of tanycytes, or other modified cells such as those of the *subfornical organ*, the *organum vasculosum* (*intercolumnar tubercle*) of the lamina terminalis, the *subcommissural organ*, and those lining the *pineal*, *suprapineal*, and *infundibular recesses* (*see* Knigge *et al.* (eds) 1975)—collectively the *circumventricular organs*.

The floor of the diencephalon takes part in the formation of the *hypothalamus*, including the mamillary bodies, the tuber cinereum and infundibulum of the hypophysis.

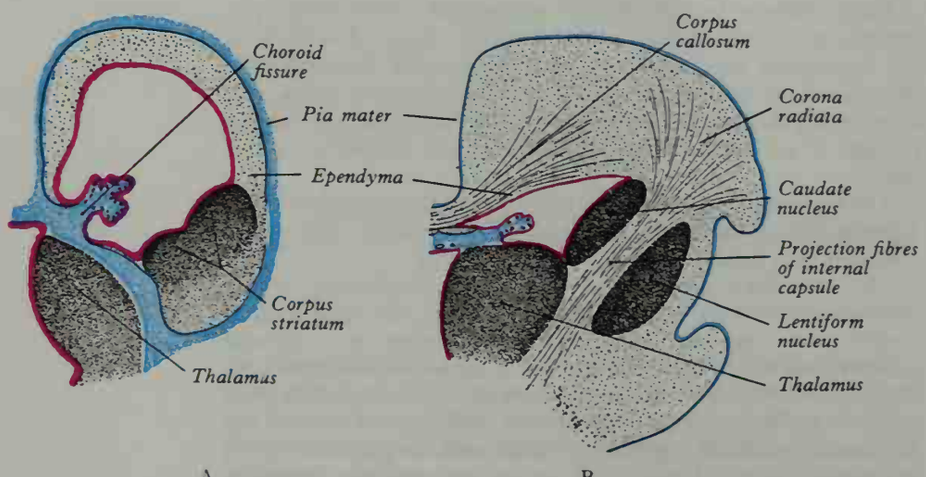
The *mamillary bodies* arise as a single thickening, which becomes divided by a median furrow during the third month. Anterior to them the *tuber cinereum* develops as a cellular proliferation which extends forwards as far as the infundibulum. In front of the tuber cinereum the floor of the diencephalon gives origin to a wide-mouthed diverticulum, which grows towards the stomatodeal roof and comes into contact with the posterior aspect of a dorsally directed ingrowth from the stomatodeum (Rathke's pouch, p. 199). These two diverticula, the one derived from the floor of the neural tube and the other from the roof of the stomatodeum, together form the *hypophysis cerebri* (**2**.94). In the base of the neural outgrowth an extension of the third ventricle persists as the infundibular recess.

The optic vesicles, which are described with the development of the eye (p. 176), are derived from the lateral wall of the prosencephalon before the telencephalon can be identified. They are usually regarded as derivatives of the diencephalon, and the

optic chiasma indicates the boundary between the diencephalon and the telencephalon.

The telencephalon consists of two lateral diverticula connected by a median region (the *telencephalon impar*). From the latter develops the anterior part of the cavity of the third ventricle, closed below and in front by the *lamina terminalis*. The lateral diverticula are outward pouchings of the lateral walls of the prosencephalon, which may correspond to the alar laminae, although this is uncertain; the cavities are the future lateral ventricles, and their walls the nervous tissue of the cerebral hemispheres. The roof plate of the median part of the telencephalon remains thin, and is continuous behind with the roof plate of the diencephalon. In the floor plate and lateral walls of the prosencephalon, ventral to the primitive interventricular foramina, the anterior parts of the *hypothalamus* are developed; these include the optic chiasma and the optic recess. The optic chiasma is formed by the meeting and partial decussation of the optic nerves in the ventral part of the lamina terminalis, and from it the optic tracts subsequently grow backwards to end in the diencephalon and midbrain.

The cerebral hemispheres arise as diverticula of the lateral walls of the telencephalon, with which they remain in continuity around the margins of the large, interventricular foramina except caudally, where they are continuous with the anterior part of the lateral wall of the diencephalon (**2**.69A, B); as growth proceeds the hemisphere enlarges forwards, upwards and backwards and acquires an oval outline, with medial and superolateral walls and a floor. As a result the medial surfaces are separated from each other by a cleft, the *longitudinal fissure*. At this stage the floor of the cleft is the epithelial roof plate of the telencephalon, which is directly continuous caudally with the epithelial roof plate of the diencephalon (**2**.69C), as already stated above.



The rostral end of the oval hemisphere becomes the *frontal pole*, but, as the hemisphere expands, its original posterior pole moves relatively in a caudoventral direction in association with the growth of the caudate nucleus, to form the *temporal pole*, and a new posterior part becomes defined, which persists as the *occipital pole* of the mature brain. The great expansion of the cerebral hemispheres is characteristic of mammals and especially of man, and in their subsequent growth they overlap, successively, the diencephalon, the mesencephalon and the cerebellum, and the temporal lobes grow round the flanks of the brainstem.

About the fifth week a longitudinal groove appears in the anteromedial part of the floor of each ventricle. This groove deepens and forms a hollow diverticulum connected to the hemisphere by a short stalk. The diverticulum becomes connected on its ventral or inferior surface to a ganglionic mass, the cells of which receive the afferent axons of the sensory cells of the olfactory plate. As the head increases in size the diverticulum grows forwards and, subsequently losing its cavity, becomes converted into the solid *olfactory bulb*. The forward growth of the bulb is accompanied by elongation of its stalk, which forms the *olfactory tract*, and the portion of the floor of the hemisphere to which the tract is attached constitutes the *piriform area*.

The pia mater which covers the epithelial roof of the third ventricle at this stage is itself covered with loosely arranged mesenchyme. In the meshes of this tissue numerous blood vessels develop and, as we have seen (p. 169), on each side of the median plane these vessels subsequently invaginate the roof of the ventricle to form its *choroid plexuses* (Kappers 1966). The lower part of the medial wall of the hemisphere, which immediately adjoins the epithelial roof of the interventricular foramen and the anterior extremity of the diencephalon, also remains epithelial, consisting of ependyma and pia mater, while elsewhere the walls of the hemisphere are thickening to form the *pallium*. This thin part of the medial wall of the hemisphere is invaginated by vascular tissue, continuous in front with the choroid plexus of the third ventricle and constituting the *choroid plexus* of the *lateral ventricle*. This invagination occurs along a line which arches upwards and backwards, parallel with the anterior and upper boundaries of the interventricular foramen, and the curved indentation of the ventricular wall where no nervous tissue develops between ependyma and pia mater, is termed the *choroid fissure* (**2**.69C; **2**.70A, B.)

At first growth proceeds more actively in the floor and the adjoining part of the lateral wall of the developing hemisphere, and elevations formed by the rudimentary *corpus striatum* (**2**.69A) encroach on the cavity of the lateral ventricle (Cooper 1946). The head of the *caudate nucleus* appears as three successive parts, medial, lateral and intermediate, which produce elevations in the floor of the lateral ventricle. Caudally these merge to form the tail of the caudate and the *amygdaloid complex*. From the beginning they are close to the temporal pole of the hemisphere and, when the occipital pole grows backwards and the general enlargement of the hemisphere carries the temporal pole downwards and forwards, the tail is continued from the floor of the central part of the ventricle into the roof of its temporal extension as the future *inferior horn*. Anteriorly the head of the caudate nucleus extends forwards to the floor of the interventricular foramen, where it is separated from the developing anterior end of the thalamus by a groove (**2**.69B). The lentiform nucleus is developed from two laminae of cells, medial and lateral, which are continuous with both the medial and lateral parts of the caudate nucleus. The internal capsule appears first in the medial lamina and extends laterally through the outer lamina to the cortex. It divides the laminae into two, the internal parts joining the caudate nucleus and the external parts forming the lentiform nucleus. In the latter, the remaining medial lamina cells give rise predominantly to the globus pallidus and the lateral to the putamen. Subsequently the putamen expands concurrently with the intermediate part of the caudate nucleus (Hewitt 1958, 1961).

As the hemisphere enlarges, the caudal part of its medial surface overlaps and hides the lateral surface of the diencephalon (thalamic part), being separated from it by a narrow cleft occupied by vascular connective tissue. At this stage (about the end of the second month) a transverse section made caudal to the interventricular foramen passes successively through (1) the developing thalamus, (2) the narrow cleft just mentioned, (3) the thin medial wall of the hemisphere, and (4) the cavity of the lateral ventricle, with the corpus striatum in its floor and lateral wall (**2**.70A). As the thalamus increases in extent it acquires a superior in addition to medial and lateral surfaces, and the lateral part of its superior surface fuses with the thin medial wall of the hemisphere, so that, finally, this part of the thalamus is covered with the ependyma of the lateral ventricle immediately ventral to the choroid fissure (**2**.70B). As a result the corpus striatum is approximated to the thalamus and separated from it only by a deep groove, which becomes obliterated by increased growth along the line of contact. The lateral aspect of the thalamus is now in continuity with the medial aspect of the corpus striatum, so that

2.70A Diagrams illustrating transverse sections across the developing thalamus and cerebral hemisphere. Note that at the choroid fissure the vascular pia mater (blue) meets the ependyma (red) to form a choroid plexus. In A the lateral aspect of the thalamus is separated from the medial aspect of the hemisphere by an interval containing vascular mesenchyme. In B this interval has disappeared; the expanded upper surface of the thalamus is covered by the ependyma of the lateral ventricle, and the approximation of the thalamus and the corpus striatum has provided a pathway for the projection fibres of the internal capsule.

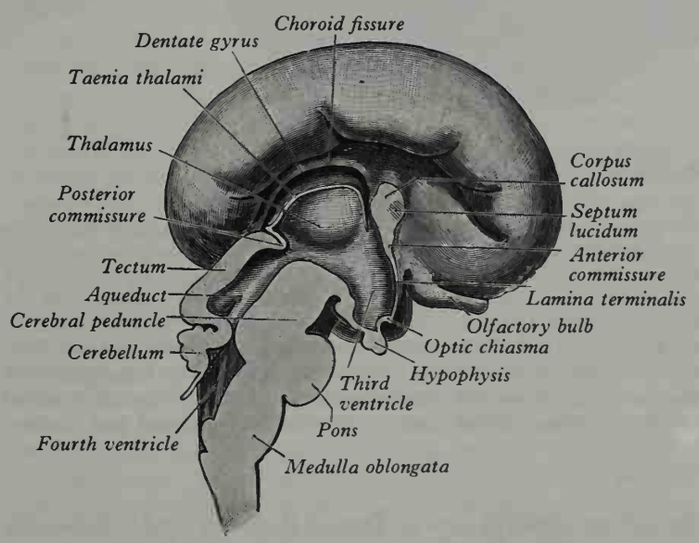
a secondary union between the diencephalon and the telencephalon is effected over a wide area, providing a route for the subsequent passage of projection fibres to and from the cortex.

The *pallial* or *cortical* area which borders the interventricular foramen and lies outside the choroid fissure constitutes the *paleopallium*. It is the first part of the cortex to undergo differentiation (*vide infra*), and at first it forms a continuous, almost circular strip on the medial and inferior aspects of the hemisphere. Below and in front, where the stalk of the olfactory tract is attached, it constitutes a part of the *piriform area*. The portion outside the curve of the choroid fissure (**2**.70B) constitutes the *hippocampal formation*. In this region the neuroblasts of the *pallium* (mantle) or developing cortex, proliferate, and the wall of the hemisphere thickens and produces an elevation which projects into the medial side of the ventricle. This elevation is the *hippocampus* (Humphrey 1964, 1967). It appears first on the medial wall of the hemisphere above the area in front of the lamina terminalis (*paraterminal area*) and gradually extends backwards into the region of the temporal pole, where it adjoins the piriform area. The marginal zone in the region of the hippocampus becomes invaded by nerve cells which form the *dentate gyrus*. This structure is practically co-extensive with the hippocampus and, like it, extends from the paraterminal area backwards above the choroid fissure and follows its curve downwards and forwards towards the temporal pole, where it runs into the piriform area. A shallow surface depression (which has been termed the *hippocampal sulcus*) grooves the medial surface of the hemisphere in the region of the hippocampal formation, but it is not responsible for the elevation which the hippocampus forms in the interior of the ventricle.

The efferent fibres from the cells of the hippocampus collect along its medial edge and run forwards immediately above the choroid fissure. Anteriorly they turn ventrally and enter the lateral part of the lamina terminalis to gain the hypothalamus, where they end in and around the mamillary body. These efferent hippocampal fibres form the *fimbria hippocampi* and the *fornix*.

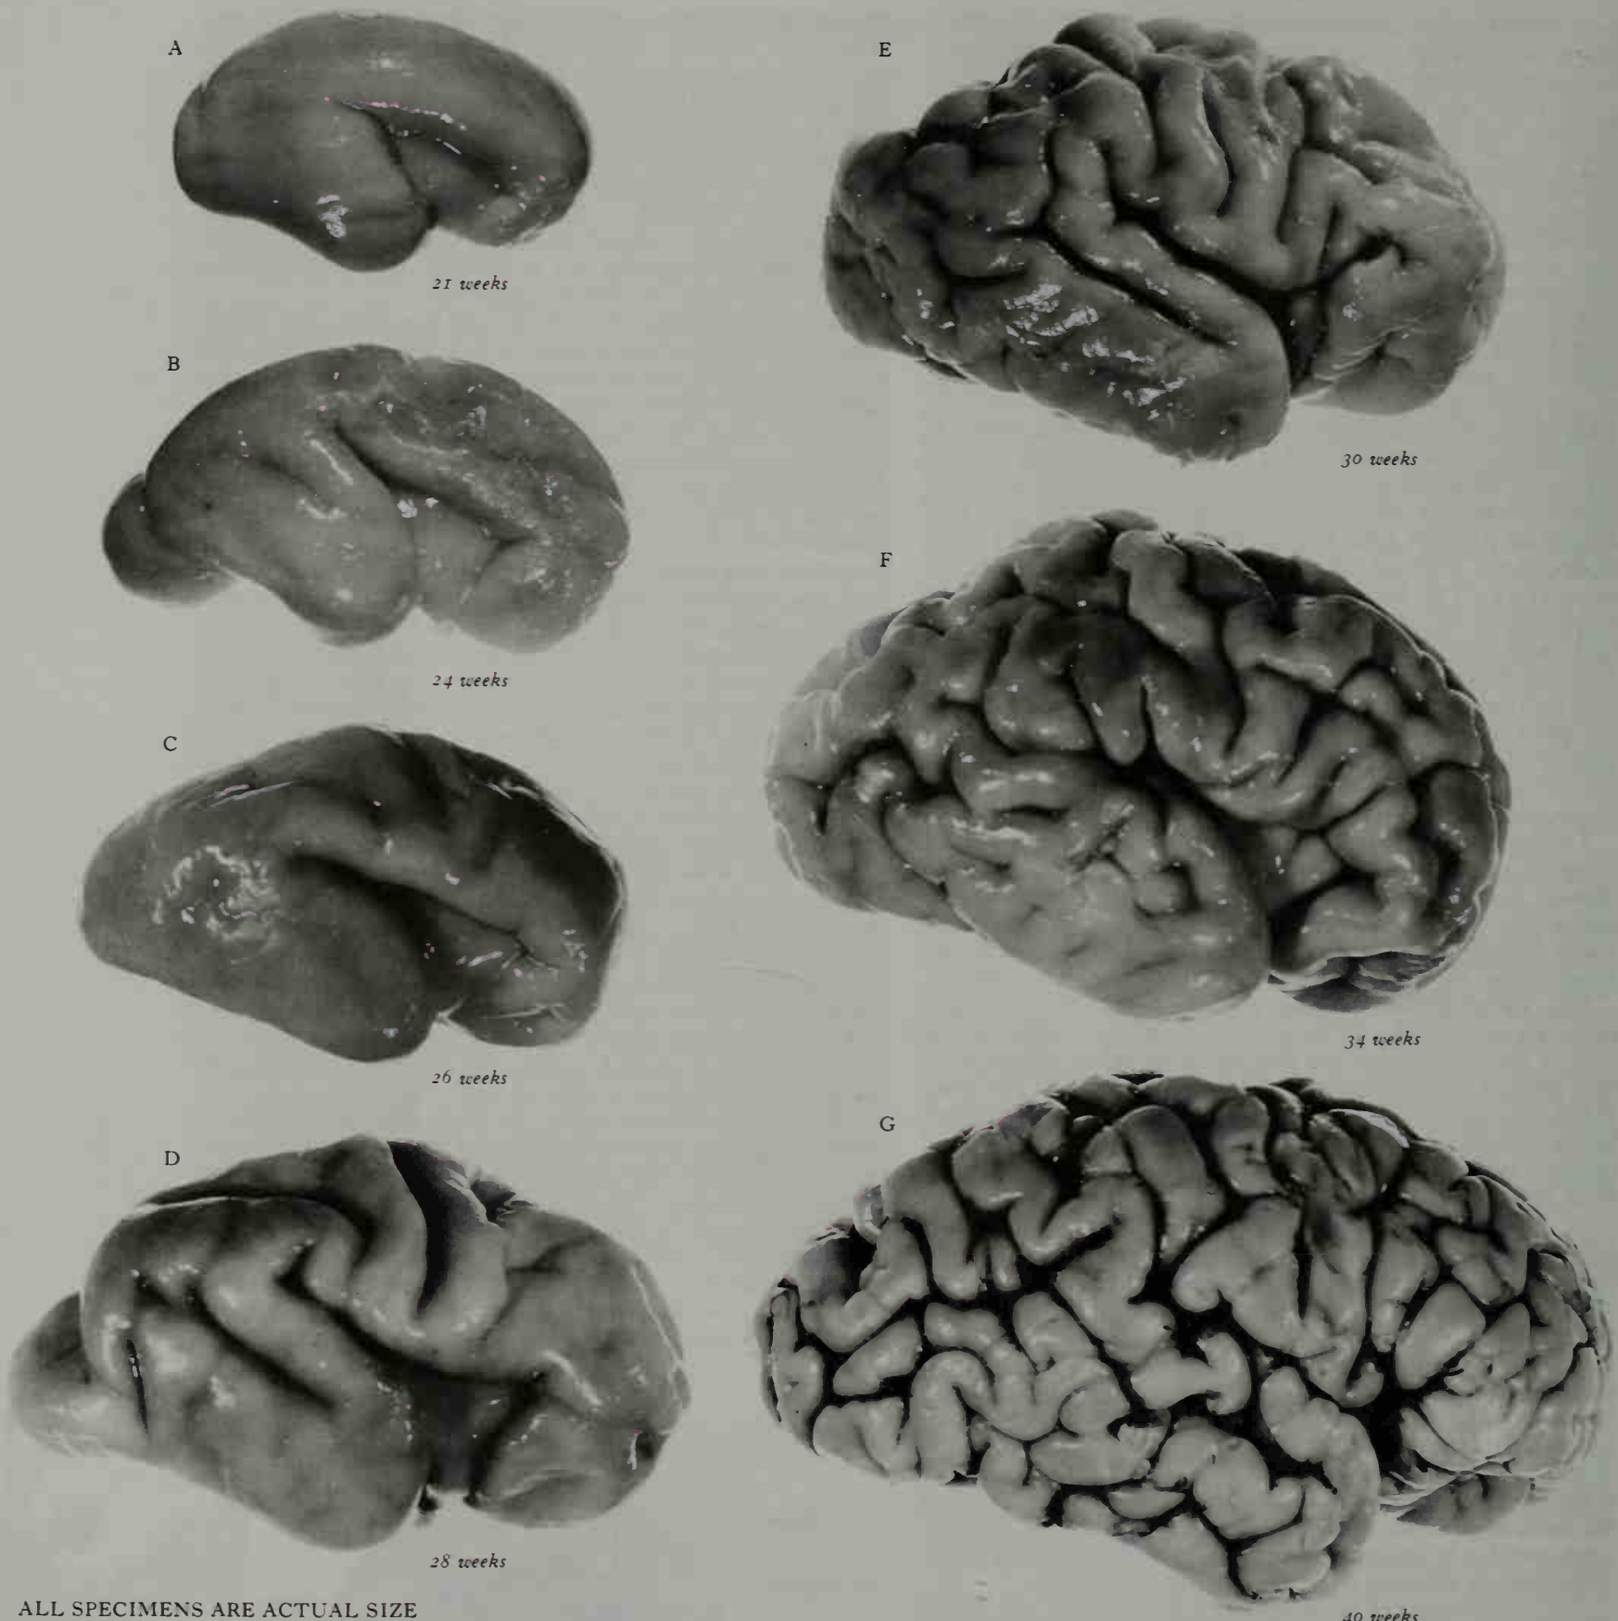
The development of the commissures effects a very profound alteration on the medial wall of the hemisphere. At the time of their appearance the two hemispheres are connected to each other by the median part of the telencephalon. The roof plate of this area remains epithelial, whilst its floor becomes invaded by the decussating fibres of the optic nerves. These two routes are thus not available for the passage of commissural fibres passing from hemisphere to hemisphere across the median plane, and these fibres therefore pass through the anterior wall of the interventricular foramen, i.e. the *lamina terminalis*. The first commissures to develop are those associated with the *olfactory areas* and *paleopallial cortex*. Fibres of the olfactory tracts cross in the ventral or lower part of the lamina terminalis and together with fibres from the piriform, and prepiriform areas, and the amygdaloid bodies, form the *anterior part* of the *anterior commissure*. In addition the two hippocampi become interconnected by transverse fibres which cross from fornix to fornix in the upper part of the lamina terminalis as the *commissure of the fornix*. Various other decussating fibre bundles (known as the *supra-optic commissures*, although they are not true commissures) develop in the lamina terminalis immediately dorsal to the optic chiasma, between it and the anterior commissure.

The commissures of the neopallium develop later and follow the pathways already established by the commissures of the limbic system. Fibres coming from the tentorial surface of the hemisphere join the *anterior commissure* and constitute its larger *posterior part*. All the other commissural fibres of the neopallium associate themselves closely with the commissure of the fornix and lie on its dorsal surface. These fibres increase enormously in number, and the bundle rapidly outgrows its neighbours to form the corpus callosum (**2**.70B).



The *corpus callosum* commences in a thick mass, the *precommissural area*, connecting the two cerebral hemispheres around and above the anterior commissure. The upper end of this area extends backwards to form the trunk of the corpus callosum. The *rostrum* of the corpus callosum develops later and separates the front end of the precommissural area from the remainder of the cerebral hemisphere. Further backward growth of the trunk of the corpus callosum then results in the entrapped precommissural area becoming stretched out to form the bilateral septum pellucidum (Hewitt 1962). As the corpus callosum grows backwards it extends above the choroid fissure, carrying the commissure of the fornix on its under surface. In this way a new floor is formed for the longitudinal fissure, and additional structures come to lie above the epithelial roof of the third ventricle. In its backward growth the corpus callosum invades the area hitherto occupied by the *upper* part of the hippocampal formation and the corresponding parts of the dentate gyrus (**2**.70B) and hippocampus are reduced to mere vestiges—the *indusium griseum* and the *longitudinal striae*.

The *inferior* regions of both the dentate gyrus and hippocampus persist and enlarge because, with the forward growth of the temporal lobes, the brainstem presents a complete barrier to further extension of the corpus callosum.



The growth of the *neopallium*, or *neocortex*, and its enormous expansion are associated with the appearance of projection fibres during the latter part of the third month. These fibres follow the pathway provided by the apposition of the lateral aspect of the thalamus with the medial aspect of the corpus striatum, and, as they do so, they divide the latter, almost completely, into a lateral part, the lentiform nucleus, and a medial part, the caudate nucleus, these two nuclei remaining confluent only in their antero-inferior regions. The corticospinal tracts begin to develop in the ninth week of fetal life and have reached their caudal limits by the twenty-ninth week. The fibres destined for the cervical and upper thoracic regions and implicated in the innervation of the upper limb are in advance of those concerned with the lower limbs, which in turn are in advance of those concerned with the face. The appearance of reflexes in these three parts of the body shows a comparable sequence (Humphrey 1960).

At the end of the third month the superolateral surface of the cerebral hemisphere shows a slight depression anterosuperior to the temporal pole. This corresponds to the site of the corpus striatum in the floor and lateral wall of the ventricle, and its presence is due to the more rapid growth of the adjoining cortical regions. This *lateral cerebral fossa* gradually becomes overlapped and submerged, and is converted into the *lateral cerebral sulcus*; its floor becomes the *insula* (**2**.71 A–G). The process, however, is not completed in its most anterior part until after birth.

The growth changes in the temporal lobe which help to submerge the insula produce important changes in the olfactory areas. The olfactory tract is continuous, on the one hand, with the *medial olfactory gyrus*, which turns upwards in front of the lamina terminalis, and, on the other hand, with the *lateral olfactory gyrus*, which is directly continuous with the piriform area. The forward growth of the temporal pole and the general expansion of the neopallium cause the lateral olfactory gyrus to bend laterally, the summit of the convexity lying at the antero-inferior corner of the

2.70B The brain of a human fetus, four months old. Medial aspect of left half.

ALL SPECIMENS ARE ACTUAL SIZE

2.71A–G A series showing the superolateral surfaces of human fetal cerebral hemispheres at the ages indicated, demonstrating the changes in size, profile and the emerging pattern of cerebral sulci with increasing maturation. Note the changing prominence and relative positions of the frontal, occipital and particularly the temporal pole of the hemisphere. At the earliest stage (A) the lateral cerebral fossa is already obvious—its floor covers the developing corpus striatum in the depths of the hemisphere and progressively matures into the cortex of the insula. The fossa is bounded by overgrowing cortical regions, the frontal, temporal and parietal opercula, which gradually converge to bury the insula; their approximation forms the lateral cerebral sulcus. By the sixth month the central, pre- and post-central, superior temporal, intraparietal and parieto-occipital sulci are all clearly visible. In the subsequent stages shown all the remaining principal and subsidiary sulci rapidly appear and by 40 weeks all the features which characterize the adult hemisphere in terms of surface topography are already present in miniature.

The photographs were kindly supplied by Dr. Sabina Strick of the Maudsley Hospital, London.

developing insula (**2.71A–G**). During the fourth and fifth months the *piriform area* becomes submerged by the adjoining neopallium, and in the adult only a part of it remains visible on the inferior aspect of the cerebrum.

Apart from the shallow hippocampal sulcus and the lateral cerebral fossa the surfaces of the hemisphere remain smooth and uninterrupted until early in the fourth month (**2.71A–G**). The parieto-occipital sulcus also appears about that time on the *medial*

aspect of the hemisphere, and its appearance is associated with the increase in the splenial fibres of the corpus callosum. At about the same period the posterior part of the *calcarine sulcus* appears as a shallow groove extending forwards from the region of the occipital pole. It is a true infolding of the cortex and forms in the long axis of the *striate area*, producing at the same time an elevation, named the *calcar avis*, on the medial wall of the posterior horn of the ventricle.

During the fifth month the *sulcus cinguli* appears on the medial aspect of the hemisphere, but it is not until the sixth month that sulci appear on the inferior and superolateral aspects. The *central, precentral* and *postcentral sulci* appear each in two parts, upper and lower, which usually coalesce shortly afterwards, although they may remain discontinuous. The *superior* and *inferior frontal*, the *intraparietal, occipital, temporal* and *collateral sulci* make their appearance during the same period, and by the end of the eighth month all the important sulci can be recognized (**2**.71A–G).

Concerning the **histogenesis** of the pallial wall of the cerebral hemisphere, an impressive literature has accumulated since the early 1930s. Nevertheless, because of the immense complexity, multiplicity of cell types, and structural heterogeneity in different locations, descriptive and experimental analyses are less well understood and documented than those appertaining to the cerebellum, with its regular, geometrically ordered microstructure (p. 166). Only the briefest review of some basic principles, together with a few introductory key references, can be encompassed in this volume, and the interested reader will find it apposite to constantly cross-refer to the sections devoted to mature neuronal and cortical architecture (pp. 802–810, 1002–1009).

The wall of the earliest cerebral hemisphere, as elsewhere in the neural tube, consists of a pseudostratified epithelium, its cells exhibiting interkinetic migration (p. 157) as they proliferate to form clones of, as yet uncommitted, germinal cells. The columnar cells elongate and (following the nomenclature of the Boulder Committee, *Anat. Rec.*, 1970 and **2**.63A) their non-nucleated peripheral processes now constitute a *marginal zone*, whilst their nucleated, paraluminal and mitosing regions constitute the *ventricular zone*. Some of the mitotic progeny now leave the ventricular zone and continue to proliferate in an *intermediate zone*. This *proliferative phase* continues for a considerable period of fetal (and in some species post-natal) life, but, as in the case of the cerebellar cortex, after a period, groups of germinal cells undergo quantal mitoses forming initially generations of *definitive neuroblasts* and later, *definitive glioblasts*, which migrate to, and mature in, their final positions. It must be appreciated, however, that these phases of proliferation, differentiation, migration and maturation, are not absolutely sequential for each cell variety, but overlap each other in space and time.

The earliest migration of definitive neuroblasts from the ventricular and intermediate zones occurs radially until they approach, but do not reach, the pial surface, their somata becoming arranged as a transient *cortical plate*. Subsequently, proliferation wanes in the ventricular zone, but for considerable periods persists in the immediately adjacent *subventricular zone*. From the pial surface, inwards, therefore, there may now be defined the following zones: marginal, cortical plate, intermediate, subventricular, and ventricular. Briefly, whilst the foregoing *terminology* is relatively recent, it has, for long, been accepted that the *marginal zone* forms the outermost layer of the cerebral cortex, the neuroblasts of the *cortical plate* form the neurons of the remaining cortical laminae (the complexity, of course, varying in different locations, and with further additions of neuroblasts from the deeper zones), whilst the intermediate zone gradually transforms into the white matter of the hemisphere. Meanwhile other deep germinal cells have been producing generations of glioblasts which also migrate into the more superficial layers. As proliferation wanes and finally ceases in the ventricular and subventricular zones their remaining cells differentiate into general or specialized ependymal cells, tanycytes, or subependymal glial cells.

Although the short account just given of the *general* histogenetic history of the cortex gained, and maintains, wide acceptance, it is of the greatest interest that, with the advent of modern nuclear labelling techniques, there has been a fundamental reappraisal of the *sequences* involved in the migratory patterns of the neuroblasts, with consequently considerable ontogenetic and phylogenetic implications.

Pioneering studies into neuroblast migration in the developing mammalian *neocortex* were made by Tilney (1933), the technique available to him at this time being analysis of sections of Nissl stained tissue. Whilst it was clear that the subpial (marginal) zone formed the plexiform lamina (I), he considered that the remaining laminae stemmed from *three* quite distinct and separate migrations of neuroblasts up to the cortical plate. The first migration he considered to differentiate into the external granular lamina (II) and the pyramidal lamina (III); the second migration forming the internal granular lamina IV; the third migration he held to form the ganglionic lamina V and the multiform lamina VI. On this view, therefore, the *outermost* layers were the *earliest* to be formed, and progressively deeper layers at successively later times. (But see Rumyantsev 1979.)

The possibility that precisely the *reverse* sequence, progressing from *deep to superficial*, was first implied by the results of X-irradiation studies by Hicks *et al.* (1959). Further irradiation studies (Berry and Eayrs 1960), and autoradiographic nuclear labelling studies (Berry and Rogers 1965) supported this contention. These seminal investigations have, in the subsequent years, been amply confirmed in the rat, mouse, opossum and golden hamster. (The individual references are too numerous to quote in this volume, but for an excellent overview of this, and many other problems appertaining to cortical histogenesis, the reader should refer to Berry 1974.) Thus, in these various mammals, apart from the pre-existing anlage of Lamina I, the first laminae to be populated are VI and V, followed sequentially by laminae IV to II. Clearly, whilst the ontogenetic timings of migrations, from these experimental sources, are not appropriate to a volume on *human* anatomy, it is assumed from comparison of purely descriptive material, that similar *patterns* of migration and elaboration occur in the human cortex. It should also be noted that, as yet only in the human cortex, a thin subpial lamina of densely staining cells, of unknown origin, or destination, has been identified (Rabinowicz 1964, 1967; Brun 1965): they are not a prominent feature of cortical histogenesis, but an analogy with the external germinal layer of the cerebellum has been suggested.

No attempt will be made here to discuss neuroblast and glioblast differentiation, migration, and maturation with the establishment of intercellular contacts, for these the reader is referred to pp. 157–160, 837, 860 (see also Molliver *et al.* 1973 and Kostović and Krmpotić 1976). However, some general hypotheses may be mentioned, involving a comparison of ontogeny and phylogeny. Firstly, all parts of the neural tube, from the presumptive spinal cord to presumptive neocortex, pass through the stage of a pseudostratified epithelium and a proliferative phase, followed by differentiation sets, with the emergence of ventricular, intermediate, and marginal zones. Neuroblast migration, target cell contact and maturation (or, in some locations, *degeneration* and *cell death*), whilst *still confined to* the deeper reaches of the intermediate zone, are the principal events in spinal cord development. Throughout the encephalon, however, the primary difference is the *continued migration* of neuroblasts, and their ultimate maturation, far *beyond* the confines of the intermediate zone, forming either nuclear masses, variously displaced from the ventricular and aqueductual channels, or, in the 'roof-brain' regions, reaching the subpial marginal zones forming, initially, a simple cortical plate of neuroblasts. The latter then differentiates into subzones, showing a tangential *laminar* organization, whilst, in some locations, there emerges a well-defined *columnar* radial organization. Such cortical dispositions are evident in the hemispheric forebrain, tectal midbrain, and cerebellar hindbrain. In the pallial walls of the mammalian cerebral hemisphere, the phylogenetically *oldest regions*, and the *first* to differentiate during ontogeny, are those that *border* the interventricular foramen, and its extension the choroidal fissure. There exists an increasingly complex level of organization, from three to six tangential laminae, passing from the dentate gyrus and cornu ammonis, through the subiculum, until the general neocortex is reached. The *deepest*, and phylogenetically oldest *tangential laminae* are the first to be populated by migrating neuroblasts, more superficial layers being

added in sequence, their neuroblasts migrating through the older layers; the number of superadded laminae depending upon the location with respect to the choroidal fissure. These broad patterns have been demonstrated by nuclear labelling studies, not only in the neocortex, but also in the dentate gyrus and hippocampus (*see*, for example, Angerine 1975; Altman and Bayer 1975).

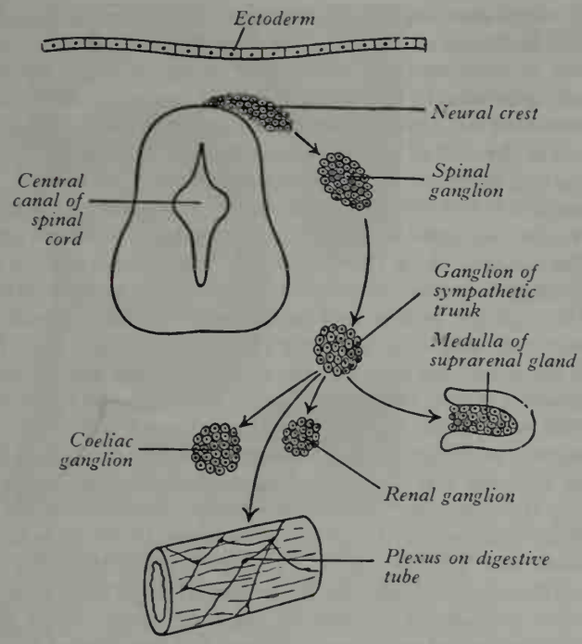
The state of differentiation at birth and at various post-natal stages, as seen in Golgi (metal impregnation) preparations, has been described in considerable detail elsewhere (Conel—a series of publications 1939–59). However, the *mechanisms* whereby variation in cell type, number, dendritic patterns and connectivity arise, are completely unknown. Nevertheless, gross nutritional deficiencies, endocrine imbalances, sensory deprivation, neurotropic viruses, vascular abnormalities and perinatal anoxia may all disturb the normal pattern.

At birth the volume of the brain is approximately *25 per cent* of its volume in adult life. The greater part of the increase occurs during the *first year*, at the end of which the volume of the brain has increased to *75 per cent* of its adult volume. The growth can be accounted for partly by increase in the size of nerve cell somata, the profusion and dimensions of their dendritic trees, axons and their collaterals, and by growth of the neuroglial cells and cerebral blood vessels, but it is the acquisition of myelin sheaths by the axons which is principally responsible for it. The great sensory pathways, visual, auditory and somatic, become myelinated first, and the motor fibres later. During the second and subsequent years, growth proceeds much more slowly, and the brain attains its adult size by the seventeenth or eighteenth year. This continued growth is connected with the continued myelination of various groups of nerve fibres.

A summary of the parts derived from the cerebral vesicles is as follows:

Rhombencephalon (or hindbrain)	1. Myelencephalon	Medulla oblongata Caudal part of the 4th ventricle Inferior cerebellar peduncles
	2. Metencephalon	Pons Cerebellum Middle part of the 4th ventricle Middle cerebellar peduncles
	3. Isthmus rhombencephali	Anterior medullary velum Superior cerebellar pundunclles Rostral part of the 4th ventricle
Mesencephalon (or midbrain)		Cerebral peduncles Tegmentum Tectum Aqueduct
Prosencephalon (or forebrain)	1. Diencephalon	Thalamus Metathalamus Subthalamus Epithalamus Caudal part of the hypothalamus Caudal part of the 3rd ventricle
	2. Telencephalon	Rostral part of the hypothalamus Rostral part of the 3rd ventricle Cerebral hemispheres Lateral ventricles Pallium Corpus striatum

THE CRANIAL NERVES AND THE NEURAL CREST



With the exception of the olfactory and optic nerves, which will be considered separately, the cranial nerves are developed in a similar manner to the spinal nerves.

The motor fibres of the cranial nerves to striated muscle are the axons of cells in the ventral lamina of the midbrain and hindbrain which grow outwards to their muscle fibres of distribution, but whereas the motor fibres of the spinal nerves form one series, those of the cranial nerves form two, which are derived from the medial and lateral parts of the ventral lamina respectively. The first series (*somatic efferent*) comprises the oculomotor, trochlear, abducent and hypoglossal nerves, supplying somite-derived muscles or their homologues; the second (*branchial efferent*) comprises the accessory nerve, and the motor parts of the trigeminal, facial, glossopharyngeal and vagus nerves, all of which supply the *striated* muscles derived from the branchial arches, or from post-branchial 'visceral' mesoderm. (It should be recalled, however, that some authorities regard the mesoderm of the branchial arches and immediate post-branchial region as neither somatic nor visceral, but *mixed*, being *unsplit lateral plate* since it is devoid of a coelomic cavity.)

As the lips of the neural groove fuse with each other in the region of the hindbrain and midbrain, a *neural crest* is formed which is homologous with the neural crest of the trunk, flanking the spinal cord (p. 112). (For a review of the origin, migration and differentiation of neural crest cells, consult Weston 1970; Bellairs 1971; Leikola 1976; Fujita 1976; Pearse 1977.) The ganglia of the vagus, glossopharyngeal, vestibulocochlear (in part), facial and trigeminal nerves are derived from the neural crest, but they migrate ventrally and soon come to lie on the ventrolateral aspect of the hindbrain. The vestibulocochlear nerve ganglion is also believed to receive contributions from the wall of the otocyst. There is also descriptive and experimental evidence, mainly from lower vertebrates, that overlying ectodermal thickenings or *placodes* contribute to the ganglia of the trigeminal, facial, vestibulocochlear, vagus and glossopharyngeal nerves. It is claimed that these contributions give rise to the *special somatic afferent* (acoustic and lateral line) and the *special visceral afferent* (chiefly gustatory) components of these nerves. The development of these cranial nerve ganglia and the role of the ectodermal placodes in the human embryo, however, still need clarifying (*see* p. 116). Caudal to the ganglion of the vagus nerve the occipital region of the neural crest is concerned with the ganglia of the accessory and hypoglossal nerves. Rudimentary ganglion cells may occur along the hypoglossal nerve in the human embryo; they undergo regression later. Ganglion cells are also found on the developing spinal root of the accessory nerve and these are believed to persist in the adult. The central processes of the cells of these various ganglia, where they persist, form the sensory roots of the cranial nerves and enter the dorsal lamina of the hindbrain; their peripheral processes join the efferent components of the nerve to be distributed to the various tissues innervated. Some incoming fibres from the facial, glossopharyngeal and vagus nerves collect to form an oval bundle, termed the *tractus solitarius* (p. 903), on the lateral aspect of the myelencephalon. This bundle is the homologue of the oval bundle of the spinal cord, but in the hindbrain it becomes more deeply placed by the overgrowth, folding and subsequent fusion of tissue, derived from the rhombic lip, on the external aspect of the bundle.

The Autonomic Nervous System

The ganglion cells of the *sympathetic system* are derived from the neural crest through the medium of the *primitive spinal ganglia* (p. 160). Certain of the cells in the ventral parts of the latter migrate towards the sides of the aorta, where they subsequently form the *ganglia of the sympathetic trunks*, and certain other associated cells (*vide infra*). Others migrate still further and eventually form the subsidiary sympathetic ganglia such as the coeliac and renal (**2**.72). The original migration is limited to the thoracic and upper lumbar regions. Thereafter the chain grows headwards and tailwards until the whole trunk is laid down. The view has also been advanced that the sympathetic ganglion cells are, at least in part derived from cells which migrate from the *ventral lamina* along the ventral nerve roots. The results of destruction of the neural crest in chick embryos and of excision of the neural crest and portions of the neural tube in frog embryos have been somewhat contradictory in the hands of different investigators. On the whole the balance of the evidence favours the earlier view.

2.72 Diagram showing some derivatives of the neural crest.

The ganglion cells of the cranial part of the *parasympathetic system* are probably derived from the neural crest through the medium of the primitive ganglia of the oculomotor, trigeminal, facial, glossopharyngeal and vagus nerves. The *ciliary ganglion* is formed by cells which migrate from the trigeminal ganglion along the ophthalmic nerve, but it is almost certainly reinforced by cells migrating from the nucleus of the oculomotor nerve along which a few scattered cells are always demonstrable in postnatal life. The *pterygopalatine ganglion* receives contributions from the ganglia of the trigeminal and facial nerves, the *otic* from that of the glossopharyngeal, and the *submandibular* from that of the facial cranial nerve.

The origin of the enteric ganglia in the walls of the gastro-intestinal tract has been disputed, but a critical review of the available evidence (Andrews 1971), suggested that both the vagal neural crest, and that of the trunk may provide sources, but further evidence was awaited. Recently ('Le Douarin and Teillet 1974) studying explants of quail neural crest into the chick confirmed that avian enteric neuroblasts have both a vagal and lumbo-sacral neural crest origin.

The Neuroglia

The glial cells are partly neurectodermal and partly mesodermal in origin. The ventricular zone lining the early central canal of the spinal cord and the cavities of the brain give rise, as we have seen (p. 157), to two types of cell in the intermediate zone—initially neuroblasts which differentiate into neurons, and later, glioblasts which differentiate first into *astroblasts* and *oligodendroblasts*, which mature into astrocytes and oligodendrocytes (for their mature morphology and hypothesized functional roles, *see* p. 834). In the early stages the glioblasts have processes which extend outwards to form the outer limiting membrane deep to the pia mater and inwards to form the inner limiting membrane around the central cavity. As the glioblasts differentiate into primitive neuroglial cells some lose their connexions with both inner and outer limiting membranes, others gain an attachment to the pia by small pial feet and still others remain lining the central canal and cavities of the brain as generalized or specialized ependymal cells, including tanycytes, but lose their peripheral attachments. In some situations, as in the anterior median fissure of the spinal cord, the ependymal cells retain their attachments to both the inner and outer limiting membranes. (For further comments *see* pp. 157, 837.)

In contrast to astrocytes and oligodendrocytes which are ectodermal in origin, the microglia are mesodermal derivatives. They appear in the central nervous system after this has been penetrated by blood vessels and invade it in large numbers from certain restricted regions, whence they spread in what has picturesquely been called 'fountains of microglia', to extend deeply amongst the nervous elements. Their origin has been variously ascribed to perivascular mesenchyme cells, vascular endothelial cells, and even to blood-borne leucocytes (p. 837).

The Meninges

The meninges may be divided in development into the *pachymeninx* (dura mater) and *leptomeninges* (arachnoid and pia mater). Experimental work in lower vertebrates indicates that the dura mater is mesodermal (derived, at least in part, from the sclerotomes) in origin, whilst the arachnoid and pia mater are closely associated in their development, being ectodermal in origin and largely derived from neural crest cells (Harvey and Burr 1926, and for a recent review *see* Gil and Ratto 1973). However, morphological studies on the spinal meninges of human embryos suggest that all three membranes are derived from the loose mesenchyme of sclerotomic origin surrounding the spinal cord, hence termed the *meninx primitiva*. Neural crest cells mingle with this mesenchyme and, as mentioned above, appear to be predominantly involved in the formation of the pia mater (Sensenig 1951, Weston 1970, Gil and Ratto 1973, Leikola 1976). In the head, the mesoderm from which the cranial dura mater develops is closely associated at first with the mesenchyme which is chondrified and ossified to form the skull, and these layers are only clearly differentiated as the venous sinuses develop. For an interesting study of pre- and post-natal growth of the tentorium cerebelli, with a mathematical analysis *see* Klintworth (1967).

The Chromaffin Organs

The tissue from which the sympathetic ganglia are formed is, at first, a mass of relatively undifferentiated *sympatho-chromaffin cells* but later, a number of cell varieties which may be roughly grouped into *small* and *intermediate-sized neuroblasts* (*sympathoblasts*), and *large*, initially rounded *phaeochromocytoblasts*. The intermediate-sized neuroblasts differentiate into the typical multipolar postganglionic sympathetic neurons (which secrete noradrenalin at their terminals) of classical autonomic neuroanatomy. The small 'neuroblasts' have only come into prominence in recent years: they are currently the subject of intense scrutiny, and they will unquestionably cause a radical reappraisal of autonomic terminology, and views concerning ganglionic transmission. Ultrastructural, and specialized light-microscopic fluorescence techniques led them to be termed firstly, small granulated cells, and latterly, *small intensely fluorescent* (SIF) cells, types I and II. Both have been shown (at least in some species and sites) to be dopamine-storing and secreting cells. It is postulated that type I function as true interneurons, synapsing with the principal post-ganglionic neurons. Type II are thought to operate as *local neuroendocrine cells*, secreting dopamine into the ganglionic microcirculation. Both types of SIF cells probably modulate the principal preganglionic/postganglionic synaptic transmission (for a discussion and bibliography *see* Chiba *et al.* 1977). The *large* cells differentiate into masses of columnar or polyhedral *phaeochromocytes* ('classical' chromaffin cells) which secrete either adrenalin or noradrenalin. These cell masses are termed *paraganglia* and may be situated near, on the surface of, or embedded in the capsules of the ganglia of the sympathetic chain, or in some of the large autonomic plexuses (*see* p. 1454 and **8**.204). The largest members of the latter are the *para-aortic bodies* which lie along the sides of the abdominal aorta in relation to the inferior mesenteric artery. During childhood the para-aortic bodies and the paraganglia of the sympathetic chain partly degenerate and can no longer be isolated by gross dissection, but even in the adult body chromaffin tissue can still be recognized microscopically in these various sites (p. 1454). It may be noted here that both the phaeochromocytes and the SIF cells, using a wider and more recent classification, are regarded as chromaffin; they belong to the APUD series of cells, and are paraneuronal in nature (*see* further discussions on pp. 115, 1455).

The Suprarenal Glands

Each suprarenal gland consists of a cortex of mesodermal origin and a medulla of ectodermal origin. The cortex develops during

the second month as a proliferation of coelomic mesothelium into the underlying mesenchyme between the root of the dorsal mesogastrium and the mesonephros (Keene and Hewer 1927; Crowder 1957). (An older view that two separate proliferations form at first a fetal cortex before the definitive cortex, has not been corroborated.) The proliferating tissue extends from the level of the sixth to the twelfth thoracic segments. It is soon disorganized dorsomedially by invasion into it of sympathochromaffin tissue from adjacent sympathetic ganglionic masses to form the medulla and also by the development of venous sinuses. The latter are joined by capillaries which arise from adjacent mesonephric arteries and penetrate the cortex in a radial manner. When the proliferation of the coelomic epithelium ceases the cortex becomes enveloped ventrally, and later dorsally, by a mesodermal capsule which is probably derived from the mesonephros. The nests of cortical cells under the capsule are the rudiment of the *zona glomerulosa* of the suprarenal. These nests proliferate cords of cells which pass deeply between the capillaries and sinusoids. The cells in these cords degenerate in a somewhat erratic fashion as they pass towards the medulla, becoming granular, eosinophilic and ultimately being autolysed. These cords of degenerating cells constitute the *fetal cortex*, which undergoes a rapid degeneration during the first two weeks after birth resulting in a marked shrinkage of the gland. The *fascicular* and *reticular* zones of the adult cortex are proliferated from the glomerular zone after birth and are fully differentiated by about the twelfth year. Their cells mature more slowly than those of the fetal cortex.

Pigment cells occurring in connective and epithelial tissues are believed to be derived solely from neural crest cells. Such *melanoblasts* migrate to almost all parts of the body and synthesize melanin; when fully loaded they are termed *melanocytes* (Wilde 1961; see also p. 43).

Development of Special Sense Organs

THE NOSE

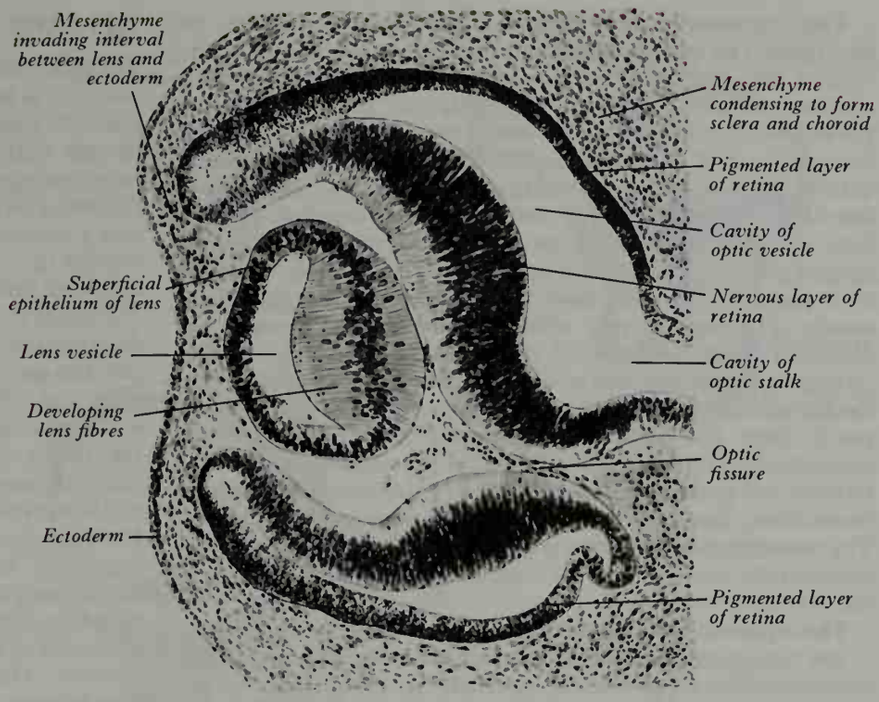
The development of the external nose and nasal cavities have already been considered (pp. 148–49).

The *olfactory nerves* are developed from the placodal cells which line the olfactory pits; these cells proliferate and give rise to *olfactory cells*. Their central processes are usually described as growing into the overlying olfactory bulb and thus forming the olfactory nerves. It has been claimed that the olfactory cells are from the first connected with the overlying brain by bridges of cytoplasm, within which the olfactory nerve fibres are developed (Smith 1908; Ballantyne 1925). More recent accounts, however, suggest that the earliest pioneer neurites are naked cytoplasmic processes which cross a mesenchyme-filled gap between the placode and the superjacent brain. Later, these, and subsequent generations of neurites become enclothed in Schwann cell processes, presumably derived from the rostral neural crest (Pearson 1941; Van Campenhout 1956; Dejean, Hervouët and Leplat 1958).

THE EYES

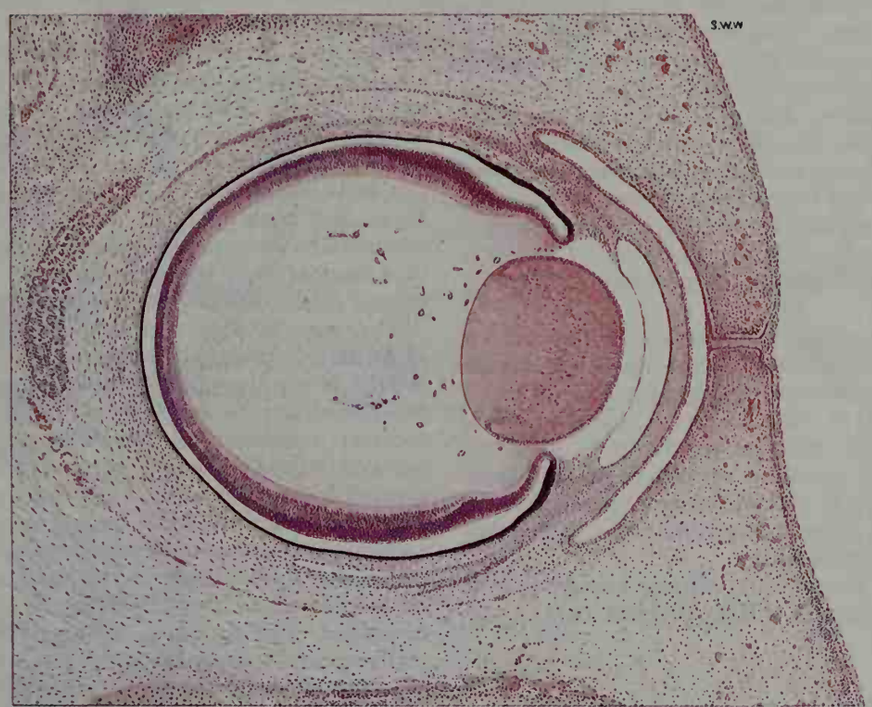
The rudiments of the eyeballs appear as two hollow diverticula from the lateral aspects of the forebrain (Mann 1964; Duke-Elder 1963; O'Rahilly 1966, 1975). These rudiments are visible some time before the closure of the rostral neuropore; after its closure they are known as the *optic vesicles*. Their formation is dependent on the organizing influence of the mesoderm of prechordal plate origin which underlies this part of the neural tube. They project towards the sides of the head, and the distal part of each expands while the proximal part remains narrow as the *optic stalk* (**2**.73A, B). Under the inductive influence of the subjacent optic vesicle the small area of ectoderm overlying it becomes thickened and depressed in its centre. (The classical experiments of Spemann in this field were largely responsible for initiation of the concept of embryonic induction—*see* p. 83.) This *lens pit* deepens and its edges come together and fuse to enclose a hollow *lens vesicle* (**2**.73A) which soon loses its connexion with the surface ectoderm and is the rudiment of the lens. The outer wall of the optic vesicle increases in thickness and undergoes invagination to form the *optic cup*, consisting of two strata of cells (**2**.73A). These two strata are continuous with each other at the cup's margin, which grows forwards at the end of the third month, overlapping the front of the lens, and converge to form the edge of the future pupil. The invagination is not limited to the outer wall of the vesicle, but involves also its caudal surface and extends in the form of a groove for some distance along the optic stalk. Thus, for a time, a wide hiatus, the *optic* or *choroidal fissure*, exists in the caudal part of the cup. Through the groove and fissure mesenchyme extends into the optic stalk and cup, carrying the *hyaloid artery* with it; as growth proceeds, the edges of the fissure become approximated and they close during the seventh week, including the artery in the distal part of the stalk. Failure of the optic fissure to close is a very rare anomaly and there is always a corresponding deficiency in the choroid and the iris (*congenital coloboma*). It must be noted, however, that localized deficiencies of the choroid and iris may occur quite independently, and in such cases the retina is normal (Lopashov and Stroeva 1961). Although the cavity of the optic vesicle is largely obliterated by the invagination to form a cup, the space does persist, in a sense, at the microscopic level as the interval between rod and cone processes and the ciliated apices of the pigmented cells of the most external layer of the retina (p. 1163). The 'space' is of course originally continuous with that of the cerebral vesicle; it is also the site of pathological detachment of the retina.

The retina develops from the optic cup (**2**.73B, C). Its two layers are at first equipotential and mutually interchangeable. Depending on contact with surrounding mesoderm, however, the external stratum of the cup remains a single layer of cells, which assume a columnar shape, acquire pigment, and form the *pigmented epithelium of the retina*, the pigment first appearing in the cells near the edge of the cup. Under the influence of the lens the cells of the internal stratum proliferate and form a layer of considerable thickness from which are developed the nervous elements and the sustentacular fibres (cells) of the retina, together with a portion of the vitreous body. In the region of the cup which overlaps the lens the inner stratum is not differentiated into nervous elements, but persists as a layer of columnar cells which, together with the corresponding part of the pigmented layer, form the double epithelium of the *ciliary* and *iridial parts* of the retina.



The cells of the inner layer of the cup proliferate and form an outer *nuclear zone* and an inner *marginal zone*, devoid of nuclei. At 12 mm the cells of the nuclear zone invade the marginal zone, and at 17 mm the nervous stratum of the retina consists of inner and outer *neuroblastic layers*. The inner neuroblastic layer gives origin to the ganglion cells, the amacrine cells and the somata of the sustentacular fibres (of Müller); the outer neuroblastic layer is the source of the horizontal and rod- and cone-bipolar neurons and probably the rod and cone cells, which first appear in the central part of the retina. By the eighth month all the layers of the retina can be identified. For recent bibliographies on retinal development, including ultrastructural studies, consult Spira and Hollenberg (1973); Fisher and Linberg (1975); Warwick (1976).

The deepest part of the optic fissure is at the centre of the floor of the optic cup. In this situation, which later is the site of the *optic disc*, the inner (neural) cell layer of the cup is continuous with the corresponding invaginated cell layer of the optic stalk and, as a result, the developing nerve fibres of the ganglion cells can pass directly into the wall of the stalk to convert it into the *optic nerve*. The fibres of the optic nerve begin to acquire their myelin sheaths shortly before birth, but the process is not completed until some time after birth. The *optic chiasma* is formed by the meeting and partial decussation of the fibres of the two optic nerves, and it marks the junction of the telencephalon with the diencephalon in the floor of the third ventricle. Beyond the chiasma the fibres are continued backwards as the optic tracts principally to the lateral geniculate bodies.



The lens is developed from the lens vesicle (**2**.73A), which is overlapped by the margin of the cup and becomes separated from the overlying ectoderm by mesenchyme. The cells forming the posterior wall of the vesicle lengthen and are converted into the lens fibres, which grow into and fill its cavity (**2**.73B, C). The cells

2.73A Section through the developing eye of a human embryo. 8 mm C.R. length. The thick nervous and the thinner pigmented layers of the retina and the developing lens are shown. Stained with haematoxylin and eosin. Magnification × *c.* 114. (From material loaned by Professor R. J. Harrison.)

2.73B A section through the developing eye of a human embryo, 13·2 mm long. (G. L. Street, *Contr. Embryol.*, **32**, 1948.)

2.73C Section through the eye of a human embryo. 40 mm C.R. length. Note the layers of the retina, developing lens, pupillary membrane, cornea, conjunctival sac, anterior and posterior aqueous chambers, the developing vitreous body, and condensing circumoptic mesenchyme, and the fused eyelids. Stained with haematoxylin and eosin. Magnification × *c.* 62.

forming the anterior wall retain their cellular character, and form the epithelium on the anterior surface of the fully developed lens; at the equator of the lens the gradual transition of the cells into lens fibres can be observed; lens fibre differentiation and growth continues throughout life. Characteristic ultrastructural changes have been described (Wulle and Lerche 1967). By the second month the lens is invested by a vascular mesenchymal condensation termed the *vascular capsule* of the lens, the ventral part of which, covering the lens, is named the *pupillary membrane*; the blood vessels supplying the dorsal part of this capsule are derived from the *hyaloid artery*, those for the ventral part from the anterior ciliary arteries. By the sixth month all the vessels of the capsule are atrophied except the hyaloid artery, which becomes occluded during the eighth month of intrauterine life. Prior to this, during the fourth month, the hyaloid artery gives off retinal branches, and its proximal part persists in the adult as the *central artery of the retina*. The *hyaloid canal*, which carries the artery through the vitreous, persists after the vessel has become occluded. In the newly born child it extends more or less horizontally from the optic disc to the posterior aspect of the lens but, when the adult eye is examined with a slit-lamp, it can be seen to follow a wavy, curved course, sagging downwards as it passes forwards to the lens (Mann 1927). With the loss of its blood vessels the vascular capsule of the lens disappears, but sometimes the pupillary membrane persists at birth, giving rise to the condition termed *congenital atresia of the pupil*.

The vitreous body is developed between the lens and the optic cup. The lens rudiment and the optic vesicle are at first in contact with each other, but after the closure of the lens vesicle and the formation of the optic cup the former is withdrawn from the retinal layer of the cup; the two, however, remain connected by a network of delicate cytoplasmic processes. This network, derived partly from the cells of the lens and partly from those of the retinal layer of the cup, is the *primitive vitreous body*. At first these cytoplasmic processes spring from the whole of the retinal layer of the cup, but later are limited to the ciliary region, where by a process of condensation they appear to form the *ciliary zonule*. The mesenchyme which enters the cup through the choroidal fissure and around the equator of the lens becomes intimately united with this reticular tissue, and also contributes to the formation of the vitreous body, which is therefore derived partly from the ectoderm and partly from the mesoderm. Considerable controversy regarding the precise derivation of the vitreous still persists. There are probably three sources: the local *mesenchyme*, the lens (*ectoderm*) and the retina (*neurectoderm*). The mesodermal component is probably represented only by the juxtazonular vitreous and the vitreous immediately adjacent to the hyaloid vestiges.

The aqueous chamber of the eye appears as a cleft in that part of the mesenchyme which intervenes between the lens and the ectoderm. The mesenchyme superficial to the cleft forms the *substantia propria* of the cornea that deep to the cleft the mesenchymal stroma of the *iris* and the *pupillary membrane*. The cornea is induced by the lens and optic cup. The corneal epithelium is formed from the surface ectoderm and the endothelium of the anterior chamber from mesenchyme (O'Rahilly and Meyer 1959; Coulombre 1964). When the pupillary membrane disappears the anterior and posterior chambers of the eye communicate with each other.

The sclera and choroid are derived from the mesenchyme surrounding the optic cup, and the anterior part of the choroid is modified to form the *ciliary body* and *ciliary processes*. The fibres of the *ciliary muscle* are derived from the mesoderm, but those of the *sphincter* and *dilatator pupillae* are of neurectodermal origin, being developed from the cells of the pupillary part of the optic cup, as is the double epithelium on the posterior (lenticular) aspect of the iris.

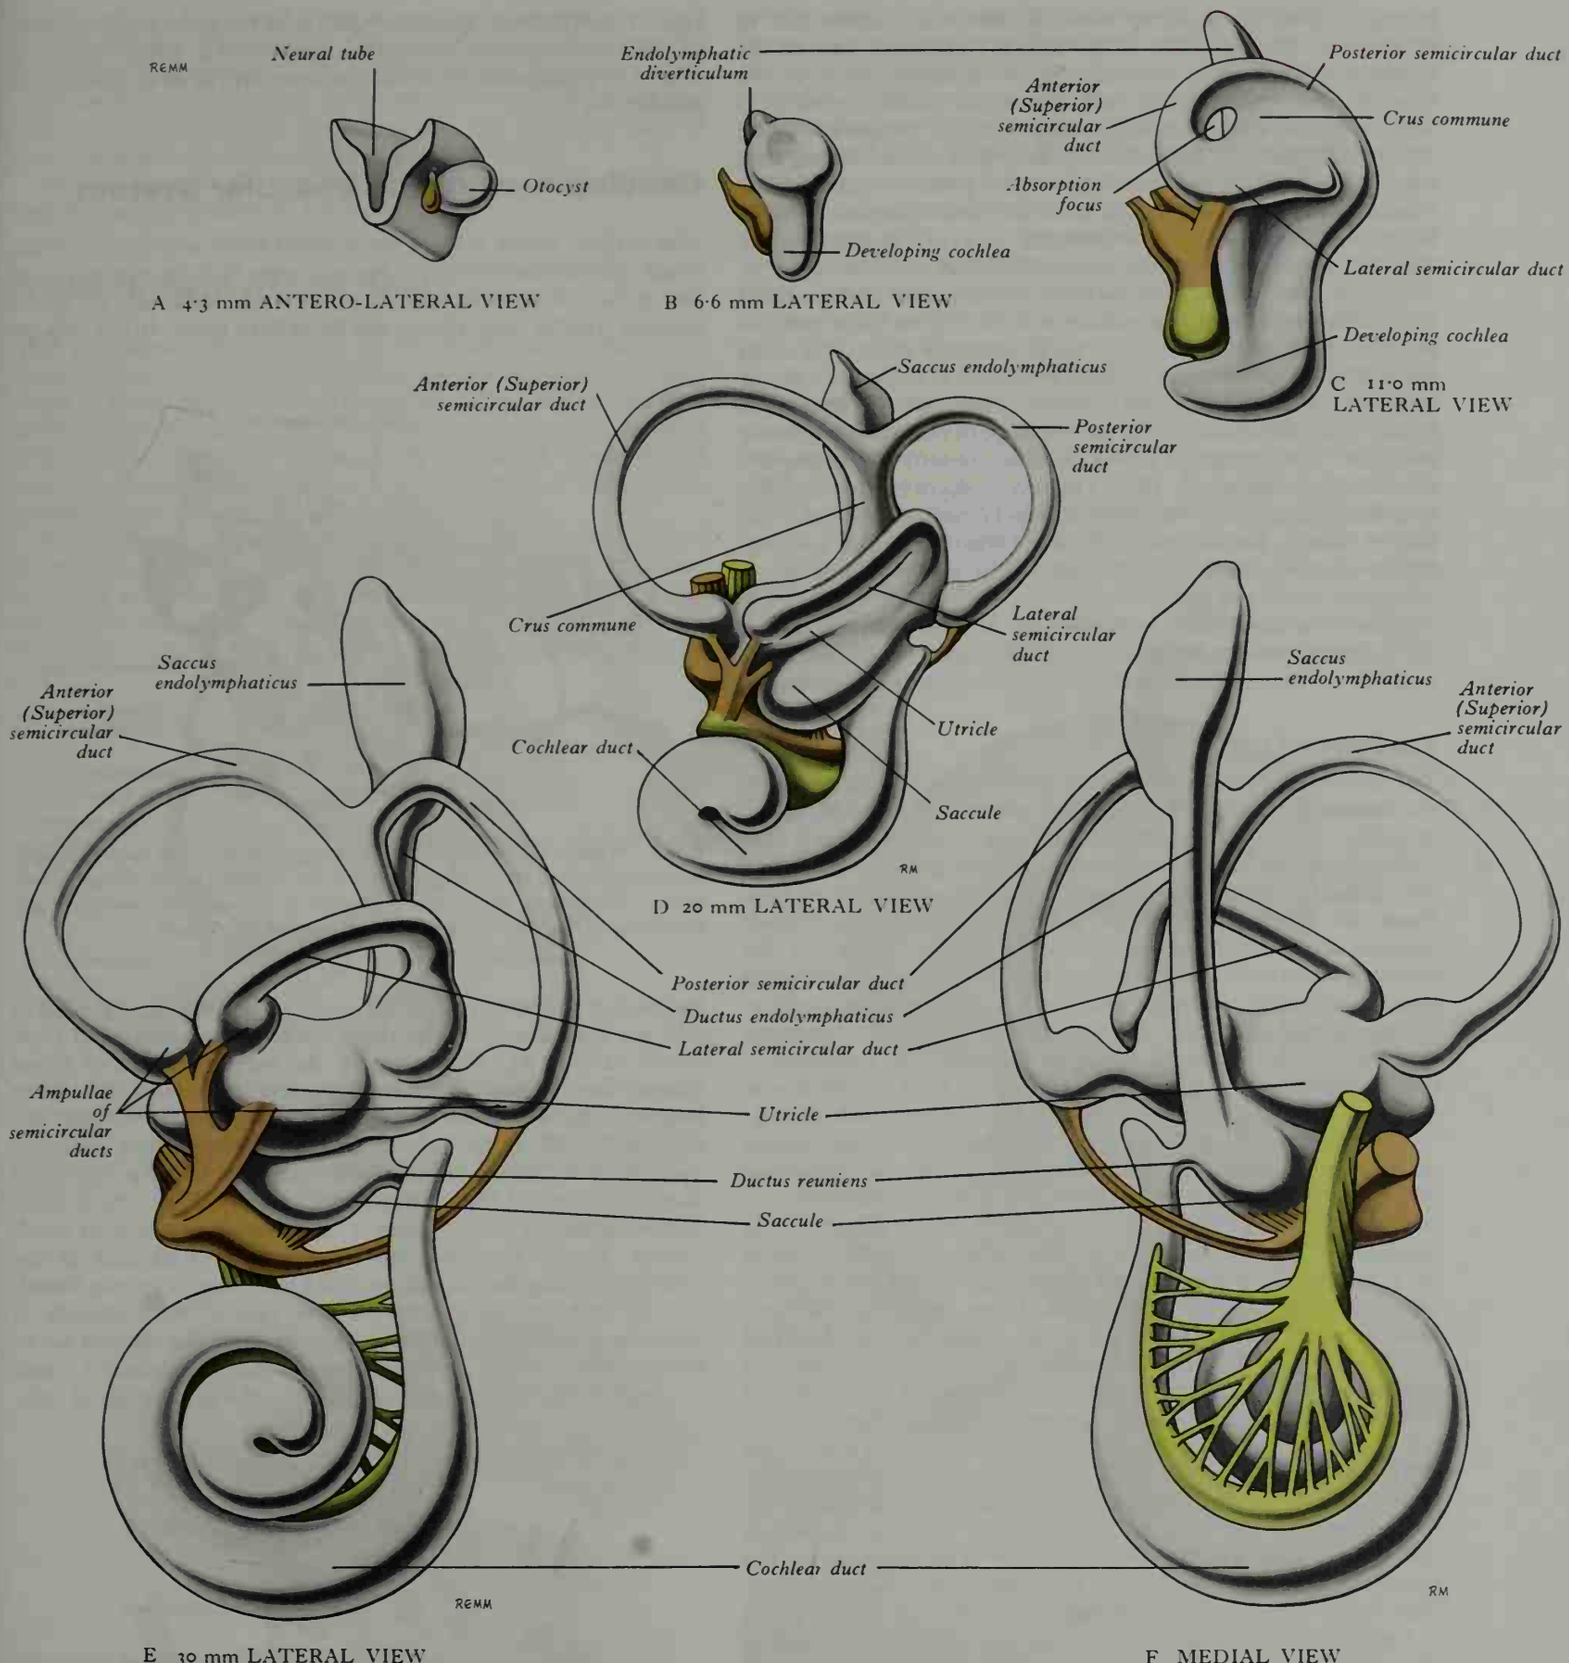
The *eyelids* are formed as small cutaneous folds (**2**.73C). About the middle of the third month their edges come together and unite over the cornea; they are usually said to remain united until about the end of the sixth month. In the most recent study, however, Jain *et al.* (1972) concluded that the separation is slow but completed a month earlier (5·1 months, 155 mm stage). The same observers, from examination of 20 human embryos and fetuses, also stated that the tarsal plates and glands begin to develop respectively at 55 mm and 75 mm stages.

For the chronology of development of the human eye, at embryonic and fetal stages consult O'Rahilly (1966, 1975).

The Lacrimal Apparatus

The epithelium of the alveoli and ducts of the *lacrimal gland* arise as a series of tubular buds from the ectoderm of the superior conjunctival fornix; these buds are arranged in two groups, one forming the gland proper, and the other its palpebral process. The *lacrimal sac* and *nasolactimal duct* are considered to be derived from the ectoderm in the nasomaxillary groove between the lateral nasal elevation and the maxillary process (p. 149). This thickens to form a solid cord of cells which sinks into the mesenchyme; during the third month the central cells of the cord break down, and a lumen is acquired. In this way the *nasolacrimal duct* is established. The lacrimal canaliculi arise as buds from the upper part of the cord of cells and secondarily establish openings (*puncta lacrimalia*) on the margins of the lids; the inferior canaliculus cuts off a small part of the lower eyelid to form the *lacrimal caruncle*. The epithelium of the cornea and conjunctiva is of ectodermal origin, as are also the eyelashes and the lining cells of the tarsal and other glands which open on the margins of the eyelids.

For general accounts of ocular developmental abnormalities consult Dejean, Hervouet and Leplat (1958), and Mann (1964).



THE EARS

The rudiments of the **internal ears** appear shortly after those of the eyes, as two patches of thickened, surface epithelium, the *otic placodes*, situated in the region of the hindbrain. These patches, though surrounded by general skin ectoderm, are probably neurectodermal in character. Each placode is invaginated, becoming an *otic pit* (**2**.112A). The mouth of the pit is then closed, and a vesicle, termed the *otocyst* (auditory or otic vesicle), is formed (**2**.74A); it is initially piriform in shape, and from it the epithelial lining of the *membranous labyrinth* is derived (**2**.74A–F). A vertical infolding of its wall progressively marks off a tubular diverticulum on the medial side. This diverticulum differentiates into the *ductus* and *saccus endolymphaticus*, and it communicates with the remainder of the vesicle, which is termed the *utriculosaccular chamber* and is placed laterally. From the dorsal part of this chamber three compressed diverticula appear as disc-like evaginations; the central parts of the walls of the discs coalesce and disappear, while the peripheral portions of the discs persist to form the *semicircular ducts*; the anterior duct is the first, and the lateral the last, to be completed. From the ventral part of the utriculosaccular chamber arises a medially directed evagination which becomes coiled and forms the *cochlear duct*, the proximal extremity of which is subsequently constricted to form the *ductus reuniens*. The central part of the chamber now represents the membranous vestibule and is subdivided into a smaller ventral part, the *saccule*, and a larger dorsal part, the *utricle*, mainly by a horizontal infolding which extends deeply from the lateral wall, towards the opening of the ductus endolymphaticus, leaving only a narrow communication, the *utriculosaccular duct*, between the subdivisions. This duct becomes acutely bent on itself. During this period the membranous labyrinth undergoes a rotation so that the long axis, originally vertical, becomes more or less horizontal (Bast and Anson, 1949). Subsequently, otocyst derived cells (having contributed placodal cells to vestibulo-cochlear ganglion) differentiate into the specialized paraneuronal hair cells of the utricle, saccule, ampullae of the semicircular ducts, and organ of Corti; they also differentiate into various specialized sustentacular cells, and the unique epithelia of the stria vascularis and endolymphatic sac. The remainder form the general epithelial lining of the rest of the membranous labyrinth.

The mesenchyme surrounding the various parts of the epithelial labyrinth is converted into a cartilaginous *otic capsule*, and this is finally ossified to form the *bony labyrinth* of the internal ear. For a time the cartilaginous capsule is incomplete, and the cochlear, vestibular, and facial ganglia are situated in the gap between its canalicular and cochlear parts. These ganglia are soon covered by an outgrowth of cartilage, and at the same time the facial nerve is covered in by a growth of cartilage from the cochlear to the canalicular part of the capsule. In the embryonic connective tissue between the cartilaginous capsule and the epithelial wall of the labyrinth the perilymphatic spaces are developed. The rudiment of the *periotic cistern* or vestibular perilymphatic space can be seen in an embryo of from 30 to 40 mm in length, in the reticulum between the saccule and the fenestra vestibuli (Streeter 1917). The scala tympani is next developed, and begins opposite the fenestra cochleae; the scala vestibuli is the last to appear. The two scalae gradually extend along each side of the ductus cochlearis, and when they reach the tip of the ductus an opening, the helicotrema, is developed between them. The modiolus and the osseous spiral lamina of the cochlea are not preformed in cartilage but are ossified directly from connective tissue.

The Middle Ear Cleft

The auditory tube and tympanic cavity are developed from a hollow, termed the *tubotympanic recess* (Frazer 1914), between the first and third branchial arches, the floor of the recess consisting of the second arch and its limiting grooves. By the forward growth of the third arch the inner part of the recess is narrowed to form the tubal region, and the inner part of the second arch is excluded from this portion of the floor. The more lateral part of the recess subsequently develops into the *tympanic cavity*, and the floor of

2.74A–F A series of diagrams showing the stages in the development of the membranous labyrinth from the otocyst, at the embryonic stages and viewed from the aspects indicated. Note also the relationship of the vestibular (orange) and cochlear (yellow) parts of the vestibulocochlear nerve. (From a series of models prepared by His.)

this part forms the lateral wall of the tympanic cavity up to about the level of the chorda tympani nerve. From this it will be seen that the lateral wall of the tympanic cavity contains first and second arch elements, the first arch being limited to the part in front of the anterior process of the malleus. The second arch forms the outer wall behind this, and turns on to the back wall to take in the tympanohyal region. Recent observations, however, indicate that the tympanic cavity is derived wholly from the first pouch (Kanagasuntheram 1967). The tubotympanic recess is at first on the inferolateral aspect of the cartilaginous otic capsule, but as the latter enlarges the relations become altered and the tympanic cavity comes to lie anterolateral to the capsule. A cartilaginous process grows out from the lateral part of the capsule to form the tegmen tympani, and it curves caudally to form the

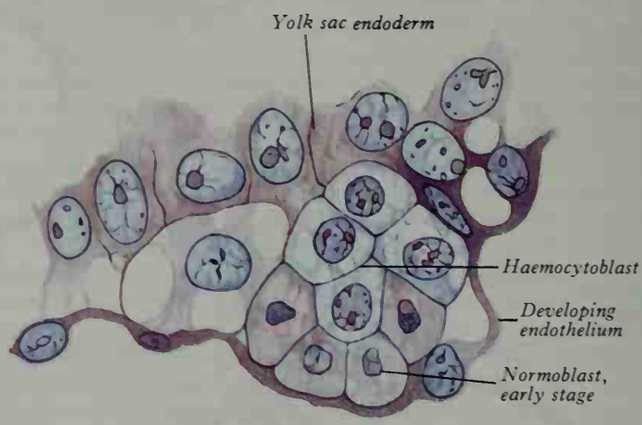
lateral wall of the auditory tube. In this way, subsequent to ossification, the tympanic cavity and the proximal part of the auditory tube become included in the petrous region of the temporal bone. During the sixth or seventh month the mastoid antrum appears as a dorsal expansion of the tympanic cavity. Much of the cavity's basic development thus occurs during *fetal* life (Bok 1966). A recent study of the posterior part of the tympanic cavity, and in particular of the sinus tympani, a recess between the promontory and pyramid (p. 1195), emphasizes the late fetal development of this region (Bollobás and Hajdu 1975).

The opinion generally held as to the development of the ossicles of the middle ear is that the *malleus* is derived from the dorsal end of the ventral mandibular (Meckel's) cartilage (**2**.58), the *incus* from the dorsal cartilage, which probably corresponds to the quadrate bone of birds and reptiles. The *stapes* is developed mainly from the dorsal end of the cartilage of the second or hyoid arch, and first appears as a ring (*annulus stapedis*) encircling the small stapedial artery (p. 187). The primordium of the stapedius muscle appears close to the artery and facial nerve at the end of the second month, and at almost the same time the tensor tympani begins to appear near the extremity of the tubotympanic recess (Candiollo and Levi 1969).

At first the ossicles are embedded in the mesenchymal roof of the tympanic cavity, and their extraneous origin is indicated in the adult by the covering which they receive from its mucous lining.

The External Ear

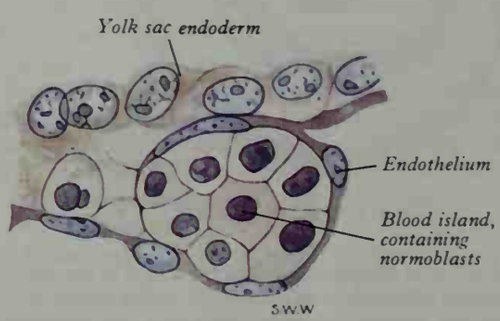
The external acoustic meatus is developed from the dorsal end of the hyomandibular or first branchial groove. Close to its dorsal extremity this groove extends inwards as a funnel-shaped tube (*primary meatus*) from which the cartilaginous portion and a small part of the roof of the osseous portion of the meatus are developed. From this funnel-shaped tube a solid epidermal plug extends inwards along the floor of the tubotympanic recess; by the breaking down of the central cells of this plug the inner part of the meatus (*secondary meatus*) is produced, while the deepest cells of the ectodermal plug form the epidermal stratum of the tympanic membrane. The fibrous stratum of the *tympanic membrane* is formed from the mesenchyme which extends between the meatal plate and the endoderm of the floor of the tubotympanic recess.



The development of the **auricle** is initiated by the appearance of six hillocks which form round the margins of the dorsal portion of the hyomandibular groove. Of the six, three are situated on the caudal edge of the mandibular arch and three on the adjoining cranial edge of the hyoid arch (**2**.111F). These hillocks appear at the 4 mm stage, but they tend to become obscured as development proceeds and of those on the mandibular arch only the most ventral, which subsequently forms the *tragus*, can be identified throughout (**2**.55). The remainder of the auricle owes its development to proliferation of the mesenchyme of the hyoid arch (Streeter 1922), which extends forwards round the dorsal end of the remains of the hyomandibular groove, forming a keel-like elevation—the forerunner of the *helix*. The contribution made by the mandibular arch to the auricle is greatest at the end of the second month; as growth continues, it becomes relatively reduced, so that eventually the area of skin supplied by the mandibular nerve extends very little above the tragus (**7**.280). The lobule is the last part of the auricle to develop.

The rudiment of the eighth nerve appears in the fourth week as the *vestibulocochlear ganglion*, which lies between the otocyst and the wall of the hindbrain. At first it is fused with the ganglion of the facial nerve (*acousticofacial ganglion*) but later the two separate. The cells of the ganglion are mainly derived from the neural crest, but probably some cells come from the neuroectoderm of the otocyst. The auditory ganglion divides into vestibular and cochlear parts, each associated with the corresponding division of the eighth nerve. The cells of these ganglia remain bipolar throughout life, each sending a proximal fibre into the brainstem, and a peripheral fibre to the internal ear. These neurons are also unusual in that many of their *somata* become enveloped in thin *myelin sheaths*.

The ganglionic fibres just described provide, of course, the afferent, sensory innervation of the labyrinthine hair cells. The latter soon become associated with the outgrowing axons from cells of the superior olivary complexes of the pons which provide an efferent innervation termed the olivocochlear bundle (pp. 904, 909). Developmental details of the latter are, however, lacking in mankind.



Development of the Vascular System

The earliest blood vessels are derived from *angioblastic tissue*, which differentiates from the mesenchyme in three regions: (*a*) in the surface of the yolk sac, (*b*) in the body stalk, and (*c*) in the chorion (Hertig 1935; Bloom and Bartelmez 1940). In the yolk sac

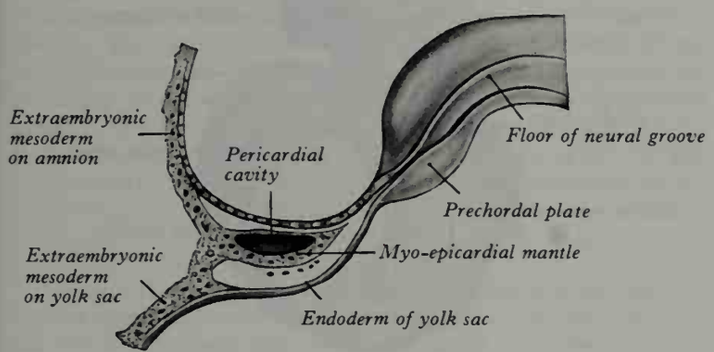
and base of the body stalk small, more or less spherical groups of cells are found early in the third week. They are termed *blood islands* (**2**.75A, B). The stages of the transformation of blood islands into blood-containing vessels have not yet been demonstrated in detail, but it is generally believed that the peripheral cells of the islands become flattened and form the vascular endothelium, while the central cells become converted into primitive red blood corpuscles (**2**.75B). Later these small blood-containing spaces form a continuous network of small vessels. In the chorionic end of the body stalk and in the mesoderm lining the chorion typical blood islands are not found, but the cells of the mesoderm give rise to solid strands of angioblasts. Each strand contains two or three rod-shaped nuclei arranged in a single row and soon comes to contain a space occupied by one or more nucleated haemoglobin-containing cells.

2.75B A part of a section through the wall of the yolk sac of an early human embryo, to show a developing blood vessel including a blood island. (Hamilton, Boyd and Mossman's *Human Embryology*, 1945. Reproduced by permission of the authors and publishers.)

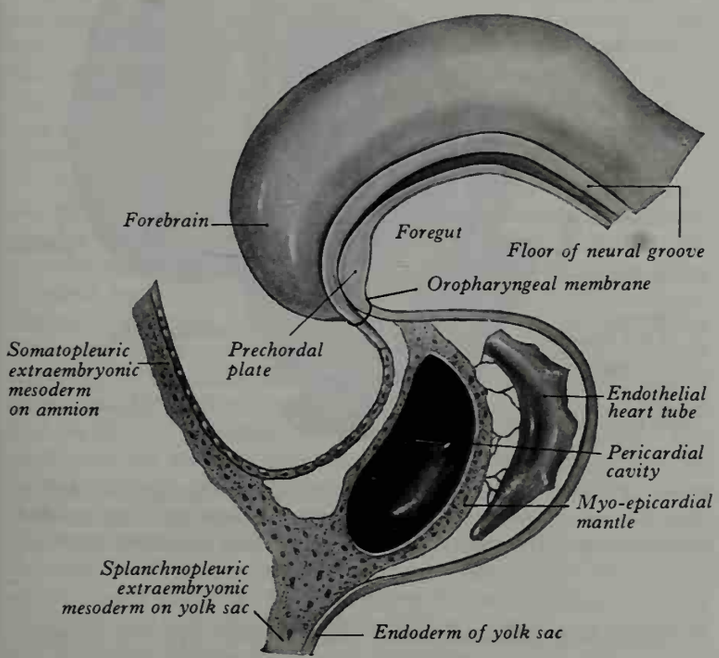
These spaces coalesce to form blood vessels, which are therefore lined by derivatives of the mesoderm: the precise source of their contained blood cells is uncertain. The earliest blood vessels, therefore, are formed at several separate centres; from the walls of these vessels buds grow out, become canalized, converted into

new vessels, and join with those of neighbouring areas to form a close meshwork. The heart and the blood vessels of the embryo arise from angioblastic tissue differentiated from the intra-embryonic mesoderm. Prior to the establishment of the circulation (p. 120), new vessels develop *in situ*, but thereafter they all take origin as outgrowths from pre-existing vessels.



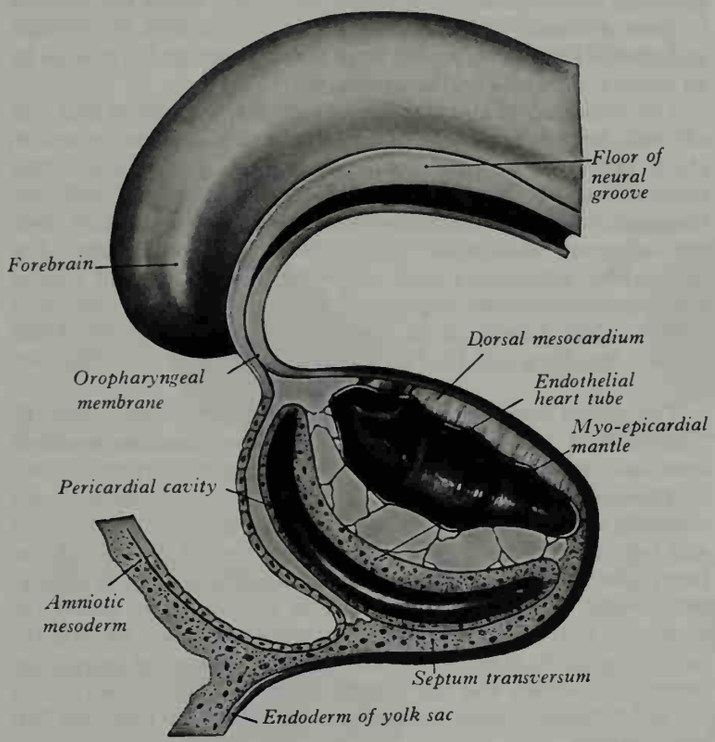
The subsequent development of the blood corpuscles has already been described (p. 121).

Development of the Heart



The precocious development of the heart has already been mentioned (p. 120). In placental vertebrates it is the earliest major organ to function; for obvious nutritive reasons it must not only accommodate a stream of blood but also begin to propel it (p. 183). These early *functional* demands on the heart represent an important factor in the dynamics of its development (Sabin 1924; Johnstone 1925).

The early appearance of cardiac activity in the tubular hearts of chick (Sabin 1924; Johnstone 1925; Patten and Kramer 1933) and rat (Goss 1952) embryos was noted many years ago. This is first manifested by arrhythmic and sporadic ventricular contractions, which are rapidly superseded by regular peristaltic activity propagated along the atrioventricular tube. Earlier observers also described the formation of functional valves by the accumulation, subjacent to the endothelium, of *cardiac jelly* or *subendocardial reticulum*. This occupies a large space between the primitive endocardium and myoepicardial mantle (*vide infra* and **2**.76C, D). These rapid and critical early events in cardiac morphogenesis have been re-examined more recently with improved techniques, including electron microscopy, especially in the mouse (Challice and Viragh 1973). As the simple heart tube elongates and develops an asymmetrical twist, a succession of cavities, joined by more constricted regions, begin to define the sinus venosus, atrium, ventricle and bulbus cordis. At first these are somewhat cylindrical, but they rapidly become more spherical (within 24 hours in the mouse). Coincidentally, myoblastic strands invade the subendocardial reticulum from the cells of the myoepicardial mantle, and these form a complex network of intercommunicating *trabeculae* external to, but ultimately indenting and becoming clothed by endocardium. In many vertebrate groups the myocardium remains predominantly trabecular in arrangement, but in birds and mammals a compact layer of cardiac muscle develops external to the trabeculae. The latter also persist but constitute a lesser volume of the propulsive tissue.



These early events in cardiac development provide an approximate parallel between phylogeny and ontogeny. The

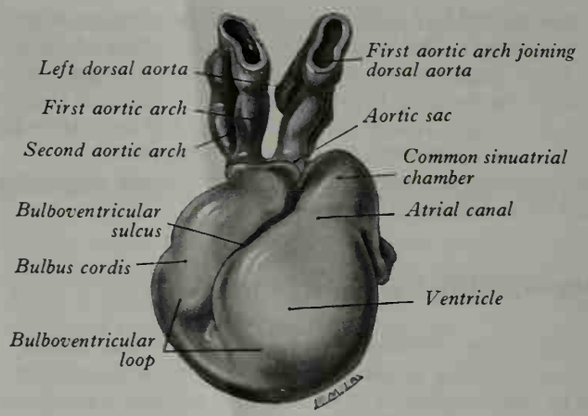
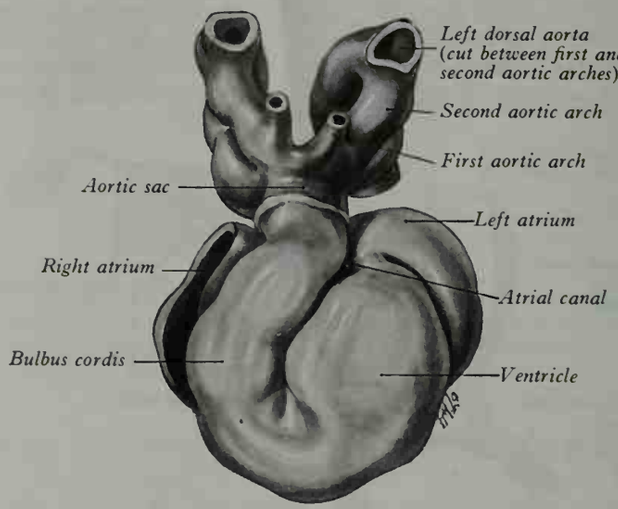
evolution from a 'trabecular' heart to an organ with rounder chambers and a largely compacted myocardium is likely to be an expression of increased efficiency. An attempt to demonstrate this by mathematical analysis (Challice and Viragh 1974) provides some corroboration and also an explanation for the persistence of the internal trabeculation in the mammalian heart (p. 638). In the account which follows, attention is necessarily concentrated upon the complex changes which transform a tube into a chambered septate human heart. It is also necessary to keep in mind that at every stage the heart must also function as a circulatory pump.

The human heart, as in all vertebrates, is formed by the fusion of two symmetrically developing tubes (p. 121), but the fusion is gradual, commencing at the bulbar or arterial end and extending to the venous end (Tandler 1912; Davis 1927).



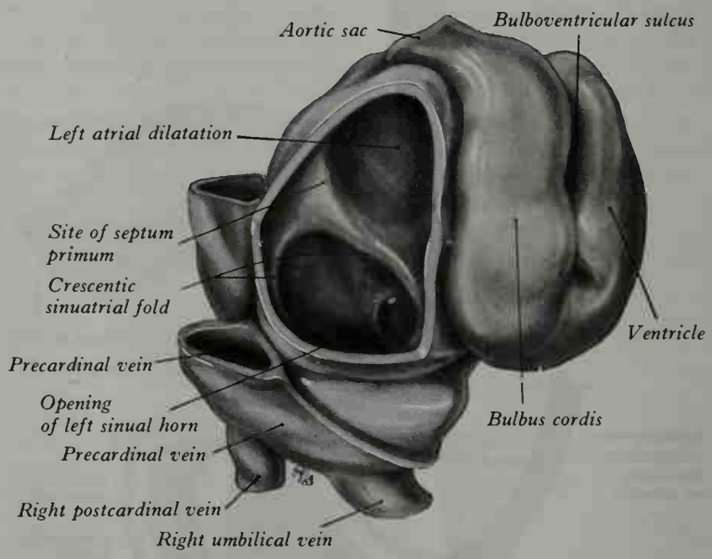
The pericardial cavity can be identified before the head fold is formed or while it is in process of formation, at a stage when the embryo possesses only two somites. The heart is then represented by groups of angioblasts which lie between the pericardium and the endoderm of the yolk sac (**2**.76A). At this stage the ventral (or yolk sac) wall of the pericardium, which will form both the epicardium and the myocardium, is thicker than the dorsal wall and is termed the *myo-epicardial mantle*. When the head fold is formed, the mantle becomes the dorsal wall of the pericardium and lies ventral to the foregut. While this reversal of the pericardium is taking place (**2**.76B, C), the *cardiogenic mesoderm* gives rise to two paramedian endothelial tubes which rapidly fuse to form a tubular heart. Except at its venous end the tubular endothelial heart is separated from the myo-epicardial mantle by an interval occupied by the *cardiac jelly*.

The proximity of the presumptive cardiac mesoderm and yolk sac endoderm at this stage of development is suggestive, and in chick embryos, at least, experimental studies indicate that movements, determination of polarity and regional differentiation of the cardiac mesoderm are in some way dependent upon the adjacent endoderm, and perhaps also ectoderm. For discussions concerning such experimental studies and related questions such as the importance of haemodynamic influences consult Orts Llorca *et al.* (1964, 1967a and b), De Haan (1968), Stalsberg and De Haan (1968), Bellairs (1971), Balinsky (1975).



The dorsal aortae arise *in situ* as paired endothelial vessels. They extend caudally into the body stalk, where they establish continuity with the umbilical arteries, which precede them in time of appearance. At their cranial ends the dorsal aortae curve ventrally round the sides of the foregut to reach the pericardium and become continuous with the cranial end of the endothelial heart tube, thus forming the first pair of aortic arches (**2**.77A). In lower vertebrates the heart and aortae are laid down before the formation of the head fold and the arteries communicate with the caudal end of the heart. When the head fold forms, the ends of the heart are reversed and the cranial ends of the dorsal aortae are curved forwards round the sides of the foregut to form the first aortic arches.

A transverse groove appears on the surface of the heart tube about its middle and indicates the junction of the *bulbus cordis* with the *ventricle*. The bulbus is situated cranial to the groove and is continuous with the first pair of aortic arches. The ventricle shows a second groove at its caudal end where it opens into a *common atrium*, which lies at first in the floor of the pericardium (the future *septum transversum*) and is disposed transversely. On each side the common atrium is joined caudally by a short venous trunk, formed by the union of the corresponding umbilical vein with veins issuing from the *vitelline* (yolk sac) *plexus*. These trunks represent the right and left *horns* of the *sinus venosus* so that the common atrium may justifiably be termed a *common sinuatrial chamber*.



Early in the fourth week the heart tube undergoes a striking change. Hitherto the pericardium has been increasing in length proportionately with the heart, but now the heart tube begins to grow more rapidly than the pericardium and, as a result, the bulboventricular tube bulges ventrally and caudally, forming a U-shaped loop of which the bulb forms the right limb and the ventricle the left. On account of this loop—which is a conspicuous feature throughout the fourth and fifth weeks—a deep *bulboventricular sulcus* is apparent on the outside of the heart (**2**.77A) and a corresponding *bulboventricular ridge* projects into the interior. The dorsolateral recesses of the pericardium deepen and approach one another (**2**.76D) and their opposed walls fuse, completing the myo-epicardial covering of the heart and converting its hitherto broad dorsal attachment into a dorsal

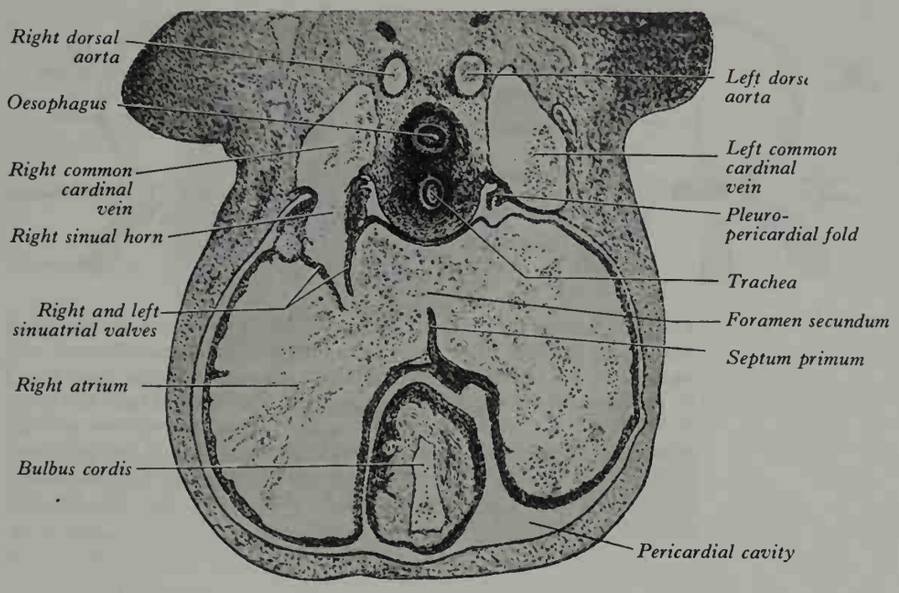
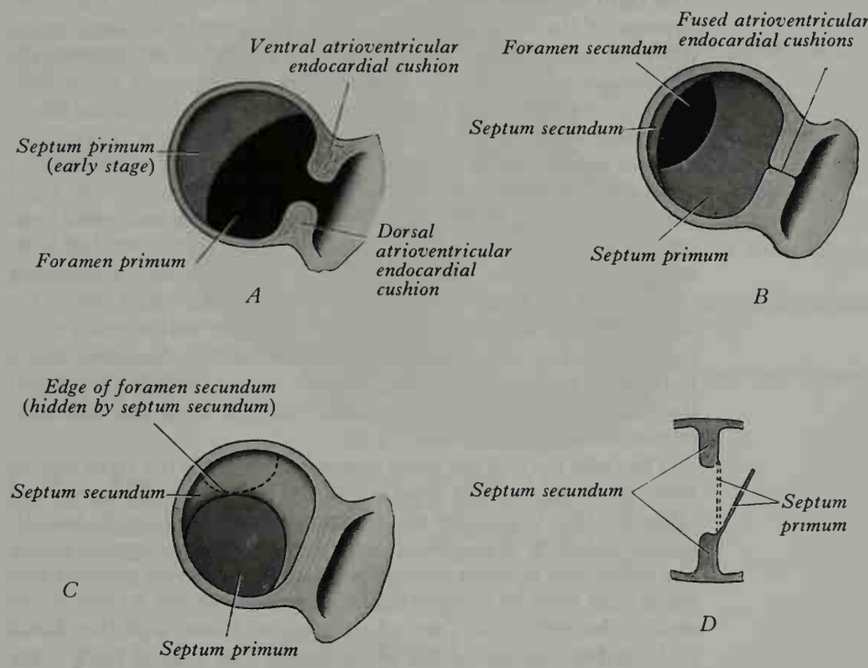
cardiac mesentery. This *dorsal mesocardium* is transient and when it breaks down early in the fourth week a passage is established across the pericardial cavity from side to side dorsal to the heart. This persists as the *transverse sinus* of the pericardium. While these changes are occurring in the bulboventricular region, the atrial part is not unaffected, for the atrioventricular opening moves cranially and to the left, and both parts of the common atrial or sinuatrial chamber grow cranially into the pericardial cavity dorsal to the ventricle. Owing to these changes the atrioventricular canal for a time connects the *left* atrium to the ventricle and venous blood from the right side has to pass through both atria.

At this stage (**2**.80A), reached about the middle of the fourth week, the bulbus cordis communicates with the dorsal aortae through the first pair of aortic arches, and these are connected with the capillary plexus associated with the developing cerebral vesicles. From this plexus the primitive head vein passes caudally, but it ends blindly before it reaches the heart. The intersegmental arteries are beginning to grow out from the dorsal aorta on each side but they have not yet established connexions with the corresponding veins; and the postcardinal veins, which later drain the body wall caudal to the heart, are only in process of development. The umbilical arteries and veins are defined and, early in the fourth week, their terminals and radicles, respectively, link up with the capillaries which have developed in the chorionic villous stems, establishing the chorionic part of the circulation. Despite the fact that the channels for the remainder of the circulation are only partially established there is good ground for assuming, on the analogy of observations made on the living chick embryo, that the heart begins to contract about this time. Under the conditions which exist the result can only be of an 'ebb and flow' nature, but this serves to effect some movement in the nutritive fluid which fills the pericardial cavity, the coelomic ducts and the exocoelom (p. 116) and on which the embryo still depends to a considerable extent.



Towards the end of the fourth week the connexion between the bulbus cordis and the first pair of aortic arches lengthens to form the *truncus arteriosus*, and the cranial end of this vessel becomes connected to the dorsal aortae by the remaining five pairs of aortic arches. By this time the venous drainage of the body wall and neural tube has been established. On each side a *precardinal vein*, from the cranial end of the embryo, unites with a *postcardinal vein* from the caudal region, to form the *common cardinal vein* (*duct of Cuvier*); the latter vessel opens close to the umbilical and vitelline veins into the dorsocaudal part of the common sinuatrial chamber.

As the chorionic circulation already exists, the embryo can now exchange material with the maternal blood in the intervillous space. This is not effected suddenly, for at first the blood cells in the heart and vessels of the embryo are not numerous enough to enable it to take full advantage of this new source of nourishment, and it would appear that, until sufficient are available, the embryo continues to draw upon the coelomic fluid.

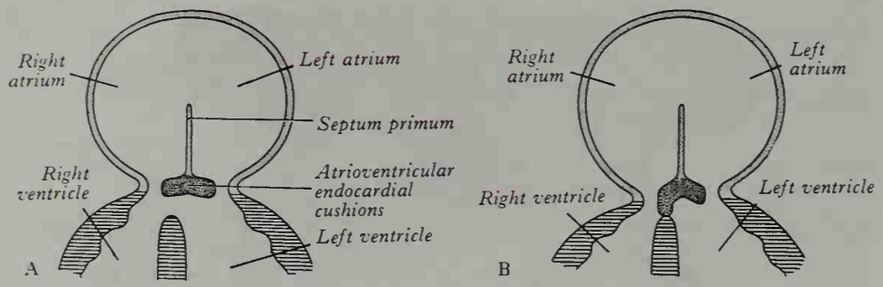


The separation of the *sinus venosus* from the *atrium* completes the definition of the primitive chambers of the heart. A crescentic groove appears on the left wall of the sinuatrial chamber and rapidly deepens to the right. Hence the left horn of the sinus venosus loses its connexion with the left atrium and becomes linked to the right horn by separation of the caudal part of the sinuatrial chamber, which can be regarded as the *body* of the sinus venosus. At the same time the right horn becomes more clearly demarcated from the right atrium and its wide connexion with the atrium (**2**.77C) becomes relatively smaller (Foxon 1955). The right and left parts of the atrium grow cranially to occupy the dorsal part of the pericardial cavity, and later they bulge forwards at the sides of the bulb (**2**.78A).

The embryo has now attained a length of nearly 4 mm (**2**.80B). It possesses 28 somites and has almost completed the fourth week of development. From this stage onwards it is more convenient to deal with the individual chambers than with the development of the heart as a whole.

It must be noted at this point that the above account of early cardiogenesis, though widely subscribed to, is not without its critics. In considering the factors govering cardiac development—phylogenetic, ontogenetic, and physiological—

2.78A Transverse section of a human embryo, 8 mm long. Observe how the atria bulge forwards on each side of the bulbus cordis. The septum primum has broken down in its dorsal region and the two atria communicate through the ostium secundum or foramen ovale.



2.78B Diagrams representing three stages in the development of the atrial septum, viewed from the right side. The heart has been divided in its long axis to the right of its median plane and only the atria and the adjoining part of the ventricular cavity are depicted.

A The septum primum has not yet obliterated the original communication between the two atria and the atrioventricular endocardial cushions have not yet fused.

B The atrioventricular endocardial cushions have fused with each other and with the septum primum, which has broken down in its dorsal part. The foramen secundum, thus formed, subsequently moves to the position shown in C.

C The septum secundum has formed and hides the foramen secundum, the margins of which are indicated by the curved, dotted line.

D A section to show the valve-like character of the foramen secundum. When the pressure in the right atrium exceeds that in the left atrium, blood passes from the right to the left side of the heart, but when the two pressures are equal the septum primum assumes the position indicated by the dotted outline.

2.78C Diagram to show two stages in the formation of the adult ventricular septum. In A the right and left ventricles communicate with each other, but in B the interventricular communication has been closed by the fusion of the ventricular septum with the enlarged right extremity of the fused a.v. cushions. Note the position of the septum primum relative to the fused a.v. cushions, and observe that in B cushion tissue intervenes between the two ventricles (membranous part of ventricular septum), and also between the *right* atrium and the *left* ventricle (atrioventricular septum).

the last is usually underestimated and the first is perhaps stated too dogmatically (Foxon 1955). Ontogenetic mechanisms must conform to the early demand for a functioning heart, and cardiogenesis is not necessarily a mere repetition of phylogenetic steps, which are themselves uncertain, however plausible they may seem (De Vries and Saunders 1962).

THE SINUS VENOSUS

The right horn of the sinus venosus increases rapidly in size at the expense of the left, owing to the changes already outlined and to those brought about in the originally symmetrical arrangement of the umbilical and vitelline veins by the development of the liver (p. 193). As a result of these changes the vitello-umbilical blood flow enters the right horn through a wide but short vessel, the *common hepatic vein*, which becomes the cranial end of the inferior vena cava. In addition to this the right horn receives the right common cardinal vein (from the right side of the body wall) and the body of the sinus, which conveys the blood from the left horn and left common cardinal vein. Later, when transverse connexions are established between the cardinal veins (**2**.88), the blood from the left body wall reaches the heart via the veins of the right side. The left common cardinal vein then becomes much reduced in size and forms the oblique vein of the left atrium and the fold of the left caval vein, while the left horn and the body persist as the *coronary sinus* (**2**.88).

The right horn of the sinus venosus opens into the right atrium through its dorsal and caudal walls. The orifice, elongated and often slit-like, is guarded by two muscular folds, the *right* and *left venous valves* (**2**.78A). These two valves meet at the cranial end of the orifice and become continuous with a fold which projects into the atrium from its roof, termed the *septum spurium*. At the caudal end of the orifice the two valves meet and fuse with the dorsal endocardial cushion of the atrial canal. The cranial part of the right venous valve disappears, but its position is indicated in the adult heart by the crista terminalis of the right atrium; its caudal part forms the valve of the coronary sinus and most of the valve of the inferior vena cava. The medial (or left) end of the valve of the inferior vena cava is formed by a small fold which projects from the dorsal wall of the sinus venosus, the *sinus septum*. In the embryo the sinus septum intervenes between the orifice of the common hepatic vein and the opening of the body of the sinus.

The left venous valve blends with the right side of the atrial septum and usually no trace of it can be seen in the adult heart.

As the venous valves undergo these changes the right horn of the sinus venosus becomes incorporated in the right atrium and forms its dorsal wall, medial to the crista terminalis. This part of the adult atrium is termed the *sinus venarum*.

THE RIGHT AND LEFT ATRIA

As already stated, the common atrium is derived from the cranial part of the sinuatrial chamber. It receives the opening of the sinus venosus in its dorsocaudal part and to the right of the median plane, while it communicates ventrally with the ventricle through the atrioventricular canal, which has resumed its median position by the middle of the fifth week and then permits both right and left atria to communicate with the common ventricular cavity. Swellings appear in the ventral and dorsal walls of the atrioventricular canal in the interval between the endothelial tube and the myo-epicardial mantle. These are termed the *atrioventricular endocardial cushions* and consist of a core of mesenchyme. They encroach on the canal and eventually fuse with each other, leaving a relatively small orifice on each side. The fused cushions constitute the *septum intermedium* (of His), and the two small orifices become the right and left atrioventricular openings.

The internal separation of the two atria is effected by the growth of two septa. The first to appear is the *septum primum*, and it grows from the dorsal and cranial wall as a sickle-shaped fold (**2**.78B, A), which is separated from the left venous valve by the *interseptovalvular space*. The ventral horn of the sickle reaches the ventral atrioventricular cushion, and the dorsal horn reaches the dorsal cushion. The terms ventral and dorsal refer to the positions of the cushions after the atrium has come to lie dorsal to the bulbus cordis. Actually the ventral cushion is ventrocranial and the dorsal cushion dorsocaudal in position, but the terms ventral and dorsal are in general use and will be retained in the subsequent description. Ventral and caudal to the advancing edge of the septum the two atria communicate through the *foramen primum* (**2**.78B, *A*). Free passage of blood from the right atrium to the left is essential throughout fetal life, as the oxygenated blood from the placenta reaches the heart via the inferior vena cava (p. 665); therefore, as the foramen primum becomes reduced in size, the dorsal part of the septum primum breaks down and a new communication, the *foramen secundum*, is formed between the two atria before the end of the fifth week. The foramen primum becomes occluded completely by the fusion of the edge of the septum primum with the fused atrioventricular cushions, in the median plane. The foramen secundum enlarges sufficiently to ensure the free passage of blood from the right atrium to the left (**2**.78B), and it persists throughout intrauterine life as the *foramen ovale*. At first this opening is situated in the cranial and dorsal portion of the septum primum but its position becomes modified until it is cranioventral. Towards the end of the second month the muscular wall of the atrium becomes invaginated to form a crescentic septum on the right side of the septum primum (**2**.78B, *B*, *C*). This is the *septum secundum*, and it involves more than the whole width of the interseptovalvular space, so that the dorsal attachments of the septum primum and the left venous valve are carried into the interior of the atrium on its left and right surfaces respectively.

The superior and inferior horns of the septum secundum at first grow ventrally; but the superior horn grows much more rapidly than the inferior and fuses first with the septum intermedium; it is then continued to form the *sinus septum* (*vide supra*). Thus the free edge of the septum secundum is at first directed caudoventrally and later caudally alone; it overlaps the foramen ovale (**2**.78B, *C*, *D*) so that the septum primum can act as a flap valve. Since the blood pressure is greater in the right atrium than it is in the left, the blood flows from right to left, but not in an opposite direction. After birth the intra-atrial pressures are equalized, and the free edge of the septum primum is therefore kept in contact with the left side of the septum secundum and fusion occurs. Not infrequently the fusion is incomplete, but the opening left is usually small and valvular and has no functional significance. The free margin of the septum secundum forms the *limbus fossae ovalis* and the septum primum the floor of the *fossa ovalis* of the adult heart. An alternative derivation of the septum secundum from a ridge developing to the right of the line of fusion between the confluent endocardial cushions and the septum primum has been advanced (Odgers 1934). The dorsal horn of the septum secundum is said to incorporate part of the left venous valve. Another view embodies the above suggestion, but regards the valve as of minor importance in this connexion, describing, however, another ridge—the *septum accessorium*, in the lower part of the dorsal border of the limbus (Christie 1963).

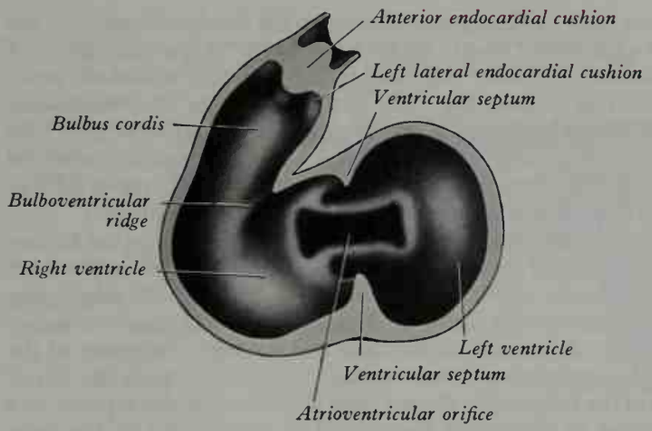
At an early stage in the development of the septum primum a

single, common pulmonary vein, of still unexplained origin, can be identified opening into the caudal part of the dorsal wall of the left atrium close to the septum. It is formed by the union of a right and a left pulmonary vein, and each of these is formed, in turn, by two small veins issuing from each developing lung bud. Subsequently the common trunk and the two veins forming it expand and are incorporated in the left atrium to form the greater part of its cavity. This expansion reaches as far as the orifices of the four veins, which thus open separately into the left atrium.

During the second month the two atria bulge ventrally one on each side of the bulbus cordis, which lies in a groove on their ventral surface (**2**.78A). These projecting parts of the atria form the auricles of the adult heart, while their dorsal regions expand to form the atria proper.

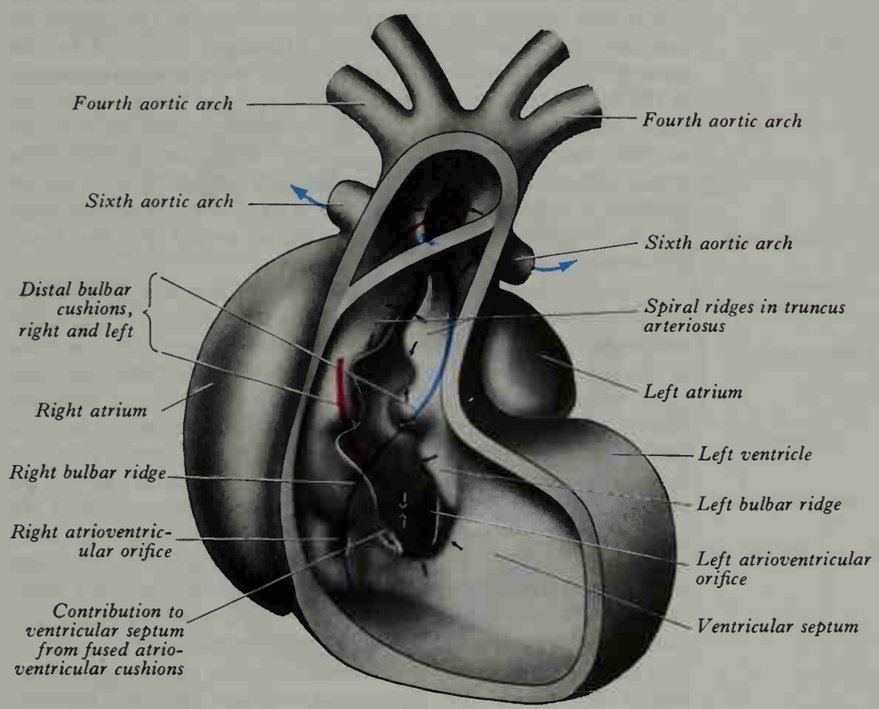
THE VENTRICLES BULBUS CORDIS AND THE TRUNCUS ARTERIOSUS

The process of separation of the ventricles is intimately related to that of the aortic and pulmonary orifices at the distal end of the bulbus, (**2**.79A) and to the division of the truncus arteriosus (p. 183) into pulmonary and aortic channels. These processes are so closely interdependent that the history of the truncus arteriosus will be dealt with in this section, although it takes no part in the formation of the heart itself, and both will be considered before the separation of the two ventricles is described.



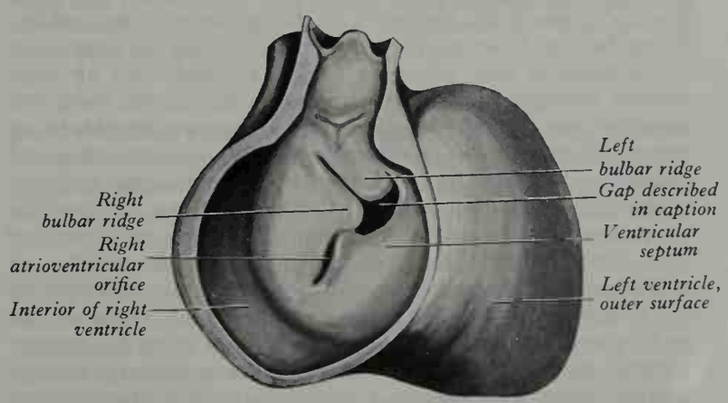
Four endocardial cushions—ventral, dorsal, right and left—form in the distal part of the bulbus, and the right and left cushions fuse to constitute the *distal bulbar septum*. This septum separates a ventral, pulmonary orifice from a dorsal, aortic orifice, and later the cushions become modified to form the *semilunar valves*.

The separation of the pulmonary trunk from the aorta is a more complicated process. Two ridge-like thickenings project into the interior of the truncus arteriosus. Proximally, the ridges project from the *lateral* walls of the vessel, but further away from the heart, the right ridge passes obliquely on to the *ventral* and then the *left* wall, while the left ridge, extends on to the *dorsal* wall and then the *right* wall (**2**.79B). The ridges are therefore spiral, and their fusion forms the *spiral aorticopulmonary septum*. At its proximal end this septum meets and fuses with the distal bulbar septum, and on account of its spiral character the pulmonary trunk, which lies ventral to the aorta at its orifice, curves round to its left side as it ascends, and finally lies dorsal to it (**2**.79B). At its distal end the aorticopulmonary septum meets the dorsal wall of the aortic sac (*see* p. 187) cranial to the point where it is joined by the sixth pair of aortic arches, and as a result these arches become branches of the pulmonary trunk, while the other aortic arches are left in communication with the aorta (**2**.79B).



The separation of the two ventricles from each other leaves the right ventricle in communication with the right atrium and with the pulmonary artery, and the left ventricle in communication with the left atrium and the aorta. This involves a series of complex changes in which three distinct factors contribute to the formation of the adult ventricular septum—(*a*) the *ventricular septum*, (*b*) the *proximal bulbar septum*, and (*c*) the *atrioventricular endocardial cushions*.

(*a*) During the fifth week the right and left definitive ventricles are indicated as slight projections on the external surface of the primitive common ventricle. It is uncertain whether the right ventricle is a derivative of the common ventricle, or of the caudal end of the primitive bulbus, or of both. In either event, the appearance of a crescentic ridge in the inside of the heart indicates the separation between the two ventricles and, as the heart enlarges, this ridge deepens to form the *ventricular septum*. The dorsal and ventral horns of the septum meet and fuse with the corresponding endocardial cushions of the atrioventricular canal near their *right* extremities (**2**. 79A). The septum has a free sickle-shaped margin, which bounds a circular *interventricular foramen* (**2**.79B).



At first the bulboventricular junction is marked by a distinct notch on the outside of the heart (**2**.79A), and on the inside of the heart there is a corresponding *bulboventricular ridge*. This ridge is between the atrioventricular orifice and the caudal part of the bulb

2.79A A diagram showing an early stage of the relations between the atrioventricular opening and ventricles, the cavity of the bulbus cordis, and the bulboventricular ridge. The endocardial cushions at the distal end of the bulb are shown in a more differentiated state than they really exhibit at this stage. (After J. E. Frazer.)

2.79B A diagram to show the mode of formation of the septa which separate the aortic and pulmonary channels in the embryonic heart. The red arrow indicates the aortic channel and the blue arrow the pulmonary. The small black arrows indicate the direction of growth. (From a model by James Whillis.)

2.79C A diagram to show the part played by the fusion of the right and left bulbar ridges in the separation of the aortic and pulmonary channels. The darkly shaded area indicates the gap filled by the proliferation of cushion tissue (from the right extremity of the fused atrioventricular cushions) which establishes continuity between the proximal bulbar septum and the ventricular septum. Compare with **2**.79B.

(2.79A) and its absorption is essential for the development of the four-chambered heart. As a result, partly of the absorption of the bulboventricular ridge and partly of the growth of the atrioventricular region, the right extremity of the atrioventricular canal comes to lie caudal to the orifice of the bulb (2.79B). This alteration in the relative positions of the structures concerned occurs while the ventricular septum is forming, and paves the way for the completion of the process of ventricular partition.

(*b*) The *proximal bulbar septum* separates the bulbus cordis into pulmonary and aortic channels, and is formed by the *right* and *left bulbar ridges*, which are in continuity with the corresponding bulbar endocardial cushions. The right bulbar ridge grows across on to the dorsal wall of the bulb and the right extremity of the fused atrioventricular endocardial cushions to reach the dorsal end of the free, sickle-shaped edge of the ventricular septum, and in doing so obliterates the ventral or cranial part of the right atrioventricular orifice (2.79B). The left bulbar ridge grows across on to the ventral wall of the bulb to reach the ventral or cranial end of the ventricular septum. Although the two bulbar ridges fuse with each other and so separate the conus arteriosus of the right ventricle from the aortic vestibule, the caudal edge of the septum so formed is separated from the free sickle-shaped edge of the ventricular septum by a gap through which the two ventricles continue to communicate (2.79C). This gap is closed by the growth of cushion tissue (Odgers 1938) from the right extremity of the fused atrioventricular cushions, and this fuses, on the one hand, with the caudal border of the proximal bulbar septum and on the other with the margin of the ventricular septum. The dorsal part of the bulb becomes absorbed almost entirely, but its position is indicated by the dorsal wall of the aortic vestibule, which, however, is formed to a large extent by the fused atrioventricular endocardial cushions.

(*c*) At the time of their fusion the *atrioventricular endocardial cushions* are very large relative to the size of the atrioventricular orifices. The atrial septum meets the atrial surface of the cushions at their centre, but the ventricular septum meets them near their right margins. It follows that a portion of the fused cushions intervenes between the *right* atrium and the *left* ventricle, and it is this part which forms the right wall of the aortic vestibule (*atrioventricular septum*, p. 643). The membranous part of the *interventricular septum*, which is continuous dorsally with the membranous *atrioventricular septum* in the completed heart (2.78C), is formed by proliferation of cushion tissue from the right extremity of the fused atrioventricular cushions, described above (2.78C). The persistence of a communication between the two ventricles may be due to arrested development in this region.

It should be observed that the craniodorsal part of the orifice, which lies above the ventricular septum (2.79B), becomes incorporated in the aortic vestibule and thereafter serves to connect the left ventricle with the aortic channel.

The valves of the heart are primarily derived from the endocardium.

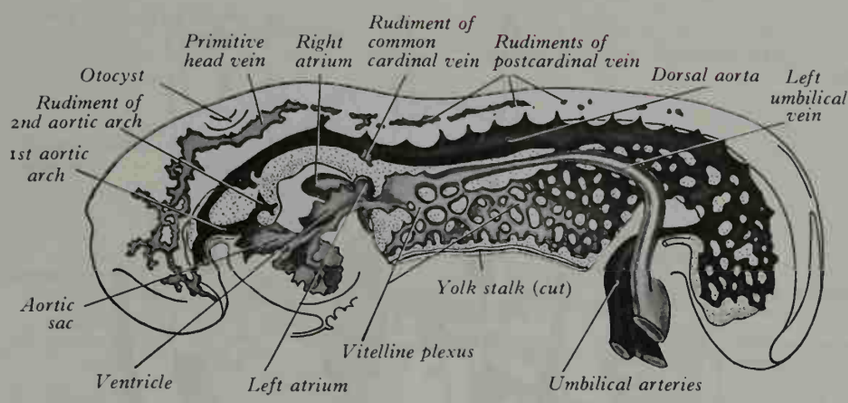
The *atrioventricular valves* develop as endothelial projections directed towards the ventricles at the atrioventricular orifices. From the first, however, they are connected with the ventricular musculature at their bases; as growth proceeds and the flaps become enlarged, these muscular trabeculae become freed and constitute the papillary muscles, their juxta-valvular ends being converted into the fibrous *chordae tendineae*. The *aortic* and *pulmonary valves* are formed from the four endocardial cushions which appear at the distal end of the bulbus cordis. The completion of the distal bulbar septum results in the division of each lateral cushion into two parts, so that the number of thickenings is increased to six, of which three are associated with the pulmonary orifice and three with the aortic. These are the rudiments of the aortic and pulmonary valves, while the pouches between the valves and the walls of the vessels gradually enlarge and form their related *sinuses*. Initially, one cusp of the pulmonary valve lies anteriorly and the other two posterolaterally, whereas one cusp of the aortic valve lies posteriorly and the other two anterolaterally. However, a rotation of the heart to the left before birth changes the orientation of the cusps of the pulmonary and aortic valves and this is reflected in the various schemes for the designation of these cusps in the mature heart (*see* p. 651).

The development of the chambers of the heart has now been traced to a stage at which the main features of the adult heart are established. It is to be noted that the pattern has developed in such a way as to provide for the sudden establishment of the pulmonary circulation at birth, although it is adapted to the persistence of the placental circulation for the remainder of fetal life. The presence of the ductus venosus ensures that the oxygenated blood gains the right atrium with the minimum loss of oxygen to the liver. It has been claimed that relatively little admixture of oxygenated and deoxygenated blood occurs in the *right* atrium (Barclay *et al.* 1939) and that nearly all the oxygenated blood passes through the foramen ovale into the left atrium, so gaining the *left* ventricle, aorta, and systemic circulation. However, there is evidence for the opposing view that there is considerable mixing of the superior and inferior vena caval streams in the right atrium (Born *et al.* 1954; Lind and Wegelius 1954). Because the transition from a placental to a pulmonary circulation occurs suddenly at birth, the right ventricle and the pulmonary trunk of the fetus are relatively large, although only a small amount of blood passes through the lungs. In fact most of the blood expelled by the right ventricle into the pulmonary trunk passes through the ductus arteriosus into the descending aorta, and in order that this can occur it must be under higher pressure than the blood in the aorta. On this account the muscular wall of the right ventricle is thicker than the wall of the left ventricle, a condition which persists throughout fetal life but is progressively reversed after birth. The origin of the carotid and subclavian arteries from the aorta above the point at which it is joined by the ductus arteriosus may be correlated with the relatively rapid growth of the brain, demanding a copious blood supply, and with the more advanced development of the upper limbs, relative to the lower, at birth.

In the early stages of development the arteries of the embryo are disproportionately large and their walls consist of little more than a single layer of endothelium. At this time the cardiac orifices are also relatively large and the force of the cardiac contraction is weak. As a result, despite the rapid rate of contraction, the circulation is sluggish, but this is compensated for by the fact that the tissues are able to draw nourishment, not only from the capillaries, but also from the large arteries. As the heart muscle strengthens, the cardiac orifices become both relatively and absolutely reduced in size, the large arteries acquire their muscular walls and they too undergo a relative reduction in size. From this time onwards the embryo is dependent for its nourishment on the expanding capillary beds and henceforth the larger arteries function merely as distribution channels to keep them constantly supplied.

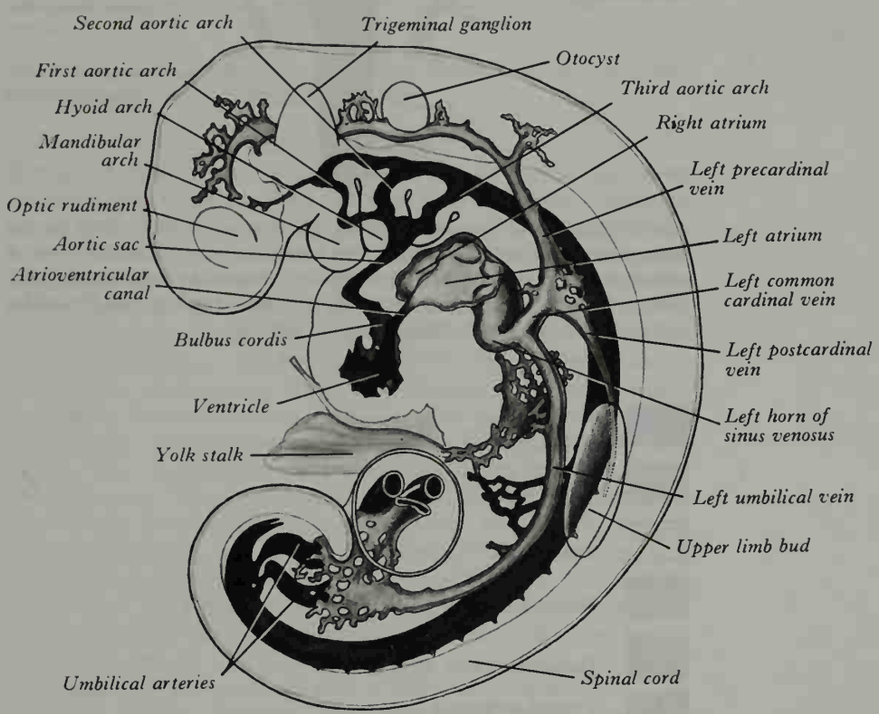
The conducting system of the heart is first identifiable towards the middle of the sixth week of embryonic life. Some investigators claim that the first part to appear is the *atrioventricular node* which develops as an outgrowth from the dorsal part of the muscular ring surrounding the atrioventricular canal. The *atrioventricular bundle* is an extension of this which passes distally behind the dorsal endocardial cushion to the free edge of the ventricular septum, where it gives rise first to the left and then to the right limbs of the bundle (Shaner 1929; Walls 1947). Others maintain that the stem of the atrioventricular bundle appears first as a derivative of the musculature of the dorsal wall of the atrioventricular canal. From this, differentiation spreads proximally to form the atrioventricular node and distally to form the right and left limbs of the bundle (Field 1951; Muir 1954). From its earliest appearance the whole complex is continuous with the muscular tissue of the atrium and ventricular wall, and this condition persists to adult life.

The *sinuatrial node* is the last part of the conducting system to appear, and its site is indicated by an aggregation of nerve cells and fibres in the wall of the superior vena cava just above its junction with the atrium, before nodal tissue itself can be recognized in the latter part of the third month. A narrow band of muscle in the ventrolateral surface of the superior vena cava is modified into the characteristic adult histological structure (p. 661). Although at first situated in the superior vena cava, in late fetal life it becomes incorporated into the atrial wall at the upper end of the sulcus terminalis. Its cranial edge, however, remains in continuity with the muscular coat of the vessel, although



elsewhere it is continuous with the muscular wall of the atrium. The node does not appear until the right horn of the sinus venosus has been incorporated in the right atrium. Sinuatrial nodal tissue appears at an earlier relative stage in some rodents, and recently a *left* sinuatrial node has been described in the murine embryo (Heintberger 1974) as a transient structure. The occurrence of such a bilateral symmetry has been hypothecated in mankind but never substantiated (Patten 1956).

A recent study of conducting tissue development in human embryos emphasizes the basic difficulty of identifying such tissue, particularly in its earlier stages of differentiation (Wenink 1976). The previous views, stated above, which derived elements of the conducting system from part of the muscular rings between successive chambers of the primitive heart tube, were largely confirmed. However, it was claimed that *all* the rings were so involved, and that after complex repositioning during folding of the heart tube, the entire system is derived from them.



The *intrinsic nerves* of the heart, consisting of groups of ganglion cells associated with the great arteries, atria, and atrioventricular grooves, together with a developing epicardial plexus, are observable from the 15 mm stage (Navaratnam 1965; Smith 1970). For a highly detailed description of the state of development of the *extrinsic nerves* of the heart in a human embryo of 8 weeks consult Smith (1971), and Gardner and O'Rahilly (1976).

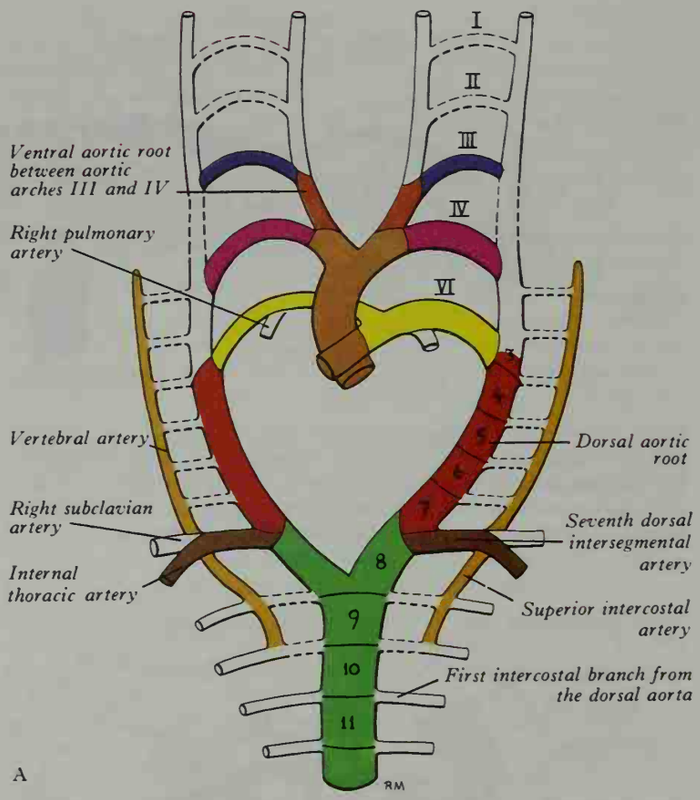
It will be noted that the heart commences to beat (p. 183) prior to the development of the conducting system, and that the circulation is established before a competent valvular mechanism has been laid down. The latter fact has been associated (Streeter 1945) with the incompressible but displaceable character of the cardiac jelly occupying the myoendocardial interval (p. 182).

A brief summary of the common congenital abnormalities of the heart will be found on p. 666.

2.80A The blood vascular system of a human embryo with 14 paired somites. Estimated age, 23½ days. C.R. length 2·4 mm. Magnification × *c.* 45. The arteries and veins are only in process of development, so that no true circulation is possible at this stage. Only the endothelial lining of the heart tube is shown. (G. L. Streeter, *Cont. Embryol.*, **30**, 1942.)

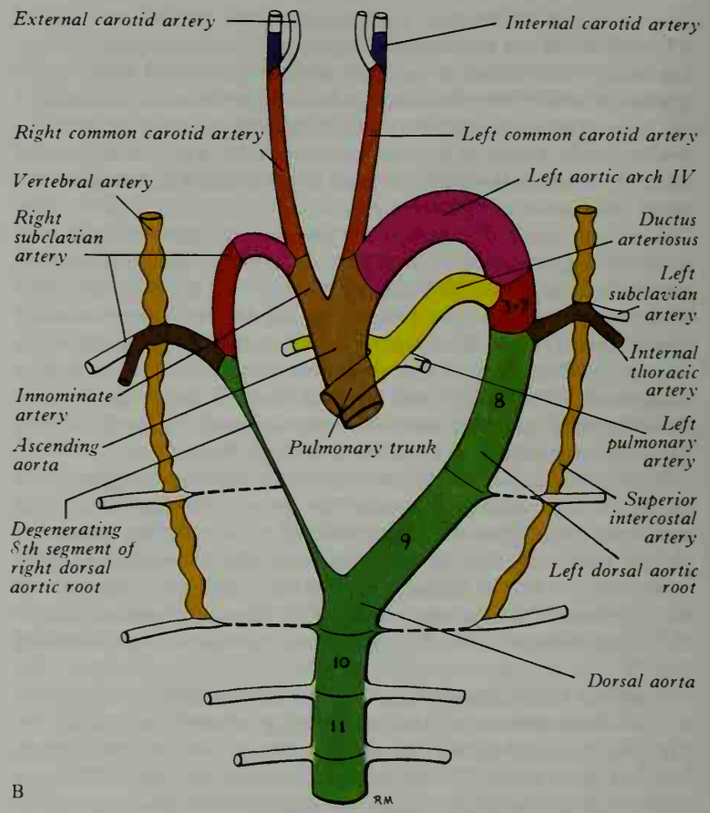
2.80B Profile reconstruction of the blood vascular system of a human embryo, having 28 somites. C.R. length, 4 mm. Estimated age, 26 days. *Note.* Only the endothelial lining of the heart chambers is shown and, as the muscular wall has been omitted, the pericardial cavity appears much larger than the contained heart. Observe that the atrioventricular canal still connects the left atrium with the single ventricle. (G. L. Streeter, *Contr. Embryol.*, **30**, 1942.)

FURTHER DEVELOPMENT OF THE ARTERIES



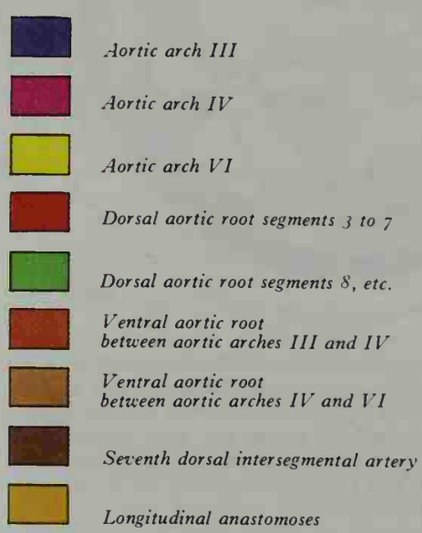
Apart from the aortae none of the main vessels of the adult arise as single trunks in the embryo. Along the course of each vessel a capillary network is first laid down, and by the selection and enlargement of definite paths in this network the larger arteries and veins are defined. The branches of the main arteries are not always simple modifications of the vessels of the capillary network, but may arise as new outgrowths from the enlarged stem.

As stated above, subsequent to the formation of the head fold each primitive aorta consists of ventral and dorsal parts which are continuous through the first aortic arch. The dorsal aortae run caudally, one on each side of the notochord, but in the fourth week they fuse from about the level of the fourth thoracic to that of the fourth lumbar segment to form a single *descending* aorta. Although in many animals paired ventral aortae arise from the truncus arteriosus and course headwards on the ventral surface of the pharynx, in the human embryo the ventral aortae are fused and form a dilated *aortic sac* (*see* **2**.80A and consult Congdon 1922). The first aortic arches run through the mandibular arches, and caudal to them five additional pairs are developed within the corresponding branchial arches; so that, in all, six pairs of aortic arches are formed (**2**.81A). The fifth arches are atypical and probably transient, at most, in man.

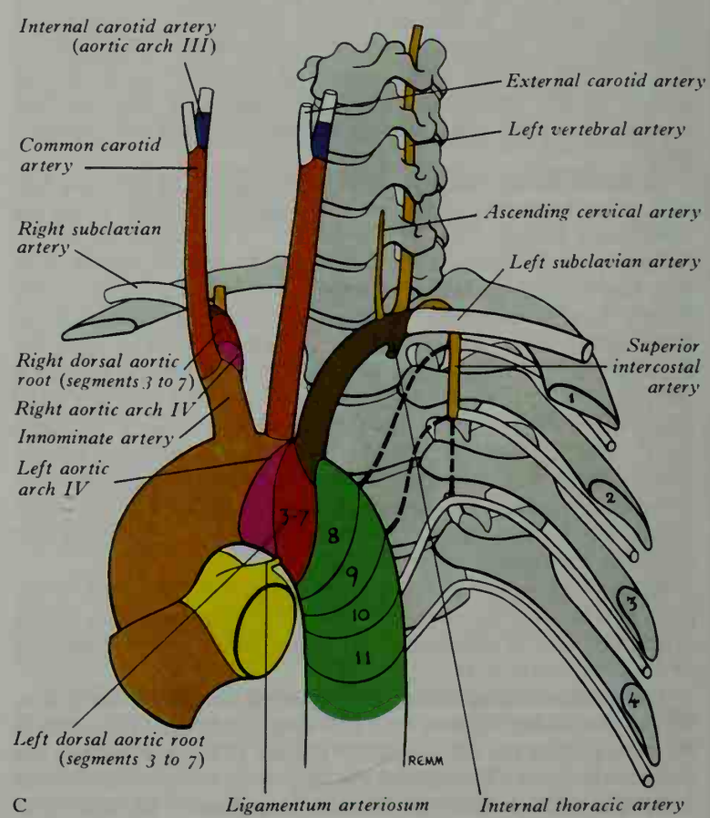


In fishes the aortic arches persist and give off branches to the gills, in which the blood is oxygenated. In mammals some of the arteries remain as permanent structures, while others disappear or are obliterated (**2**.81A–C).

The aortic sac represents fused, paired ventral aortae (**2**.80A, B). As the embryo grows and the aorticopulmonary septum is formed, part of the caudal end of the sac is incorporated in the pulmonary trunk. The cranial end of the sac becomes drawn out into *right* and *left limbs* as the neck lengthens. The right limb becomes the brachiocephalic trunk and the left limb forms that part of the arch of the aorta which lies between the origin of the brachiocephalic trunk and the left common carotid artery. The remainder of the sac contributes to the formation of the arch of the aorta.



The aortic arches (**2**.81A–C), with the exception of the fifth, are developed in a craniocaudal sequence, but the more cranial are in process of disappearing before the caudal ones are completed. The *first* and *second aortic arches* are already dwindling by the time the third is established. The first disappears entirely. The dorsal end of the second arch or *hyoid* artery remains as the stem of the *stapedial artery*, while the remainder of this arch artery also disappears (**2**.82). The external carotid artery first appears as a sprout which grows headward from the aortic sac close to the ventral end of the third arch artery. The common carotid arises from an elongation of the adjacent part of the aortic sac, and the third arch artery becomes the proximal part of the internal carotid artery. (Evidence against this view, however, has also been recorded: *see*, for example. Moffat 1959; Adams 1957.) The *fourth aortic arch* on the right side forms the proximal part of the right subclavian artery, whilst the corresponding vessel on the left side is believed to constitute the arch of the aorta between the origins of the left common carotid and left subclavian arteries. It is

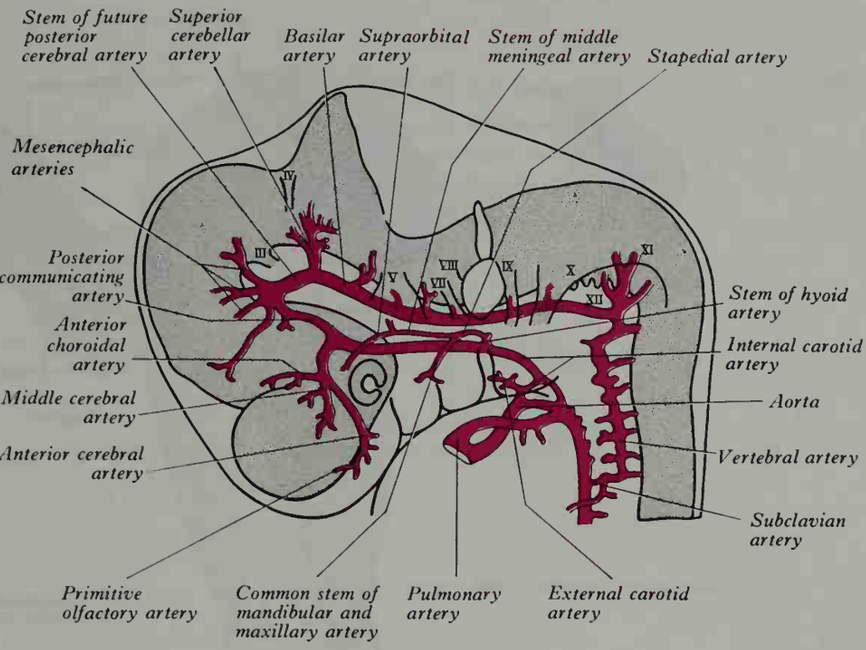


2.81A Schematic diagram showing the various components of the embryonic aortic arch complex in the human embryo. Structures which do not persist in normal development are indicated by interrupted lines. Roman numerals refer to the branchial arches concerned, and the arabic numerals indicate the metameric body segments.

2.81B A diagrammatic ventral view of the aortic arch complex of a human embryo of 15 mm crown-rump length. Note the asymmetry in the pattern that has developed by this stage Compare with 2.81A and C.

2.81C A diagram of the adult human aorta and its branches viewed from the left ventrolateral aspect, showing the position and relative sizes of the definitive contributions from the various embryonic components shown in 2.81A and B.

(2.81A–C are based on the work of A. Barry, with the kind permission of the author and the *Anatomical Record*, **111**, 1951.)

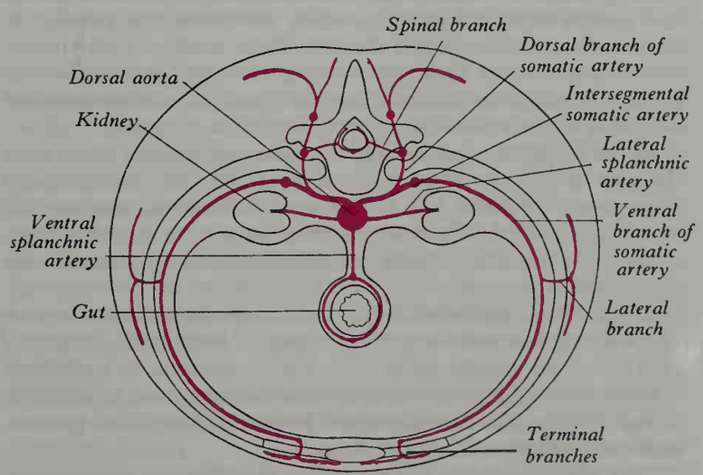


difficult to assess accurately the contributions of the *fourth aortic arches* and it has been variously claimed that the left fourth aortic arch is subsequently drawn into the descending or ascending limbs of the *definitive aortic arch* and that the corresponding vessel on the right contributes to the formation of the brachiocephalic artery. The identity and status of the *fifth aortic arch* is uncertain; it is incomplete and usually connects the fourth aortic arch or subjacent aortic sac with the dorsal end of the sixth aortic arch, whereas the other aortic arches pass between the aortic sac and dorsal aorta. The fifth aortic arch eventually disappears on both sides. From its inception the *sixth aortic arch* is associated with the developing lung buds. These are at first supplied by a capillary plexus from the aortic sac. Later this plexus becomes connected to the dorsal aorta, and the sixth aortic arch is constituted from the resulting vascular connexion between the aortic sac and the dorsal aorta, and continues to supply the developing lung buds. When the *truncus arteriosus* becomes

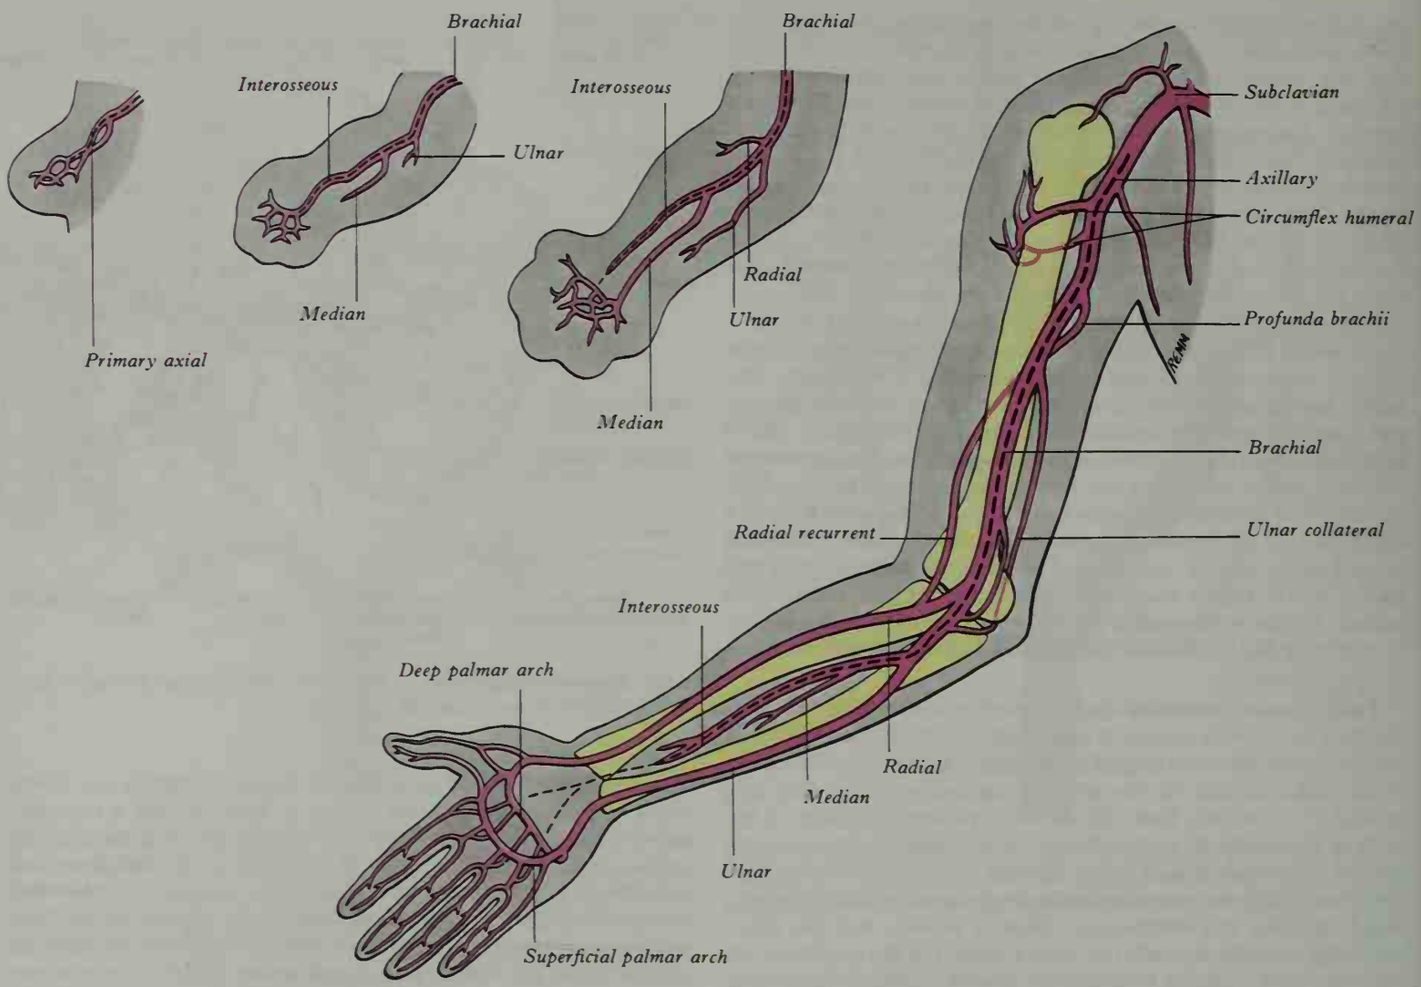
divided into the pulmonary trunk and ascending aorta the sixth aortic arches remain continuous with the former. On the right side the ventral part of the sixth aortic arch persists as the proximal part of the right pulmonary artery, but its dorsal portion disappears, possibly due to a decreased blood flow resulting from the partitioning of the aortic and pulmonary bloodstreams (Navaratnam 1963). On the left side the ventral part of the sixth aortic arch is absorbed into the pulmonary trunk, while its dorsal portion persists as the *ductus arteriosus*, which functions during intrauterine life but becomes obliterated after birth and forms the fibrous *ligamentum arteriosum* (p. 665).

The transformation of the aortic arches described above is conditioned by environmental changes, and results largely from changes in the pharynx and from the descent of the heart. The whole period of transformation can be divided into two phases, the branchial and postbranchial. In the *branchial phase*, which lasts until about the 12 mm C.R. length stage, the arrangement of the aortic arches resembles that in lower vertebrates. In this phase the course of the blood from the heart to the dorsal aorta follows a succession of different pathways—first aortic arch, first and second aortic arches, second and third aortic arches, third and fourth aortic arches and finally third, fourth and sixth aortic arches. In the *postbranchial phase*, which extends onwards into intrauterine life the human pattern and disposition of the vessels is established.

The cranial arteries (**2**.82) develop as follows (Padgett 1948). The *internal carotid artery* is formed from the third arch artery, the dorsal aorta cranial to this and a forward continuation which differentiates, at the time of regression of the first and second aortic arches, from the capillary plexus extending to the walls of the forebrain and midbrain. At its anterior extremity the *primitive internal carotid artery* divides into cranial and caudal divisions, the former terminating as the *primitive olfactory artery*, which supplies the developing olfactory region, and the latter sweeping caudally to reach the ventral aspect of the midbrain. At the same time bilateral longitudinal channels differentiate along the ventral surface of the hindbrain from a plexus which is fed by intersegmental and transitory presegmental branches of the dorsal aorta and its forward continuation. The most important of the presegmental branches is closely related to the fifth nerve and is known as the *primitive trigeminal artery*. Otic and hypoglossal presegmental arteries also occur (Padgett 1948). Persistence of the latter has been surveyed by Nakayama *et al.* (1970). The longitudinal channels later connect, cranially, with the caudal divisions of the internal carotid arteries, each of which gives rise to an *anterior choroidal artery* and supplies branches to the diencephalon and the midbrain, and caudally with the vertebral arteries through the first cervical intersegmental arteries. Fusion of the longitudinal channels results in the formation of the *basilar artery*, whilst the caudal division of the internal carotid artery becomes the *posterior communicating artery* and the stem of the *posterior cerebral artery*. The remainder of the last-named vessel develops at a comparatively late stage, probably from the stem of the posterior choroidal artery which is annexed by the caudally expanding cerebral hemisphere, its distal portion becoming a choroidal branch of the posterior cerebral artery. In the rat, where the vascular pattern is essentially similar to that in man, this artery is derived from the posterior communicating artery, the common stem of origin of the posterior choroidal, mesencephalic and diencephalic arteries, together with a new channel formed in the plexus on the medial wall of the cerebral hemisphere initially supplied by the anterior choroidal artery (Moffat 1961a). The cranial division of the internal carotid artery gives rise to the *anterior choroidal*, *middle cerebral* and *anterior cerebral arteries*, the stem of the primitive olfactory artery remaining as a small medial striate branch of the anterior cerebral artery. In the rat the primitive olfactory artery and its recurrent branch form the anterior cerebral artery, the territory of which is initially supplied by the primitive maxillary and the cranial ramus of the internal carotid arteries (Moffat 1961b). The *cerebellar arteries*, of which the superior is the first to differentiate, emerge from the capillary plexus on the wall of the rhombencephalon.



The source of the blood supply to the territory of the fifth cranial nerve varies at different stages in development. When the



2.82 Diagram to show the origins of the main cranial arteries. (After D. H. Padgett, *Contr. Embryol.*, **32**, 1948.)

first and second aortic arch arteries begin to regress the blood supply to the corresponding arches is derived from a transient vessel termed the *ventral pharyngeal artery*, which grows into the region from the aortic sac. It terminates by dividing into *mandibular* and *maxillary branches*. Later a vessel, the *stapedial artery*, develops from the dorsal stem of the second arch artery, and passes through the ring of the stapes to anastomose with the cranial end of the ventral pharyngeal artery and thereby to annex its terminal distribution. The fully developed stapedial artery possesses three branches, the *mandibular*, *maxillary* and *supraorbital*, which follow the divisions of the fifth cranial nerve (**2**.82). The mandibular and maxillary branches arise by a common stem. When the external carotid artery emerges from the base of the third arch it incorporates the stem of the ventral pharyngeal artery, and its maxillary branch communicates with the common trunk of origin of the maxillary and mandibular branches of the stapedial artery and annexes these vessels. The proximal part of the common trunk forms the stem of the *middle meningeal artery*. More distally the meningeal artery is represented by the proximal part of the supraorbital artery. The maxillary artery becomes the infraorbital vessel and the mandibular branch forms the inferior alveolar artery.

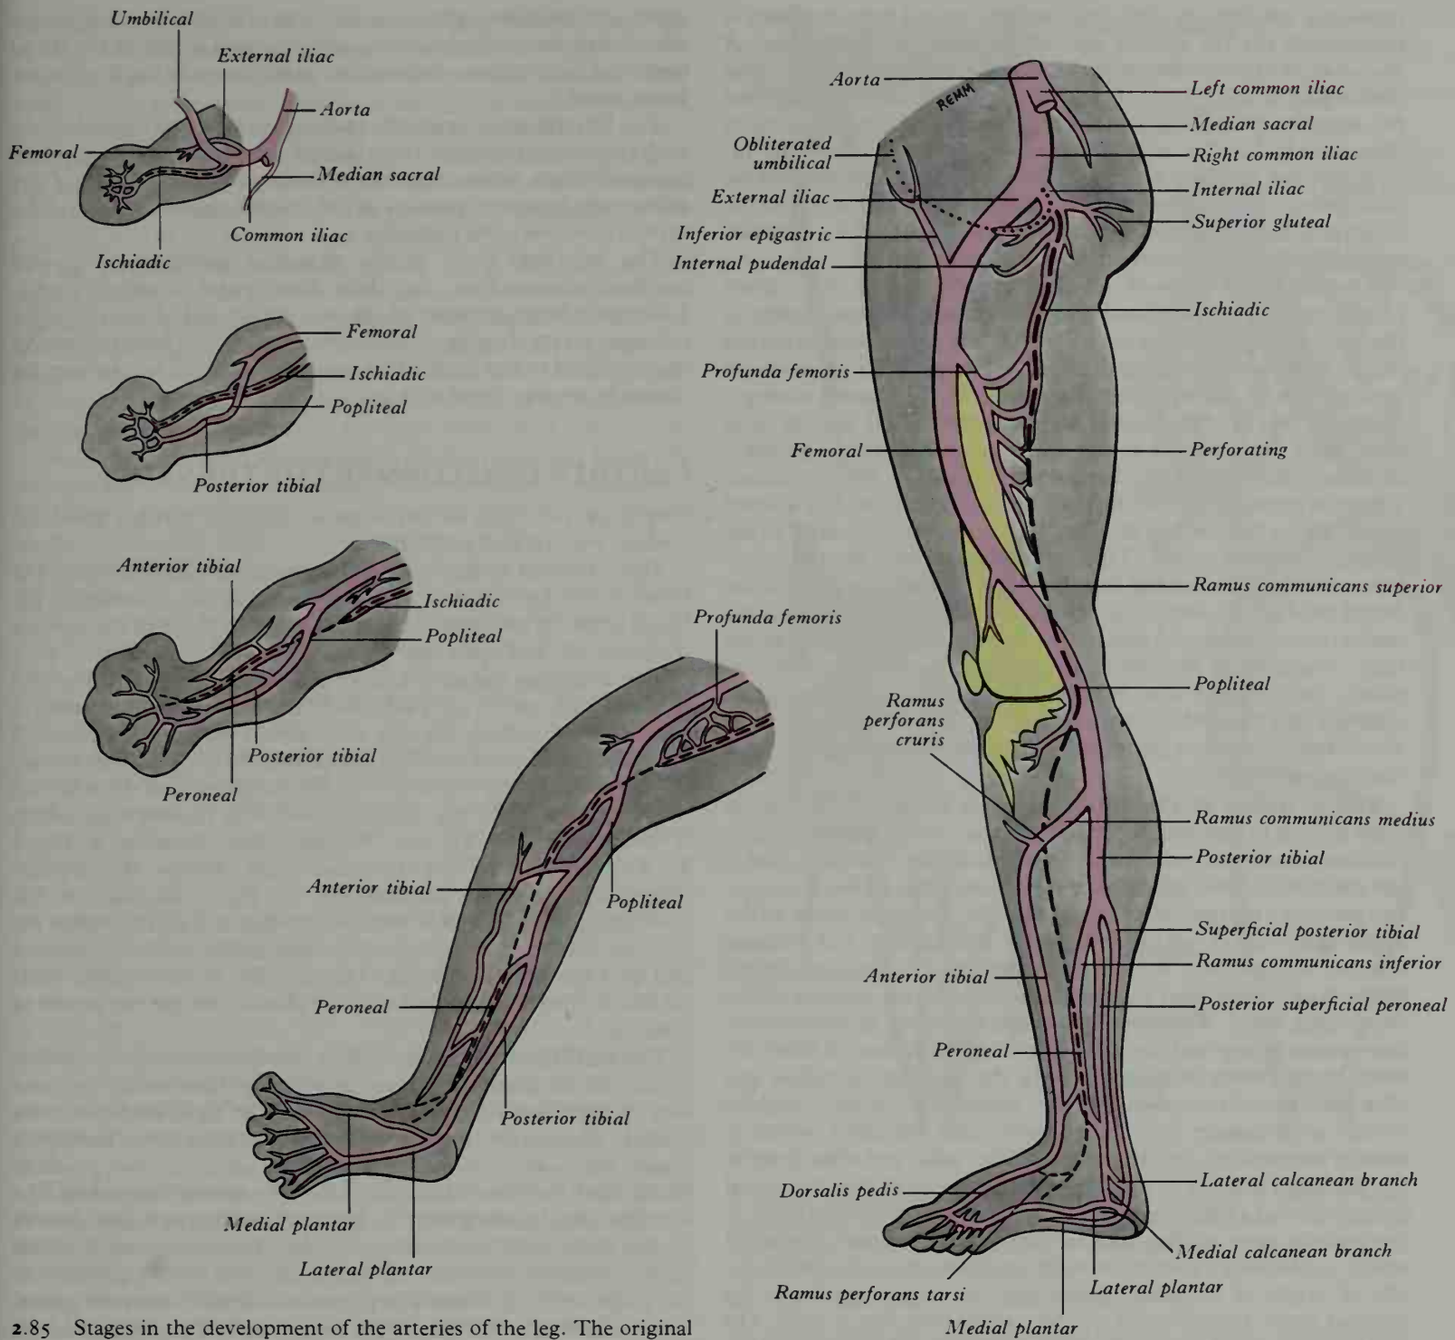
When the definitive *ophthalmic artery* differentiates as a branch of the terminal part of the internal carotid artery, it communicates with the supraorbital branch of the stapedial artery, the distal

2.83 Diagram of the segmental and intersegmental arteries. Note the positions of the longitudinal anastomoses.

2.84 Stages in the development of the arteries of the arm. The original path of the axis artery is indicated by an interrupted line (After Patten.)

part of which becomes the *lacrimal artery*. This retains an anastomotic connexion with the middle meningeal artery. The dorsal stem of the original second arch artery remains as a *caroticotympanic branch* of the internal carotid artery.

The dorsal aortae (2.81A–C) persist on the cranial side of the third aortic arches and form the continuations of the internal carotid arteries. The part of the dorsal aorta between the third and fourth aortic arches is known as the *ductus caroticus* and it disappears; but from the fourth arch to the point of origin of the seventh intersegmental artery the dorsal aorta becomes part of the right subclavian artery (2.81A–C). Caudal to the seventh intersegmental artery the right dorsal aorta disappears as far as the point where the two dorsal aortae fuse to form the descending thoracic aorta. The part of the left dorsal aorta between the third and fourth arches disappears, while the remainder persists to form the descending part of the arch of the aorta. A constriction, the *aortic isthmus*, is sometimes seen in the aorta between the final site of origin of the left subclavian artery and the attachment of the ductus arteriosus (*see coarctation* of the aorta, p. 710).



In the adult, the right subclavian artery sometimes arises from the arch of the aorta distal to the origin of the left subclavian and then passes upwards and to the right behind the trachea and oesophagus. This condition may be explained by the persistence of the right dorsal aorta and the obliteration of the fourth aortic arch of the right side.

In birds the right fourth aortic arch is transformed into the arch of the aorta; in reptiles the fourth arches of both sides persist and give rise to the double aortic arch of these animals. In both these classes, development of the heart and aortic arches is probably along phylogenetic lines divergent from the mammalian pattern, and comparisons are inappropriate.

The heart originally lies ventral to the pharynx, immediately caudal to the stomatodeum (2.80A); with the elongation of the neck and the development of the lungs it recedes within the thorax, and, as a consequence, the vessels are drawn out, and the original position of the fourth and sixth aortic arches is greatly modified. Thus, on the right side the fourth aortic arch recedes to the thoracic inlet, while on the left side it descends into the thorax. The recurrent laryngeal nerves originally pass to the larynx caudal to the sixth pair of aortic arches, and are therefore affected by the descent of these structures, so that in the adult the left nerve hooks round the ligamentum arteriosum within the thorax; owing to the disappearance of the fifth and the dorsal part of the sixth aortic arch on the right side, the right recurrent laryngeal nerve hooks round the fourth aortic arch, i.e. the commencement of the right subclavian artery.

At first the aortae are the only longitudinal vessels present, for their branches all run at right angles to the long axis of the embryo. Later these transverse arteries become connected in certain situations by longitudinal anastomosing channels, which in part persist, forming such arteries as the internal thoracic, the inferior epigastric, the gastro-epiploic, etc. Each dorsal aorta gives off *segmental* branches to the digestive tube (*ventral splanchnic arteries*) and to the mesonephric ridge (*lateral splanchnic arteries*), and *intersegmental* branches to the body wall (*somatic arteries*).

The ventral splanchnic arteries are originally paired vessels which are distributed to the wall of the yolk sac, but after fusion of the dorsal aortae they appear as unpaired trunks and are distributed to the primitive digestive tube. Longitudinal anastomotic channels connect these branches along the dorsal and ventral aspects of the tube, forming dorsal and ventral splanchnic anastomoses (2.83) (Ennabli and Niveiro 1967). These longitudinal vessels obviate the need for so many 'subdiaphragmatic' ventral splanchnic arteries, and these are reduced to three— the coeliac trunk and superior and inferior mesenteric arteries. As the viscera supplied descend into the abdomen their origins migrate caudally, by differential growth; thus the origin of the

2.85 Stages in the development of the arteries of the leg. The original path of the axis is indicated by a dashed line. (After Senior.)

coelic artery is transferred from the level of the seventh cervical segment to the level of the twelfth thoracic, the superior mesenteric from the second thoracic to the first lumbar, and the inferior mesenteric from the twelfth thoracic to the third lumbar. (Above the diaphragm, however, a variable number of ventral splanchnic arteries persist, usually four or five, supplying the thoracic oesophagus.) The dorsal splanchnic anastomosis persists in the gastro-epiploic, pancreaticoduodenal, and the primary branches of the colic arteries, while the ventral splanchnic anastomosis forms the right and left gastric and the hepatic arteries. These arterial rearrangements have been investigated recently by angiography, and explanatory haemodynamic hypotheses have been advanced (Barth *et al.* 1975).

The lateral splanchnic arteries supply, on each side, the mesonephros, the testis or ovary, and the suprarenal gland; all these structures develop, in whole or in part, from the mesoderm of the mesonephric ridge (p. 213). One testicular or ovarian artery and three suprarenal arteries persist on each side. The phrenic artery branches from the most cranial suprarenal artery, and the renal artery arises from the most caudal. Additional renal arteries are frequently present and may be looked on as branches of persistent lateral splanchnic arteries.

The somatic arteries are intersegmental in position, and they persist, almost unchanged, in the thoracic and lumbar regions, as the posterior intercostal, subcostal and lumbar arteries. Each gives off a dorsal ramus which passes backwards in the intersegmental interval and divides into medial and lateral branches to supply the muscles and superficial tissues of the back (**2**.83). It also gives off a spinal branch, which enters the vertebral canal and divides into a series of branches to the walls of the osteoligamentous canal and neural branches to the spinal cord. Having produced its dorsal branch the intersegmental artery runs ventrally in the body wall, gives off a lateral branch and terminates in muscular and cutaneous rami. Before their division, the stems of the somatic arteries, at thoracic and lumbar levels, provide small rami which enter the developing vertebral bodies. For a study of these vessels in human fetuses consult Somogyi (1962).

Numerous longitudinal anastomoses link up the intersegmental arteries and their branches with one another (**2**.83). On both sides there develops a *postcostal anastomosis* which connects their dorsal branches in the intervals between the necks of the ribs and the vertebral transverse processes. This persists in the cervical region where it forms the greater part of the vertebral artery. A *post-*

transverse anastomosis also connects the dorsal branches and is responsible for the greater part of the deep cervical artery. A *precostal anastomosis* connects the intersegmental arteries beyond the origins of their dorsal branches. The ascending cervical and the superior intercostal arteries represent persistent portions of this vessel. Lastly, near the anterior median line the intersegmental arteries become linked up by a *ventral somatic anastomosis*. This bilateral vessel persists to a large extent in the adult and is represented by the internal thoracic, the superior epigastric and the inferior epigastric arteries.

The *umbilical arteries* at first appear to be the direct continuation of the primitive dorsal aortae and they are present in the body stalk before any vitelline (yolk sac) or visceral branches can be seen—an indication of the importance of the chorionic as compared with the vitelline circulation in the human embryo. After the fusion of the dorsal aortae the umbilical arteries arise from their ventrolateral aspect and pass medial to the primary excretory duct (Wolffian duct) on their way to the umbilicus. Later the proximal part of the umbilical artery is joined by a vessel which leaves the aorta at its termination and passes lateral to the primary excretory duct. This new vessel, which possibly may represent the fifth lumbar intersegmental artery, constitutes the dorsal root of the umbilical artery, the original stem being the ventral root. The dorsal root gives off the axial artery of the lower limb, branches to the pelvic viscera, and, at a more proximal point, the external iliac artery. The ventral root disappears entirely, and the umbilical artery now arises from that part of its dorsal root which lies distal to the external iliac artery, i.e. from the internal iliac artery.

The arteries of the limbs arise as a number of vessels contributing to a primitive capillary plexus, but in the upper limb bud, eventually only one trunk—the subclavian—persists, and it has the position and relations of the *seventh intersegmental artery* and probably represents its lateral branch. The main trunk to the upper limb (**2**.84), which later forms the *axillary* and *brachial arteries*, is continued into the forearm deep to the developing flexor muscle mass and terminates in a plexiform manner in the developing hand. This vessel ultimately persists as the *anterior interosseous artery* and the deep palmar arch. A branch from the main trunk passes dorsally between the developing radius and ulna and constitutes the *posterior interosseous artery*, while a second accompanies the median nerve into the hand, where it ends in a superficial capillary plexus. The *radial* and *ulnar arteries* are the latest arteries to appear in the forearm; at first the radial artery arises at a higher level than the ulnar and crosses in front of the median nerve, giving branches to the biceps. Later, the radial artery establishes a connexion with the main trunk at or near the site of origin of the ulnar artery and the upper portion of its original stem disappears to a large extent (see also p. 703). On reaching the hand the ulnar artery becomes linked up with the superficial palmar plexus, from which the superficial palmar arch is derived, while the median artery loses its distal connexions and becomes reduced to a very small vessel. The radial artery passes to the dorsal surface of the hand but, after giving off dorsal digital branches, it traverses the first intermetacarpal space and links up with the deep palmar arch.

The primary arterial trunk (**2**.85) or *axis artery* of the lower limb arises from the dorsal root of the umbilical artery, and courses along the *dorsal* surface of the thigh, knee and leg; below the knee it lies between the tibia and the popliteus and in the leg between the crural interosseous membrane and the tibialis posterior. It ends distally in a plantar network, and gives off a perforating artery which traverses the sinus tarsi and forms a dorsal network. The *femoral artery* passes along the ventral surface of the thigh, and opens up a new channel to the lower limb. It arises from a capillary plexus, connected proximally with the femoral branches of the external iliac artery and distally with the axis artery. At the proximal margin of the popliteus the axis artery gives off a *primitive posterior tibial* and a *primitive peroneal branch*, which run distally on the dorsal surface of that muscle and on the tibialis posterior to gain the sole of the foot. At the distal border of the popliteus the axis artery gives off a *perforating branch*, which passes ventrally between the tibia and the fibula and then runs downwards to the dorsum of the foot, forming the *anterior tibial artery* and the *arteria dorsalis pedis*. The primitive peroneal artery establishes one communication with the axis artery at the distal border of the popliteus and another in its course in the leg (Senior 1919, 1920).

The femoral artery gradually increases in size, and coincidentally with this increase almost the whole of the axis artery disappears; proximal to its communication with the femoral the root of the axis artery, however, persists as the *inferior gluteal artery* and the *arteria comitans nervi ischiadici*.

The proximal parts of the primitive posterior tibial and peroneal arteries fuse, but their distal parts remain separate. Ultimately large portions of the axis artery and of the primitive peroneal artery disappear, although a part of the former vessel is incorporated in the permanent peroneal artery. The changes are shown in greater detail in **2**.85.

FURTHER DEVELOPMENT OF THE VEINS

The principal veins of the embryo may be divided into two groups, visceral and parietal.

The visceral veins include two *vitelline veins* bringing the blood from the yolk sac, and two *umbilical veins* returning the blood from the placenta; these four veins run through the septum transversum, and open into the sinus venosus.

The vitelline veins (**2**.86A–C) ascend, at first anterior to and subsequently one on each side of the digestive tube. A transverse anastomosis connects the two veins across the ventral surface of the tube, and beyond this they are connected to each other by two further anastomotic channels, one on the dorsal and the other on the ventral surface of the duodenal portion of the intestine, which is thus encircled by two venous rings forming a figure 8. The lengths of the vitelline veins within the septum transversum become surrounded by the trabeculae of the developing liver. The *liver sinusoids* develop as a plexus within the septum transversum and communicate freely with the vitelline and later the umbilical veins. The sections of the vitelline veins within the liver eventually lose their identity within the plexus of sinusoids.

The umbilical veins, ascending cranially from the umbilicus in the somatopleure, traverse the septum transversum on their way to the sinus venosus. After a time the right umbilical vein entirely disappears, but the left, which retains for a period its direct connexion with the left horn of the sinus venosus, pours its blood into the liver sinusoids and so communicates with the vitelline circulation (**2**.86B). In association with the establishment of the pulmonary circulation, venous channels develop which convey the blood from the left side of the liver to the right horn of the sinus venosus, where a large *common hepatic vein* now opens. The sinusoidal condition of the liver becomes condensed into a series of afferent vessels (*venae advehentes*) and a series of efferent vessels (*venae revehentes*) now leading to the common hepatic vein. In the process an oblique channel is differentiated from the liver sinusoids and conveys most of the blood brought by the umbilical vein direct to the common hepatic vein. This is the *ductus venosus* (**2**.86C) and it plays an essential part in the fetal circulation.

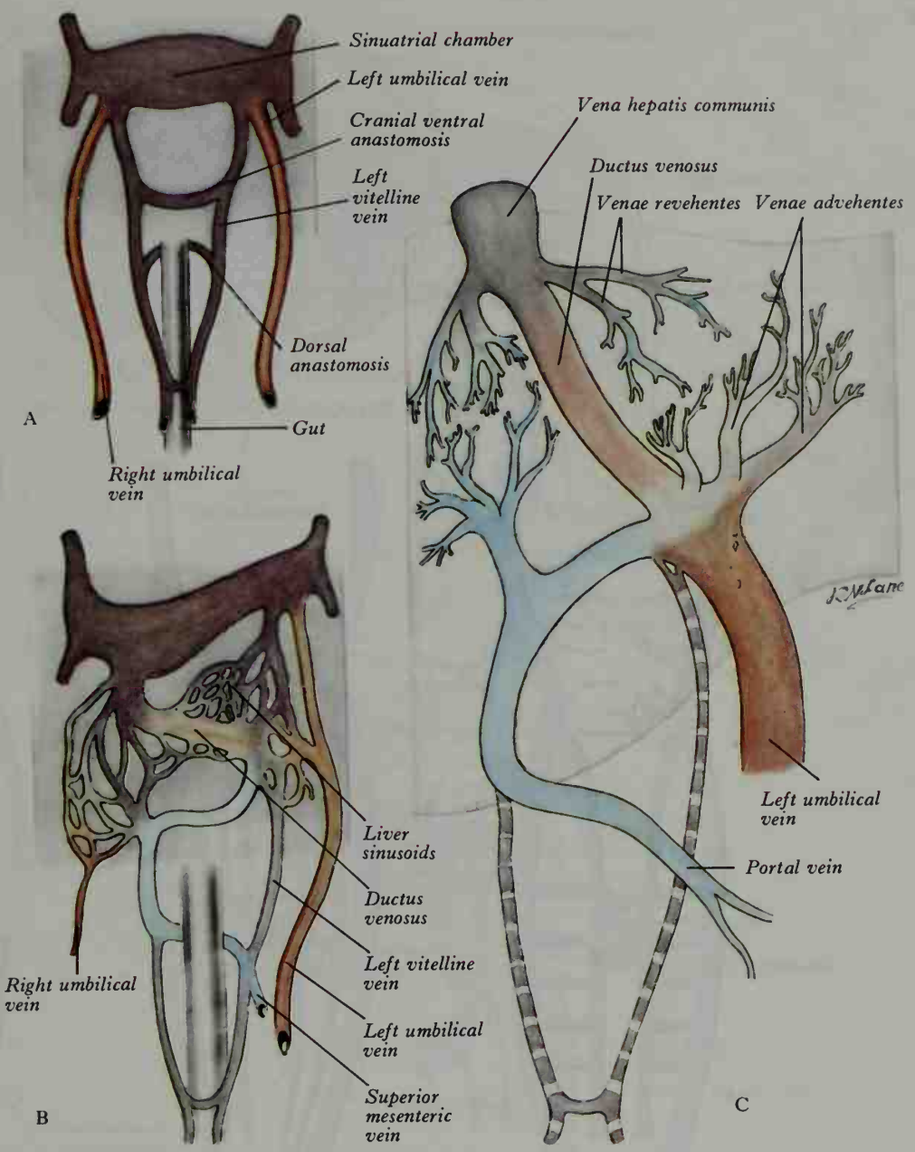
The superior mesenteric vein joins the left vitelline near the left extremity of the dorsal anastomosis. Later it is joined by the *splenic vein*, and the *portal vein* is thus established. The vitelline veins partly disappear (**2**.86C) and the portal vein is continued through the dorsal anastomosis and the cranial part of the right vitelline vein to the liver. The intrahepatic part of the right vitelline vein becomes the right branch of the portal vein, while the cranial ventral anastomosis and the intrahepatic part of the left vitelline vein form its left branch. The left umbilical vein joins the left branch of the portal vein, to which the ductus venosus is also connected. Some of the blood conveyed to the liver by the umbilical vein passes through the left venae advehentes, but the great majority of it finds its way through the ductus venosus to the *common hepatic vein* (which later forms the upper end of the inferior vena cava) and so to the right horn of the sinus venosus.

An alternative analysis (Dickson 1957) has shown that certain of the foregoing details require some modification. The ductus

venosus is primarily a *median* channel linking the most proximal of the anastomoses, the *subhepatic anastomosis* between the vitelline veins, with a further anastomosis which connects these vessels in the cranial part of the liver, termed the *subdiaphragmatic anastomosis*. The left half of the subhepatic anastomosis is later incorporated in the left umbilical vein whilst the subdiaphragmatic anastomosis contributes to the formation of the left hepatic veins and the common hepatic vein, prior to the appearance of the prerenal part of the inferior vena cava (p. 195).

The parietal or somatic veins (**2**.87, 88) are at first represented by two large vessels on each side, the *precardinal* and *postcardinal veins*; the former drain the rostral part of the embryo, and the latter the caudal part. The two veins on each side unite to form a short vessel, the *common cardinal vein*, which passes ventrally, lateral to the pleuropericardial canal (p. 209), to open into the corresponding horn of the sinus venosus (**2**.80B).

Owing to the rapid development of the head and brain the precardinal veins become enlarged. They are further augmented by the *subclavian* veins from the upper limb buds, and so come to be the chief tributaries of the common cardinal veins; these gradually assume an almost vertical position in association with the descent of the heart into the thorax. The right and left common cardinal veins are originally of the same diameter. By the development of a transverse connexion, the *left brachiocephalic vein*, between the two precardinal veins, the blood is carried across from the left to the right precardinal (**2**.88). The part of the right precardinal vein between the left brachiocephalic and azygos veins forms the upper part of the superior vena cava; the caudal part of the latter vessel (below the entrance of the azygos vein) is formed by the right common cardinal. Caudal to the branching of the left brachiocephalic vein the left precardinal and left common cardinal veins atrophy, the former constituting the terminal part of the left superior intercostal vein, while the latter is represented by the ligament of the left vena cava and the oblique vein of the left atrium (**2**.88). The remainder of the left superior intercostal vein is developed from the cranial end of the postcardinal vein and drains the second, third and, frequently, the fourth intercostal veins. The oblique vein passes downwards across the back of the left atrium to open into the coronary sinus, which, as already indicated, represents the persistent left horn of the sinus venosus. Right and left superior venae cavae are present in some animals, and occasionally persist in the human body.



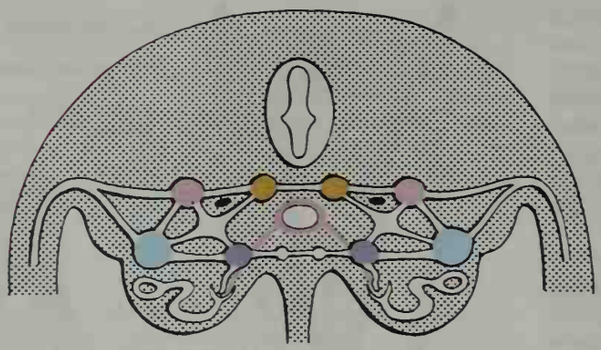
The inferior vena cava (**2**.87, 88) of the adult is a composite vessel, and the precise mode of development of its postrenal segment (caudal to the renal vein) is still somewhat uncertain. Its function is at first carried out by the right and left *postcardinal* veins, which receive the venous drainage of the lower limb buds and the pelvis and run in the dorsal part of the mesonephric ridges, receiving tributaries from the body wall (intersegmental veins) and from the mesonephroi.

A second pair of longitudinal veins, termed the *subcardinal veins*, form in the ventromedial part of the mesonephric ridges and become connected to the postcardinal veins by a number of vessels which traverse the medial part of the ridges. The subcardinal veins intercommunicate by a *pre-aortic anastomosis*, which later constitutes the part of the *left renal vein* crossing in front of the abdominal aorta.

The formation of an oblique transverse anastomosis between the iliac veins—which itself becomes the major part of the definitive *left common iliac vein*—diverts an increasing volume of blood into the right longitudinal veins, accounting for the ultimate disappearance of those on the left.

At its cranial end the subcardinal vein receives the *suprarenal vein* on each side, but on the right side it comes into intimate relationship with the liver. An extension of the vessel takes place in a cranial direction and meets and establishes continuity with a corresponding new formation which is growing caudally from the common hepatic vein. In this way on the right side a more direct route is established to the heart, and the *prerenal* (cranial) segment of the inferior vena cava is defined.

The enlargement of the metanephros diverts the postcardinal vein from its course, and the venous drainage of the mesonephric ridge is taken over by the subcardinal vein. At the same time new



2.86A–C Three stages in the development of the veins of the liver. Note, however, the results of a more detailed analysis mentioned in the text and in Dickson (1957), which differs in some respects from the views on which this illustration is based.

longitudinal channels appear and take over intersegmental venous drainage and the whole of the postcardinal vein disappears with the exception of its extreme cranial and caudal ends. There are four such channels on each side, but, so far as is known at the present, only two of them persist as large vessels in the adult: (1) A bilateral longitudinal channel forms dorsolateral to the aorta and *lateral* to the sympathetic trunk and takes over the intersegmental venous drainage from the posterior cardinal vein. This is the *supracardinal* or *thoracolumbar 'complex'*. (2) A second channel is formed on each side, also dorsolateral to the aorta but *medial* to the sympathetic trunk. This is the *azygos line vein* and, gradually it takes over the intersegmental venous drainage from the thoracolumbar line. The intersegmental veins now reach their longitudinal channel by passing *medial* to the sympathetic trunk, the relationship which the lumbar and intercostal veins exhibit thenceforward. Cranially the azygos lines join the persistent cranial parts of the posterior cardinal veins. (3) Two *subcentral veins* are laid down directly dorsal to the aorta in the interval

between the origins of the paired intersegmental arteries. These veins communicate freely with each other and with the azygos line veins, and these connexions ultimately form the retro-aortic parts of the left lumbar veins and of the hemiazygos veins. The thoracolumbar lines or *supracardinal veins*, are laid down lateral to the aorta and sympathetic trunks, which therefore intervene between them and the azygos lines. These veins communicate caudally with the iliac veins and cranially with the subcardinal veins in the neighbourhood of the pre-aortic intersubcardinal anastomosis. In addition, the supracardinal veins communicate freely with each other through the medium of the azygos lines and the subcentral veins. The most cranial of these connexions, together with the supracardinal-subcardinal and the inter-subcardinal anastomoses, complete a venous ring around the aorta below the origin of the superior mesenteric artery, termed the *'renal collar'* (Huntington 1920).

The right supracardinal vein persists and forms the greater part of the postrenal segment of the inferior vena cava, the continuity of the vessel being maintained by the persistence of the anastomosis between the right supracardinal and the right subcardinal in the 'renal collar'. The left supracardinal disappears, but the portion of the 'renal collar' formed by the left supracardinal-subcardinal anastomosis in part persists in the left renal vein. It must be added that much confusion and

disagreement exists with regard to the complicated array of longitudinal veins described above.

The *inferior vena cava* (**2**.88) is therefore formed, from below upwards, by (1) part of the right supracardinal vein, (2) an anastomosis between the right supracardinal and subcardinal veins, (3) the right subcardinal vein, (4) a new formation which connects the right subcardinal and the common hepatic veins, and (5) the common hepatic vein (Gladstone 1929). It should be noted that only the supracardinal part of the inferior vena cava receives the intersegmental venous drainage, and that the postrenal segment of the inferior vena cava is on a plane which lies dorsal to the plane of the prerenal segment. On this account the right phrenic, suprarenal and renal arteries, which represent persistent mesonephric arteries, pass behind the inferior vena cava, while the testicular or ovarian, which has a similar developmental origin, passes anterior to it.

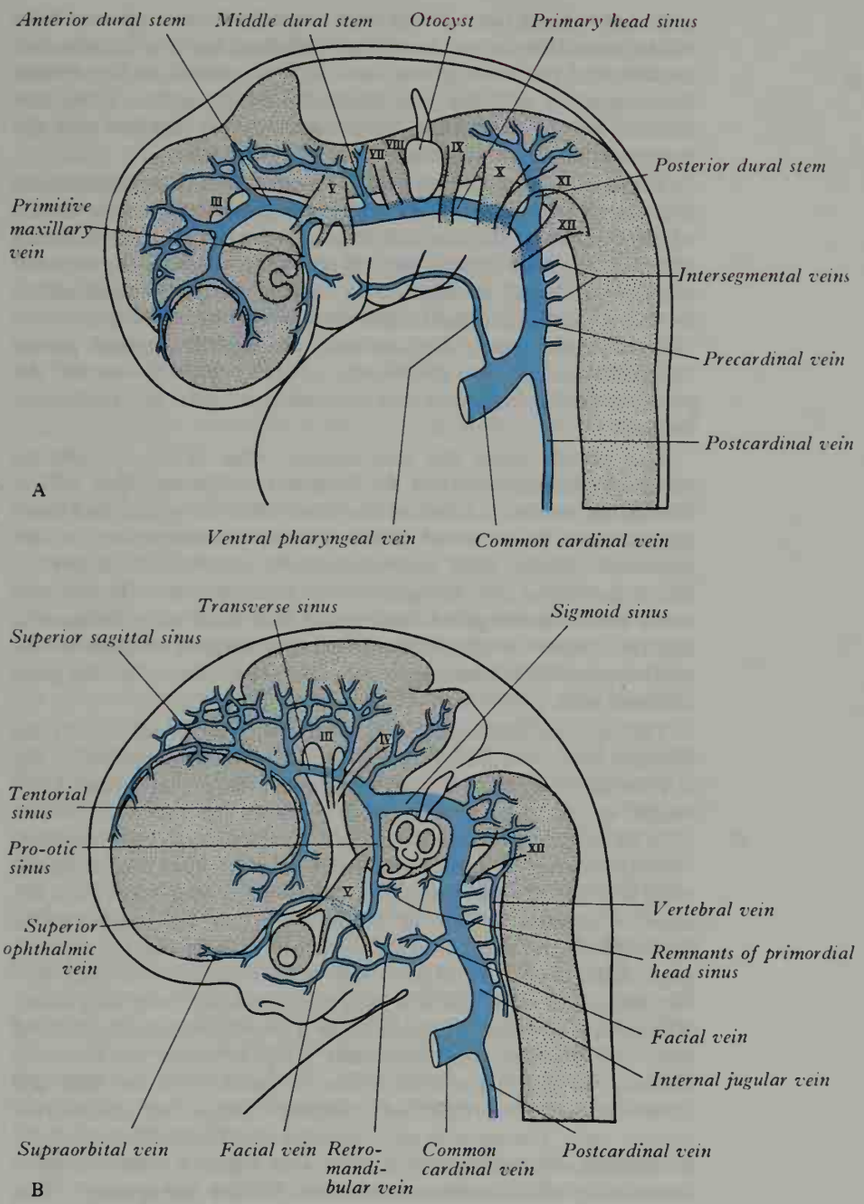
In some animals the right postcardinal vein constitutes a large part of the postrenal segment of the inferior vena cava. In these cases the right ureter, on leaving the kidney, passes medially dorsal to the vessel and then, curving round its medial side, crosses its ventral aspect. Rarely, a similar condition is found in the human subject, and indicates the persistence of the right postcardinal vein and failure of the right supracardinal to play its normal part in the development of the vessel.

The ultimate arrangement of the embryonic abdominal and thoracic longitudinal somatic veins may be summarized as follows:

(1) The terminal part of the postcardinal vein on the left side forms the distal part of the left superior intercostal vein; on the right side its cranial part persists as the terminal portion of the vena azygos.

(2) The caudal part of the subcardinal vein is partly incorporated in the testicular or ovarian vein (McClure and Butler 1925) and partly disappears. The cranial end of the right subcardinal vein is incorporated into the inferior vena cava and also forms the right suprarenal vein. The left subcardinal vein, cranial to the intersubcardinal anastomosis, is incorporated into the left suprarenal vein. The renal and testicular or ovarian veins on both sides join the supracardinal-subcardinal anastomosis. On the left side this is connected directly to the part of the inferior vena cava which is of subcardinal status through an inter-subcardinal anastomosis.

(3) The right supracardinal vein forms the postrenal segment of the inferior vena cava. The left supracardinal vein disappears entirely.



(4) The right azygos line persists in its thoracic part to form all but the terminal part of the vena azygos. Its lumbar part can usually be identified as a small vessel which leaves the vena azygos on the body of the twelfth thoracic vertebra and descends on the vertebral column, deep to the right crus of the diaphragm, to join the posterior aspect of the inferior vena cava at the upper end of its postrenal segment. The left azygos line forms the hemiazygos veins.

(5) The subcentral veins give rise to the retro-aortic parts of the left lumbar veins and of the hemiazygos veins.

(6) The veins described by some observers as the thoracolumbar lines, and probably identical with the supracardinal veins, are, in any case, of uncertain fate in later development.

The veins of the head have a complicated developmental history (**2**.89A, B; and consult—Markoski 1911; Streeter 1918; Padgett 1957).

The primary vessels consist of a close-meshed capillary plexus drained on each side by the precardinal vein, which is at first continuous cranially with a transitory channel, the *primordial hindbrain channel*, lying on the neural tube medial to the cranial nerve roots. This is soon replaced by the *primary head vein* which runs caudally from the medial side of the trigeminal ganglion, lateral to the facial and vestibulocochlear nerves and the otocyst and then medial to the vagus nerve, to become continuous with the precardinal vein. A lateral anastomosis subsequently brings it lateral to the vagus nerve. The cranial part of the precardinal vein forms the internal jugular vein; its caudal moiety has already been described on p. 193.

2.89A and B Diagrams illustrating successive stages in the development of the veins of the head and neck, (A) at approximately 8 mm and (B) at approximately 24 mm C.R. length.

The capillary plexus of the head becomes separated into three more or less distinct strata by the differentiation of the skull and meninges. The superficial vessels, draining the integument and underlying soft parts, eventually drain in large part into the external jugular system. They retain some connexions with the deeper veins through the so-called emissary veins. Deep to this is the venous plexus of the dura mater, from which the dural venous sinuses differentiate. This plexus is drained on each side by *anterior*, *middle* and *posterior dural stems*. The anterior stem drains the prosencephalon and mesencephalon and enters the primary head vein in front of the trigeminal ganglion. The middle stem drains the metencephalon and empties into the primary head vein behind the trigeminal ganglion, while the posterior stem drains the myelencephalon into the commencement of the precardinal vein (**2**.89). The deepest capillary stratum is the plexus of the pial vessels from which the veins of the brain differentiate; it drains at the dorsolateral aspect of the neural tube into the adjacent dural venous plexus. In addition the primary head vein also receives, at its cranial end, the *primitive maxillary vein*, draining the maxillary process and region of the optic vesicle.

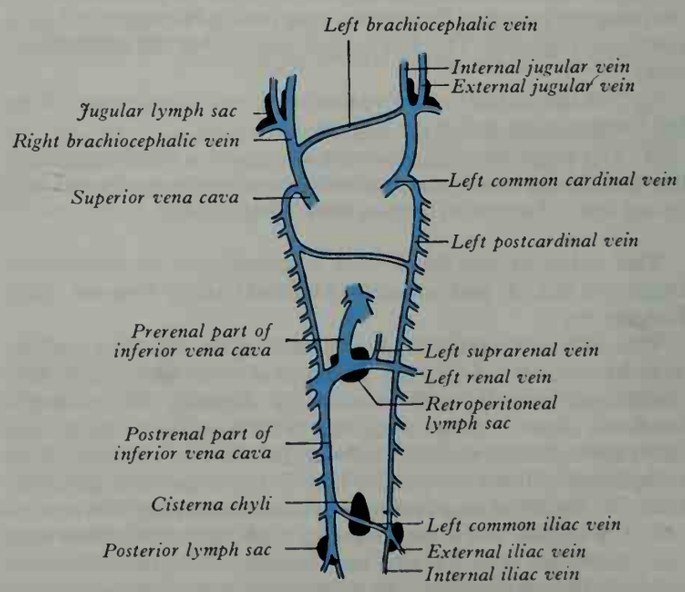
The vessels of the dural plexus undergo profound changes, largely resulting from the growth of the cartilaginous capsule of the labyrinth and expansion of the cerebral hemispheres. Owing

to the growth of the cartilaginous otic capsule the primary head vein is gradually reduced and a new channel joining the anterior, middle and posterior dural stem appears dorsal to the cranial nerve ganglia and the otic capsule (Butler 1967). This new channel joining the middle and posterior stems together with the posterior dural stem forms the adult *sigmoid sinus*.

Between the growing cerebral hemispheres and along the dorsal margins of the anterior and middle plexuses there forms a curtain of capillary veins, the *sagittal plexus*, in the position of the future falx cerebri. The dorsal part of this plexus forms the *superior sagittal sinus* and is continuous behind with the anastomosis between the anterior and middle dural stems which forms most of the *transverse sinus*. The ventral part of the sagittal plexus differentiates into the *inferior sagittal* and *straight sinuses* and the *great cerebral vein*, and drains eventually into the left transverse sinus.

The vessels along the ventrolateral edge of the developing cerebral hemisphere form the transitory *tentorial sinus*, which drains the convex surface of the cerebral hemisphere and basal ganglia and the ventral aspect of the diencephalon to the transverse sinus. With expansion of the cerebral hemispheres, and in particular the emergence of the temporal lobe, the tentorial sinus becomes elongated, attenuated and eventually disappears, and its territory of supply is drained by enlarging anastomoses of pial vessels which become the *basal veins* and drain into the great cerebral vein.

The anterior dural stem disappears and the caudal part of the primary head vein dwindles; it is represented in the adult by the *inferior petrosal sinus*. The cranial part of the primary head vein, medial to the trigeminal ganglion, persists and still receives the stem of the primitive maxillary vein. The latter has now lost most of its tributaries to the anterior facial vein, its stem becoming the main trunk of the *primitive supra-orbital vein*, which will form the *superior ophthalmic vein* of the adult. Thus the main venous drainage of the orbit and its contents is now carried via the augmented middle dural stem, now termed the *pro-otic sinus*, into the transverse sinus and at a later stage into the cavernous sinus. The *cavernous sinus* is formed from a secondary plexus, derived from the primary head vein and lying between the otic and basioccipital cartilages. This forms the *inferior petrosal sinus* and drains through the primordial hindbrain channel into the internal jugular vein. The *superior petrosal sinus* arises later from a ventral metencephalic tributary of the pro-otic sinus; it communicates secondarily with the cavernous sinus (Butler 1957, 1967). The pro-otic sinus meanwhile has developed a new and more caudally situated stem draining into the sigmoid sinus; this new stem is the *petrosquamosal sinus* (p. 746) and the pro-otic sinus becomes, with progressive ossification of the skull, diploic in position. The development of the venous drainage and portal system of the hypophysis cerebri is closely associated with that of the venous sinuses (Wislocki 1937; Niemineva 1950).



The venous drainage of the face, scalp and neck becomes established after the development of the skull. The first identifiable vessel is the *ventral pharyngeal vein*, draining the massive mandibular and hyoid arches into the common cardinal vein. With the elongation of the neck its termination is transferred to the cranial part of the precardinal vein which later becomes the internal jugular. The ventral pharyngeal vein, receiving tributaries from the face and tongue, becomes the *linguofacial* vein. With development of the facial region the primitive maxillary vein extends its drainage into the territories of supply of the ophthalmic and mandibular division of the fifth nerve, including the pterygoid and temporal muscles. Over the lower jaw it anastomoses with the linguofacial vein. This anastomosis becomes the *facial vein*; it receives a strong tributary from the temporal region, the *retromandibular* vein, and drains through the linguofacial vein into the internal jugular. The stem of the linguofacial vein is now identifiable as the lower part of the facial vein, whilst the dwindling connexion of the facial with the primitive maxillary vein becomes the deep facial vein. The *external jugular vein* is developed from a tributary of the cephalic vein from the tissues of the neck and anastomoses secondarily with the anterior facial vein. At this stage the *cephalic vein* forms a *venous ring* around the clavicle from which it is connected with the caudal part of the precardinal. The deep segment of the venous ring forms the *subclavian vein* and receives the definitive external jugular vein. The superficial segment of the venous ring dwindles, but may persist in adult life (Padgett 1957).

THE LYMPHATIC SYSTEM

Two different views are current as to the initial stages in the development of the lymphatic system (Rusznyák *et al.* 1960). According to the first view (Huntington 1908; McClure and Bulter 1925) lymphatic spaces commence as clefts in the mesenchyme, and their lining cells take on the characters of endothelium (Kampmeier 1969). These spaces form capillary plexuses from which certain *lymph sacs*, to be noted later, are derived. The connexions of the lymphatic and venous systems are regarded as entirely secondary. In contrast, however, according to Sabin (1902), the earliest lymph vessels arise as capillary offshoots from the endothelium of the veins, which form capillary plexuses. These plexuses lose their connexions with the venous system and become confluent to form lymph sacs. The balance of the evidence suggests that all but the earliest channels of the lymphatic system originate independently of the venous system and only acquire connexions with it at a later stage (Kampmeier 1969).

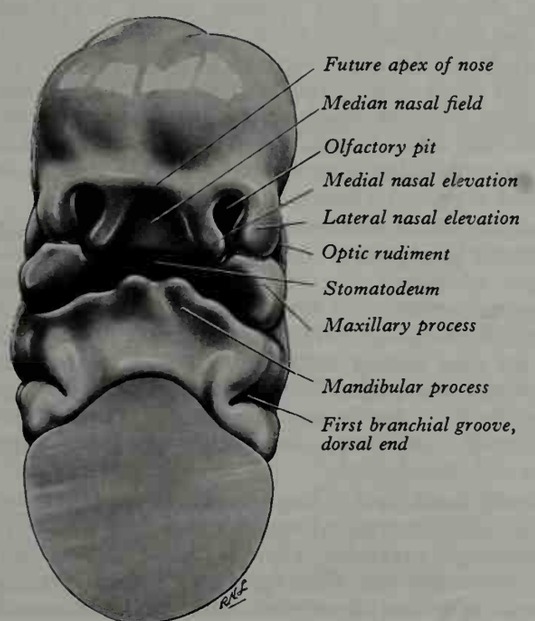
In the human embryo the lymph sacs from which the lymph vessels are derived are six in number; two paired (the *jugular* and the *posterior lymph sacs*) and two unpaired (the *retroperitoneal* and the *cisterna chyli*). In lower mammals an additional pair (the *subclavian*) is present, but in the human embryo these are merely extensions of the jugular sacs.

The position of the sacs is as follows (**2**.90): (1) the *jugular*, the first to appear, at the junction of the subclavian vein with the precardinal; (2) the *posterior*, at the junction of the iliac vein with the postcardinal; (3) the *retroperitoneal*, in the root of the mesentery near the suprarenal glands; (4) the *cisterna chyli*, opposite the third and fourth lumbar vertebrae. From the lymph sacs the lymph vessels bud out along lines corresponding more or less closely with the course of embryonic blood vessels, but many arise *de novo* in the mesenchyme and establish connexions with existing vessels. In the body wall and in the wall of the intestine (Heuer 1909), the deeper plexuses are the first to be developed; by continued growth of these the vessels in the superficial layers are gradually formed. The thoracic duct is, phylogenetically, a bilateral structure. In man it comprises the caudal part of the right vessel, a transverse anastomosis and the cranial part of the left vessel. According to the second view cited above it is formed from anastomosing outgrowths from the jugular sac and cisterna chyli. At its connexion with the cisterna chyli it is at first double, but the

2.90 A scheme showing the relative positions of the primary lymph sacs. (After F. R. Sabin.)

vessels soon join. Numerous valves are laid down in the duct during the fifth month, but many of them disappear prior to birth. Those which persist are formed in situations where the duct may be subjected to pressure, e.g. where it is crossed by the oesophagus and the aortic arch.

All the lymph sacs except the cisterna chyli are, at a later stage, divided up by a number of slender connective tissue bridges. Later they are invaded by lymphocytes and transformed into groups of lymph nodes, the lymph sinuses representing portions of the original cavity of the sac. The lower portion of the cisterna chyli is similarly converted, but its upper portion remains as the adult cisterna; in many cases the cisterna chyli is plexiform (p. 785). The siting of the major groups of lymph nodes follows a similar basic pattern amongst the mammals (Spira 1962).



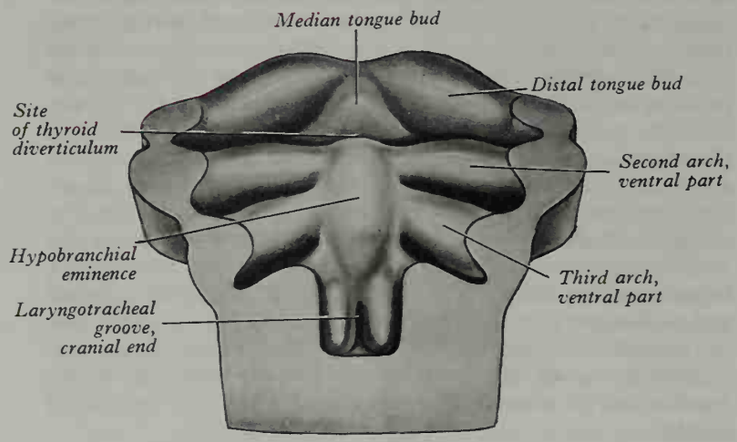
Haemal lymph nodes are said to develop as mesenchymal condensations in close relation to blood vessels rather than lymphatics (Meyer 1917).

The Development of the Alimentary and Respiratory Apparatus

THE BUCCAL CAVITY

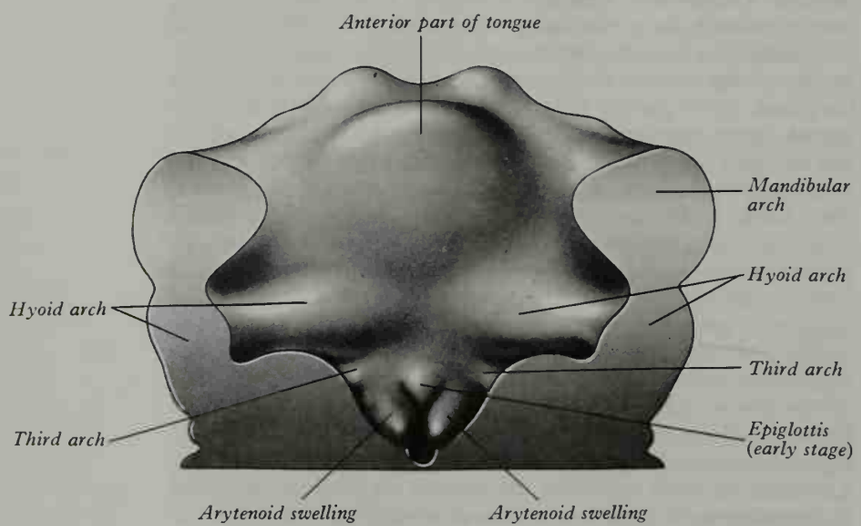
The mouth is developed partly from the stomatodeum, and partly from the floor of the cranial portion of the foregut. By the growth of the head end of the embryo and the formation of the head fold, the pericardial area and the oropharyngeal membrane come to lie on the ventral surface of the embryo (p. 120). With the further expansion of the brain, and the bulging of the pericardium, the membrane is soon depressed between the two prominences. This depression constitutes the *stomatodeum* or *primitive mouth* (**2**.33). It is lined with ectoderm, and is separated from the cranial end of the foregut by the oropharyngeal membrane, which is formed by the apposition of the stomatodeal ectoderm with the foregut endoderm; at the end of the fourth week the membrane disappears and a communication is established between the stomatodeum and the cranial end of the foregut or future pharynx. No vestige of the membrane is found in the adult, and the communication just mentioned must not be confused with the permanent oropharyngeal isthmus. The epithelium of the lips and gums and the enamel of the teeth are ectodermal in origin, being formed from the walls of the stomatodeum, but the epithelium of the tongue, which is developed in the floor of the mouth and pharynx, is derived from the endoderm. The development of the teeth and gums is described on pp. 1293–1300.

The branchial arches grow in a ventral direction and come to lie between the stomatodeum and the pericardium; with the completion of the mandibular arch and the development of the maxillary processes (p. 148), the opening of the stomatodeum assumes a pentagonal form, bounded cranially by the frontonasal process, caudally by the mandibular arches, and laterally by the maxillary processes (**2**.91). With the inward growth and fusion of the palatine processes (**2**.56B, C), the stomatodeum is divided into a nasal and a buccal part. Along the free margins of the processes bounding the mouth cavity appears a shallow groove, and the ectoderm in the floor of this groove thickens and invades the underlying mesoderm; it divides into a medial *dental lamina* and a lateral *vestibular lamina*. The central cells of the latter degenerate and break down so that the furrow becomes deepened. It may now be termed the *labiogingival groove* or *sulcus*; its inner wall contributes to the formation of the alveolar processes of the maxillae and the mandible, while its outer wall forms the lips and cheeks.



2.91 The head of a human embryo in the sixth week. Ventral aspect. (From a model by K. Peter.)

The salivary glands arise from the epithelial lining of the mouth. The *parotid gland* can be recognized in human embryos 8 mm long as an elongated furrow running dorsally from the angle of the mouth between the mandibular arch and the maxillary process. The groove, which is converted into a tube, loses its connexion with the epithelium of the mouth, except at its ventral end, and grows dorsally into the substance of the cheek. The tube persists as the *parotid duct* and its blind end proliferates to form the gland. Subsequently the size of the oral fissure is reduced by partial fusion between the maxillary and mandibular processes and the duct opens thereafter on the inside of the cheek at some distance from the angle of the mouth. The *submandibular gland* is identifiable in human embryos 13 mm long as an epithelial outgrowth from the floor of the *linguogingival groove*. It increases rapidly in size by giving off numerous branching processes which later acquire lumina. At first the connexion of the submandibular outgrowth with the floor of the mouth lies at the side of the tongue, but the edges of the groove in which it opens come together, from behind forwards, and form the tubular part of the *submandibular duct*. As a result the orifice of the duct is shifted forwards till it is below the tip of the tongue, close to the median plane. The *sublingual gland* arises in embryos about 20 mm long as a number of small epithelial thickenings in the linguogingival groove and on the lateral side of the groove, which later closes to form the submandibular duct.



The tongue appears as a small median elevation, named the *median tongue bud* (*tuberculum impar*), in the endodermal floor of the pharynx, before the branchial arches meet ventrally; it subsequently becomes incorporated in the anterior part of the tongue. A little later two oval *distal tongue buds* (*lingual swellings*) appear on the endodermal aspect of the mandibular processes. They meet each other in front, and caudally they converge on the median tongue bud, with which they fuse (**2**.92A, B). A sulcus forms along the ventral and lateral margins of this elevation and deepens to form the linguogingival groove, while the elevation constitutes the anterior or buccal (presulcal) part of the tongue.

Caudal to the median tongue bud, a second median elevation, termed the *hypobranchial eminence* (copula of His), forms in the floor of the pharynx, and the ventral ends of the fourth, the third and, later, the second visceral arches converge into it. A transverse groove separates its caudal part to form the epiglottis, while ventrally it approaches the tongue rudiment, spreading ventrally in the form of a V, and forming the posterior or pharyngeal part of the tongue. In the process the third arch elements grow over and bury the elements of the second arch, excluding it from the tongue. As a result the mucous membrane of the pharyngeal part of the tongue receives its sensory supply from the glossopharyngeal, the nerve of the third arch. In the adult the union of the anterior and posterior parts of the tongue is marked by the angulated *sulcus terminalis*, its apex at the *foramen caecum*, a blind depression produced at the time of fusion of the constituent parts of the tongue, but also marking the site of the ingrowth of the median rudiment of the thyroid gland.

At first the tongue consists of a mass of mesoderm covered on its surface by endoderm. During the second month occipital myotomes have often been stated to migrate from the lateral aspects of the myelencephalon, invading the tongue to form its

2.92A The floor of the pharynx of a human embryo at the beginning of the sixth week. (From a model by K. Peter.)

2.92B The floor of the pharynx of a human embryo, about six weeks old. (From a model by K. Peter.)

musculature. They are held to pass ventrally round the pharynx to reach its floor accompanied, necessarily, by their nerve (the hypoglossal), which therefore crosses superficial to both the internal and external carotid arteries; however, *see* p. 154.

The composite character of the tongue is indicated by its innervation. Impulses from the anterior, buccal part are mediated by (*a*) the lingual nerve, derived from the post-trematic nerve of the first arch (mandibular nerve), (*b*) the chorda tympani, the pretrematic nerve to the first arch. The posterior, pharyngeal part of the tongue is innervated by the glossopharyngeal, the nerve of the third arch. The muscles of the tongue being 'myotomic' in origin, receive their nerve supply from the hypoglossal nerve, which is serially homologous with spinal ventral nerve roots.

The sulcus terminalis cannot be distinguished earlier than the 52 mm stage according to some observers (Vij and Kanagasuntheram 1972). The vallate papillae appear at about the same time, increasing in number until the 170 mm stage. Serial reconstructions also suggest that the territory of the glossopharyngeal nerve extends considerably beyond these papillae (Watanbe *et al.* 1970).

The thyroid gland is first identifiable in embryos of about 20 somites, as a median thickening of endoderm in the floor of the pharynx between the first and second pharyngeal pouches and immediately dorsal to the aortic sac (Davis 1923). This area is later invaginated to form a median diverticulum, which appears in the latter half of the fourth week in the furrow immediately caudal to the tuberculum impar (**2.92A**). It grows caudally as a tubular duct which bifurcates and subsequently divides into a series of double cellular plates, from which the isthmus and the lateral lobes of the thyroid gland are developed. The *primary thyroid follicles* differentiate by reorganization and proliferation of the cells of these plates. *Secondary follicles* subsequently arise by budding and subdivision (Norris 1916). The claim that the fourth pharyngeal pouches contribute thyroid tissue to the lateral lobes of the gland was long disputed and seemed perhaps unlikely on the grounds of comparative embryology. (But see also below—the *ultimobranchial body*.)

The connexion of the median diverticulum with the pharynx is termed the *thyroglossal duct*. The site of its connexion with the epithelial floor of the mouth is marked by the foramen caecum. From here it extends caudally in the middle line and ventral to the primordium of the hyoid bone, behind which it may later form a recurrent loop. The distal part of the duct usually differentiates to a variable extent to form the pyramidal lobe of the thyroid. The remainder fragments and disappears, but the lingual part is often identifiable until late in fetal life and may branch and give rise to miniature salivary glands (Boyd 1963). Occasionally parts of the midline thyroglossal duct persist (occurring in lingual, suprahyoid retrohyoid, or infrahyoid positions). They may give rise to the formation of aberrant masses of thyroid tissue, cysts, fistulae or sinuses, usually in the midline (*see* p. 1449). A *lingual thyroid* situated at the junction of the buccal and pharyngeal parts of the tongue is not uncommon, but nodules of glandular tissue may also be found other than in the midline, e.g. laterally placed posterior to sternocleidomastoid, and even below the level of the thyroid isthmus (*see* p. 1449).

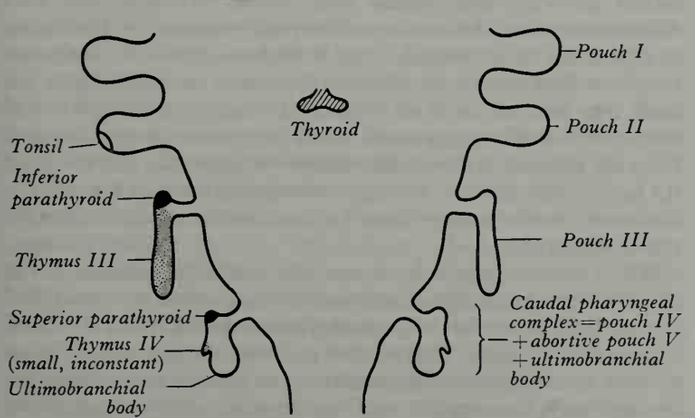
The tonsils are developed from the parts of the second pharyngeal pouches which lie between the tongue and the soft palate. The endoderm lining these pouches grows into the surrounding mesenchyme in the form of a number of solid buds. These buds are excavated by the degeneration and shedding of their central cells, and by this means the tonsillar *fossulae* and *crypts* are formed. Lymphoid cells accumulate around the crypts, and become grouped as lymphoid follicles. A slit-like *intratonsillar cleft* (**8.82** extends into the upper part of the tonsil and is a remnant of the second pharyngeal pouch.

The thymus is derived from the endoderm of the ventral part of the third pharnygeal pouch on each side (**2.93**). It cannot be recognized prior to the differentiation of the inferior parathyroid glands (*vide infra*), which occurs when the embryo is 10–12 mm long, but thereafter it is represented by two elongated diverticula which soon become solid cellular masses and grow caudally into the surrounding mesenchyme. Ventral to the aortic sac (p. 187) the two thymic rudiments meet and are subsequently united by connective tissue only; the rudiments themselves never fuse. The connexion with the third pouch is soon lost, but the stalk may persist for some time as a solid, cellular cord.

The development of thymic tissue from the ventral recess of the fourth pharyngeal pouch probably occurs in a proportion of embryos (Van Dyke 1941), although this has been denied by some authorities (Weller 1933; Norris 1938). Thymic tissue developing from this site is usually found outside the thyroid gland in close association with the superior parathyroid gland. An ectodermal contribution to the thymus, probably of placodal origin, occurs in some mammals, but a similar contribution in man cannot be regarded as proved (Garrett 1948).

Vascularized mesenchyme, including lymphoid stem cells, invades the cellular mass of the endodermal thymus and becomes partially lobulated. The cells of the cytoreticulum and the concentric corpuscles of the thymus are endodermal in origin. The epithelial character of these cells is more obvious in fetal life; some are even ciliated (Sebuwufu 1968). Lymphoid cells enter and colonize the thymus from the haemopoietic tissue stem cells during the third month, according to observations from *in vitro* and animal experiments (Averback 1960, 1961; Taylor 1965; Moore and Owen 1967).

At birth the thymus is large relative to total body weight. Its absolute weight increases in the first two years after birth, but its relative weight decreases. There is little change thereafter until about the seventh year, when rapid growth again occurs to reach a maximum at around eleven years. After this it begins to decline to an adult weight which is very variable but averages 12–15 gm. In old age the gland shrinks still further, especially after wasting diseases. For this and other reasons it is rarely identifiable in the



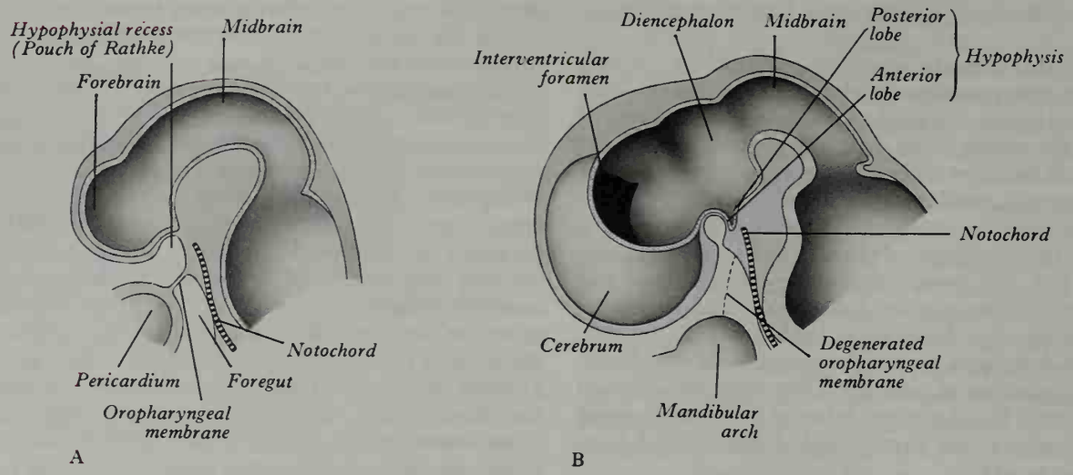
preserved cadaver of the aged (Keynes 1954; Lasi 1959; see also p. 780).

The parathyroid glands are also derivatives of the endoderm. Prior to the appearance of the thymic rudiment from the third pharyngeal pouch, the epithelium on the dorsal aspect of the pouch and in the region of its duct-like connexion with the cavity of the pharynx becomes differentiated as the primordium of the *inferior parathyroid gland*, recognizable by its cells, which stain more lightly than the other endodermal cells lining the pouch. Although the connexion between the pouch and the pharynx is soon lost, the connexion between the thymic and parathyroid rudiments persists for some time, and the latter passes caudally with the developing thymus. The *superior parathyroid glands* develop in a similar manner from the dorsal recess of the fourth pharyngeal pouches. They come into relation with, and are anchored by, the lateral lobes of the thyroid gland and thus remain cranial to the parathyroid glands derived from the third pouch (*see* p. 1453).

The ultimobranchial body has already been noted as an endodermal diverticular part of the *caudal pharyngeal complex* (**2**.93). This separates from the ectoderm of the fourth branchial cleft and loses its connexion with the pharynx by attenuation and rupture of the common pharyngobranchial duct. It becomes closely associated with the expanding lateral lobe of the thyroid gland, with the superior parathyroid (parathyroid IV) component of the complex lying dorsally and outside the thyroid gland. The remainder of the complex, which includes the ultimobranchial body and possibly some vestiges of the ventral recess of the fourth pharyngeal pouch and of the transitory fifth pharyngeal pouch, is enveloped by the thyroid gland. Although some controversy persists, it is probable that the cells of the ultimobranchial body give rise to the 'C' or parafollicular cells producing calcitonin in the thyroid gland (p. 1449) of many if not all mammals. Calcitonin has been isolated from ultimobranchial tissue in vertebrates other than mammals (Copp *et al.* 1967; Taylor 1968). The derivation of thyroid parafollicular cells has now been clearly demonstrated in embryonic sheep (Jordan *et al.* 1973).

The hypophysis cerebri has anterior and posterior lobes; the former is derived from the ectoderm of the stomatodeum, the latter from the neurectoderm of the floor of the forebrain. Previous to the rupture of the oropharyngeal membrane a saccular recess is present in the ectodermal lining of the roof of the stomatodeum. This hypophysial recess (*pouch of Rathke*) (**2**.94A) is the rudiment of the anterior lobe of the hypophysis, lying immediately ventral to the cranial border of the membrane, extending in front of the cranial end of the notochord, and in contact with the ventral surface of the forebrain. It is constricted off by the surrounding mesenchyme to form a closed vesicle, but remains for a time connected to the ectoderm of the stomatodeum by a solid cord of cells, which can be traced down the posterior edge of the nasal septum. Masses of epithelial cells form on each side and in the ventral wall of the vesicle, and the development of the anterior lobe of the hypophysis is completed by the ingrowth of a mesenchymal stroma. Differentiation of epithelial cells into stem cells and three differentiating types is said to be apparent during the early months of fetal development (Dubois 1967). Recent work also suggests that different types of cells arise in succession, and that they may be derived in differing proportions from different parts of the hypophysial recess (Conklin 1968). A *craniopharyngeal canal*, which sometimes runs from the anterior part of the hypophysial fossa of the sphenoid bone to the exterior of the skull, is often said to mark the original position of the hypophysial recess (of Rathke); traces of the stomatodeal end of the recess are occasionally present at the junction of the septum of the nose with the palate. It has been claimed, however, that the craniopharyngeal canal is a secondary formation caused by the growth of blood vessels, and is quite unconnected with the stalk of the anterior lobe (Arey 1949). Just behind the hypophysial recess a hollow diverticulum grows towards the mouth from the floor of the diencephalon (**2**.94B). This neural outgrowth forms an infundibular sac, the walls of which increase in thickness until the contained cavity is obliterated except at its upper end, where it persists as the *infundibular recess* of the third ventricle. Formed in this way the *posterior lobe* of the hypophysis becomes invested by the anterior, which extends dorsally on each side of it. In addition, the anterior lobe gives off two processes from its ventral wall which grow along the infundibulum and fuse to surround it, coming into relation with the tuber cinereum and constituting the *tuberal portion* of the hypophysis. The original cavity of the stomatodeal diverticulum remains first as a cleft, and later scattered vesicles, and can be identified readily in sagittal sections through the fully formed gland. The dorsal wall of the stomatodeal part, which remains thin, fuses with the adjoining part of the posterior lobe as the *pars intermedia*.

A small endodermal diverticulum, named *Seessel's pouch*, projects towards the brain from the cranial end of the foregut, close to the oropharyngeal membrane. In some marsupials this pouch forms a part of the hypophysis, but, in man, it apparently disappears entirely; but before doing so it may contribute some cells to the general head mesenchyme of mixed origin, and it possibly functions as an anterior head organizer (with the prechordal plate of endoderm).



2.93 A scheme showing the development of the branchial epithelial bodies. The numbered sacs are the edodermal pharyngeal pouches.

The Pharynx

The Pharynx is the cranial end of the foregut, and the branchial arches and pharyngeal pouches play an important part in its development (**2**.95A, B). The endodermal aspect of the mandibular arch in its dorsal part contributes to the formation of the lateral wall of the nasopharynx in front of the orifice of the auditory tube. The ventral end of the first pouch becomes obliterated, but its dorsal end persists and deepens as the head enlarges. It remains close to the ectoderm of the dorsal end of the first cleft (p. 145) and, together with the adjoining lateral part of the pharynx and dorsal part of the second pharyngeal pouch, constitutes the *tubotympanic recess*, which forms the tympanic cavity and the auditory tube (p. 178). The site of the second arch is partly indicated by the *palatoglossal arch*, but its dorsal end is separated from its ventral end by the forward growth of the third arch, which obliterates the intermediate part. It is believed that the site of the second pharyngeal pouch is represented by the *supratonsillar cleft*, around which the tonsil is developed. The third arch forms the *lateral glosso-epiglottic fold*, and its dorsal end takes part in the formation of the floor of the auditory tube. The ventral ends of the fourth arches fuse with the posterior part of the hypobranchial eminence and so contribute to the formation of the *epiglottis* (p. 197). The adjoining portion becomes connected to the *arytenoid swelling* and may be identified in the *aryepiglottic fold*.

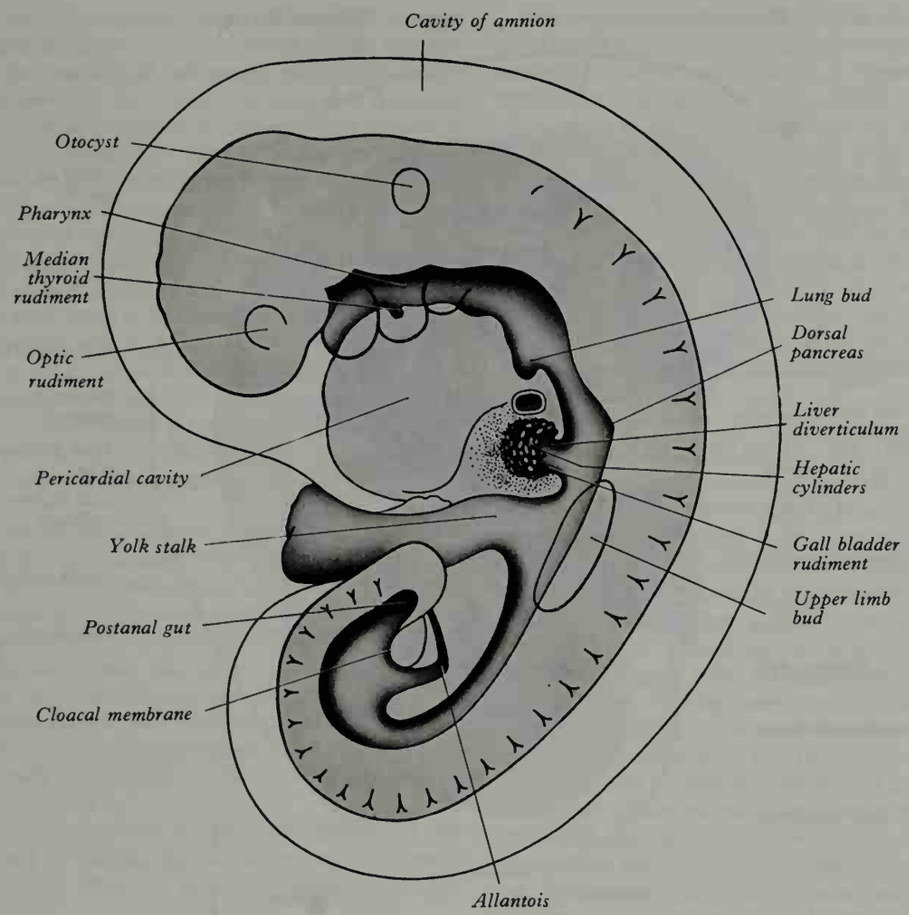
After the caudal portion of the hypobranchial eminence has separated from the dorsal part of the tongue (p. 197), it is in continuity with two linear ridges which appear in the ventral wall of the pharynx, the whole forming an inverted U, sometimes regarded as an independent formation, the *furcula* (of His). These vertical ridges have been identified as the sixth arches, placed very obliquely owing to the shortness of the pharyngeal floor compared with the greater extent of the roof. The contained groove of the furcula is carried downwards on the ventral wall of the foregut as the *laryngotracheal groove*, from which the lower part of the larynx, the trachea, bronchi and lungs are developed (p. 207). At

2.94A and B Schematic sagittal sections of heads of early embryos to show first stages in the development of the hypophysis.

the cranial end of the groove paired arytenoid swellings arise which convert the slit-like upper aperture of the respiratory system into a T-shaped opening. The aryepiglottic folds can be recognized at this stage extending from the arytenoid swellings to the epiglottis.

Development of the Post-Pharyngeal Parts of the Alimentary Tube

The part of the **foregut** caudal to the pharynx remains as a splanchnopleuric tube which elongates to form the *oesophagus*. At five weeks its epithelium is two cells thick, the luminal columnar cells developing cilia at approximately 10 weeks, and it does not differentiate into stratified squamous epithelium until the fifth month. Non-striated circular and longitudinal layers of muscle are identifiable at about the ninth week. Striated fibres begin to appear at the tenth week (Jit 1974). As the neck and thorax develop the oesophagus lengthens rapidly. At the end of the fourth or the beginning of the fifth week the *stomach* can be recognized as a fusiform dilation (**2**.95A), and beyond this the gut opens into the yolk sac; this opening is at first wide (**2**.80A), but by the fifth week it has become narrowed into a tubular *yolk stalk* (containing the endodermal *yolk duct*) (**2**.95A, B), which soon loses its connexion with the digestive tube (**2**.96). At this stage the stomach is median in position and separated from the pericardium by the septum transversum (p. 121), which extends ventrally on to the cranial side of the yolk duct. Dorsally, the stomach is related to the aorta and, owing to the presence of the pleuroperitoneal canals on each side, it is connected to the body wall by a short dorsal mesentery, the *dorsal mesogastrium* (**2**.97). This mesentery is directly continuous with the dorsal mesentery of the intestine. The liver develops as a hollow outgrowth from the ventral aspect of the foregut and grows cranially into the substance of the septum transversum (**2**.95A), this part of the septum now being termed the *ventral mesogastrium*.



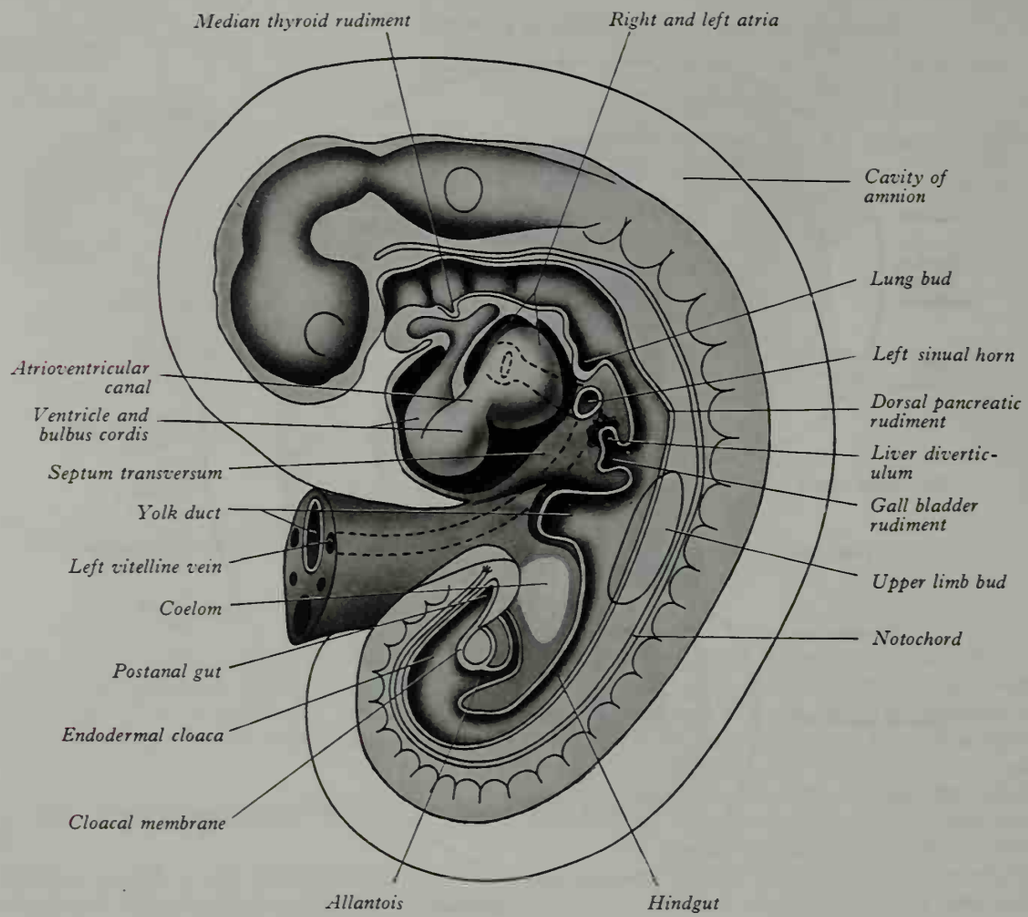
In the human embryo, at the 10 mm stage, the characteristic curvatures of the stomach are already discernible. Growth proceeds more actively along the dorsal border of the viscus; its convexity is notably increased and the rudiment of the fundus appears. As a result of the more rapid growth of the dorsal border, the pyloric end of the stomach turns ventrally and the concavity of the lesser curvature becomes apparent (**2**.96). The stomach is now displaced to the left of the median plane and rotated so that its originally right surface becomes dorsal and its left ventral. As a result the right vagus nerve is distributed mainly to the dorsal and the left mainly to the ventral surface of the organ. The dorsal mesogastrium increases in depth and becomes folded on itself; the lesser omentum becomes more transverse than anteroposterior. The pancreatico-enteric recess (p. 205), hitherto a simple depression on the right side of the dorsal mesogastrium, becomes dorsal to the stomach and excavates downwards and to the left between the layers of the folded dorsal mesogastrium. It may now be termed the inferior recess of the *bursa omentalis*. The displacement and rotation of the stomach has been attributed variously to its own growth changes, extension of the pancreatico-enteric recess and pressure by the rapidly growing liver (Kanagasuntheram 1957).

While these changes are occurring in the stomach, the **midgut** increases in length more rapidly than the vertebral column, and forms a loop, which acquires a dorsal mesentery as it lengthens, and projects into the coelomic cavity (**2**.97). The rapidly growing liver and the developing mesonephroi encroach on the available space in the coelom so much that the loop is extruded into the *umbilical coelom*, i.e., that part of the extra-embryonic coelom which lies in the proximal end of the umbilical cord (p. 123). This umbilical protrusion (often, quite inappropriately, called a 'physiological hernia') is a *normal* condition in human embryos between the 10 mm (end of fifth week) and the 40 mm (third month) stages; under abnormal conditions it may persist and be present at birth.

The rotation of the stomach reacts on the position of the duodenum, which prior to this stage is a ventrally directed loop, but is now carried dorsally and to the right. At this stage the duodenum possesses a thick mesentery which is continuous with the dorsal mesogastrium, on the one hand, and the mesentery of the intestinal midgut loop, on the other (**2**.97). Later, the approximation of the duodenum to the dorsal abdominal wall leads first to the adhesion of the right side of its mesentery to the parietal peritoneum, and later to the absorption of both layers. In this way the duodenum comes to be sessile or 'retroperitoneal'. The lining epithelium of the duodenum proliferates and almost occludes the lumen by the sixth week; the channel is re-established by the third month when the epithelium reverts to a simple columnar form.

Early in the sixth week a small diverticulum appears on the caudal limb of the midgut loop (**2**.96, 97), and this later differentiates into the *caecum* and *vermiform appendix*. Thereafter it is possible to distinguish the large from the small intestine. Until the fifth month the diverticulum has a conical outline, but from that time onwards its distal part remains rudimentary and forms the vermiform appendix, while its proximal part expands to form the caecum. At birth the vermiform appendix extends from the *apex* of the caecum; owing to unequal growth in the walls of the latter, it subsequently comes to open on the medial side of the caecum (p. 1353).

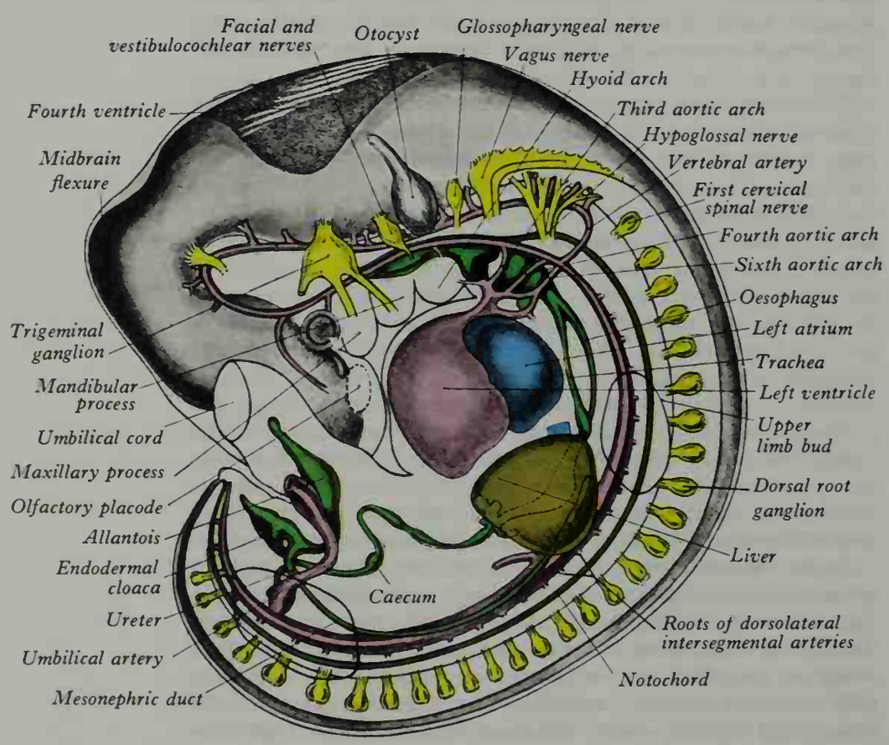
When the midgut loop enters the umbilical coelom it has already rotated through an angle of 90°, so that the proximal limb (i.e. the limb nearer to the stomach) lies to the right and the distal limb to the left (**2**.97). This relative position is roughly maintained so long as the protrusion persists, but during this period the proximal part forming the small intestine becomes elongated and coiled, and the mesentery adapts itself to these changes in the gut. The colic part of the loop elongates less rapidly and has no tendency to become coiled. By the time the fetus has attained a



2.95A The digestive tube of a human embryo with 29 paired somites, a C.R. length of 3·4 mm and an estimated age of 27 days. Note branchial development. Magnification × *c.* 25. (G. L. Streeter, *Contr. Embryol.*, **30**, 1942.)

length of 40 mm (middle of third month), the peritoneal cavity has enlarged sufficiently to allow re-entry of the midgut, and this occurs fairly rapidly, but in a definite sequence. The manner of this is important, for at this stage the gut continues the process of *rotation*, resulting ultimately, after differential growth, in the establishment of the definitive relationships which the large intestine shows in the adult, including the relation of the transverse colon to the duodenum. The process has been analysed as follows: (Fraser and Robbins 1915, may be consulted for the classical account of gut rotation: the present account, however, differs substantially from previous accounts in accord with the data presented by Harris and Jones 1976, from a radiological study of 64 fresh fetuses of 11 to 20 weeks of gestation. It should be noted, however, that interpretation of observations of the latter authors has not been followed in its entirety, and some common misconceptions stemming from the classical account will be pointed out.)

While the gut is still in the umbilical coelom the dorsal mesentery forms a median partition from the dorsal wall to the umbilicus. As the gut re-enters the abdominal cavity, the coils of the small intestine, which return first, necessarily enter to the *right* of this partition, thrusting it over to the *left* and thus determining the position of the descending colon. They pass dorsal to the superior mesenteric artery and determine its adult relationship to the horizontal part of the duodenum. This disposition of the duodenum is probably an important factor in initiating midgut rotation. The caecum is the last part to re-enter the abdomen, and it is at first on the surface of coils of ileum. Subsequently, with growth and some continued rotation the caecum is carried *dorsocaudally* and to the *right* where it comes to lie *in*, or even a little *caudal* to the diminutive *right iliac fossa*. It must be appreciated that at this stage the fetal liver is still, relatively, grossly enlarged and the caecum can be termed *subhepatic* in position, but that the term does *not* imply (as it is held to do in most textbook accounts) that the caecum returns to the right *upper* quadrant of the abdominal cavity. Harris and Jones named the midgut-derived colon *presplenic* and the hindgut-derived colon *postsplenic*, the transitional zone, of course, corresponding to the presumptive splenic flexure. At an early stage, after the completion of gut rotation, the proximal part of the presplenic colon runs largely *transversely* across the *lower* abdominal cavity, its left extremity curving cranially to reach the *primitive splenic flexure*, from which point the postsplenic colon first descends vertically, and then curves to the right, finally descending in the midline—the primitive rectum.



The longitudinal muscle coat differentiates earlier in the small than in the large intestine, and it has been suggested that this may play a role in the return of the midgut into the abdomen (Kanagasuntheram 1960). As the coils of small intestine re-enter the abdominal cavity, the mesentery of the *descending* postsplenic colon is thrust against the left dorsal abdominal wall and the opposed peritoneal surfaces become adherent and are gradually absorbed. The descending colon thus loses its mesentery and becomes sessile. Since this change takes place towards the end of the third month, the left colic vessels, whose position on the posterior abdominal wall is secondary, are ventral to such structures as the left ureter and gonadal vessels, which are primarily associated with the posterior wall. The pelvic part of the postsplenic colon, however, does not become sessile but retains its dorsal mesentery; nevertheless, the original midline parietal attachment of the latter, by *partial* adherence and fusion, gradually assumes the inverted V shape characteristic of the adult.

As the visceral surface of the enlarged liver gradually recedes towards the costal margin, the presplenic colon changes its early disposition, becoming firstly oblique, and then progressively developing its *ascending* and *transverse* parts. The former becomes sessile in the same manner as the descending colon, whilst the proximal part of the transverse colon passes ventral to the descending (second) part of the duodenum, to which it adheres. the remainder of the transverse colon retains its dorsal mesentery—the transverse mesocolon—which now has a *horizontal* parietal attachment to the head, neck and body of the

2.95B A composite diagram of a graphic reconstruction of a human embryo at the end of the fourth week. The alimentary canal and its outgrowths are shown in median section. The brain is shown in outline, but the spinal cord is omitted. The heart is shown in perspective, the left horn of the sinus venosus having been divided. The somites are indicated in outline. (After G. L. Streeter.)

developing pancreas. Whilst this is occurring the omental bursa is expanding and the transverse colon is carried dorsal to the bursa; a variable degree of fusion follows between the transverse mesocolon and the dorsal fold of that part of the dorsal mesogastrium destined to become the greater omentum (**2.97**). Meanwhile, as the hepatic flexure has gradually become defined, there has been occurring a slow, short *ascent* of the ileo-caecal junction to the upper part of the right iliac fossa, and a much more rapid ascent of the splenic flexure to its definitive position. (It should be noted that the foregoing account is in complete contrast to earlier descriptions, which maintained that the early caecum gradually *descended* by slow growth from the subhepatic right upper abdominal quadrant caudally to the right iliac fossa.)

2.96 A human embryo of 7 mm greatest length. Fifth week. Left lateral aspect. (After Thompson.)

The formation of the rectum and anal canal is associated with the growth of the tail fold, described in an earlier section (p. 120). Further, their development is intimately associated with that of the bladder and other elements of the urogenital system, hence many of the relevant illustrations appear later (*see* p. 210 and **2.107A–F**). As growth proceeds, the gut lengthens, at first *pari passu* with the embryo, and a new section of the **hindgut** can be recognized between the caudal aspect of the yolk stalk and the origin of the allantois (**2.95B**). The part of the hindgut caudal to the latter point dilates to form a pouch, termed the *endodermal cloaca*, and in its ventral wall the cloacal membrane (p. 120) can be identified in the midline (**2.107A**). By growth of the surrounding mesoderm the cloacal membrane comes to lie at the bottom of a shallow depression, the *ectodermal cloaca* (**2.107A**). The hindgut and the allantois open into the endodermal cloaca from the time of its first appearance and in the fifth week the mesonephric ducts pierce its wall. By this time the ventral part of the cloaca is wider than its dorsal part, which remains very narrow, and it is into the dorsolateral corner (lateral horn) of the ventral portion that the mesonephric duct opens (**2.107B, C**).

The mesenchyme outside the line of union of these two parts of the cloaca grows rapidly and thrusts the endodermal epithelium inwards. As a result the two walls come into apposition and fuse. This process commences opposite the connexion of the allantoic canal with the cloaca and is continued caudally to form a septum, termed the *urorectal septum*, which separates the dorsal segment

or rectum from the ventral segment, which forms the urinary bladder and the urogenital sinus (2.107B). At its caudal end the urorectal septum reaches the cloacal membrane and divides it into *anal* and *urogenital membranes*. For a time a *cloacal duct* connects the two parts of the cloaca proximal to the growing urorectal septum (2.107C), and occasionally persists as a passage between the rectum and the bladder or urethra. Anal tubercles form round the margin of the anal part of the cloacal membrane, which thus comes to lie at the bottom of a depression, the *proctodeum* (Tench 1936). With the absorption and disappearance of the anal membrane the rectum communicates with the exterior (2.107E). The lower part of the anal canal is formed from the proctodeum, but its upper part is endodermal in origin and is derived from the caudal end of the dorsal subdivision of the cloaca; the line of union corresponds with the edges of the anal valves in the adult (p. 1358). In the fourth and fifth weeks a small part of the hindgut, named the *postanal gut* (2.107A), projects caudally beyond the anal membrane; it usually disappears before the end of the fifth week.

The development of the *nerve supply* of the gut has received relatively little attention in human material. A migration of neuroblasts to establish a vagal innervation has been described in human embryos between the eighth and twelfth weeks (Okamoto and Ueda 1967), which is distributed in a craniocaudal direction to establish the myenteric plexus; the vagal ramifications in the oesophageal wall have been identified at the 15 mm stage (Lecco and Balli 1968). Ultrastructural and histochemical observations suggest that in the fetal small intestine and colon, the mucous membranes have already developed a potential for absorption (Kelly 1973; Lev and Orlic 1974).

Applied Anatomy. Abnormalities in the development of the digestive tube may lead to various disturbances which become apparent at birth or shortly after. Of these the following are the most common.

Closure of the laryngotracheal groove (p. 207) may be effected in such a way that the oesophagus is divided into two portions, a cranial, which communicates with the mouth above and ends blindly below in the neighbourhood of the tracheal bifurcation, and a caudal, which communicates below with the stomach and above with the trachea.

Congenital stricture of the small intestine is usually due to exuberant overgrowth of the lining epithelium and the formation of adhesions. This overgrowth is a normal occurrence at one stage in the development of the oesophagus and duodenum, but the lumen is soon restored. Some cases of atresia may result from interference with the blood supply (Louw 1959).

The umbilical herniation present between the 10 mm and 40 mm stages may fail to return into the abdominal cavity (p. 200) and may be present at birth.

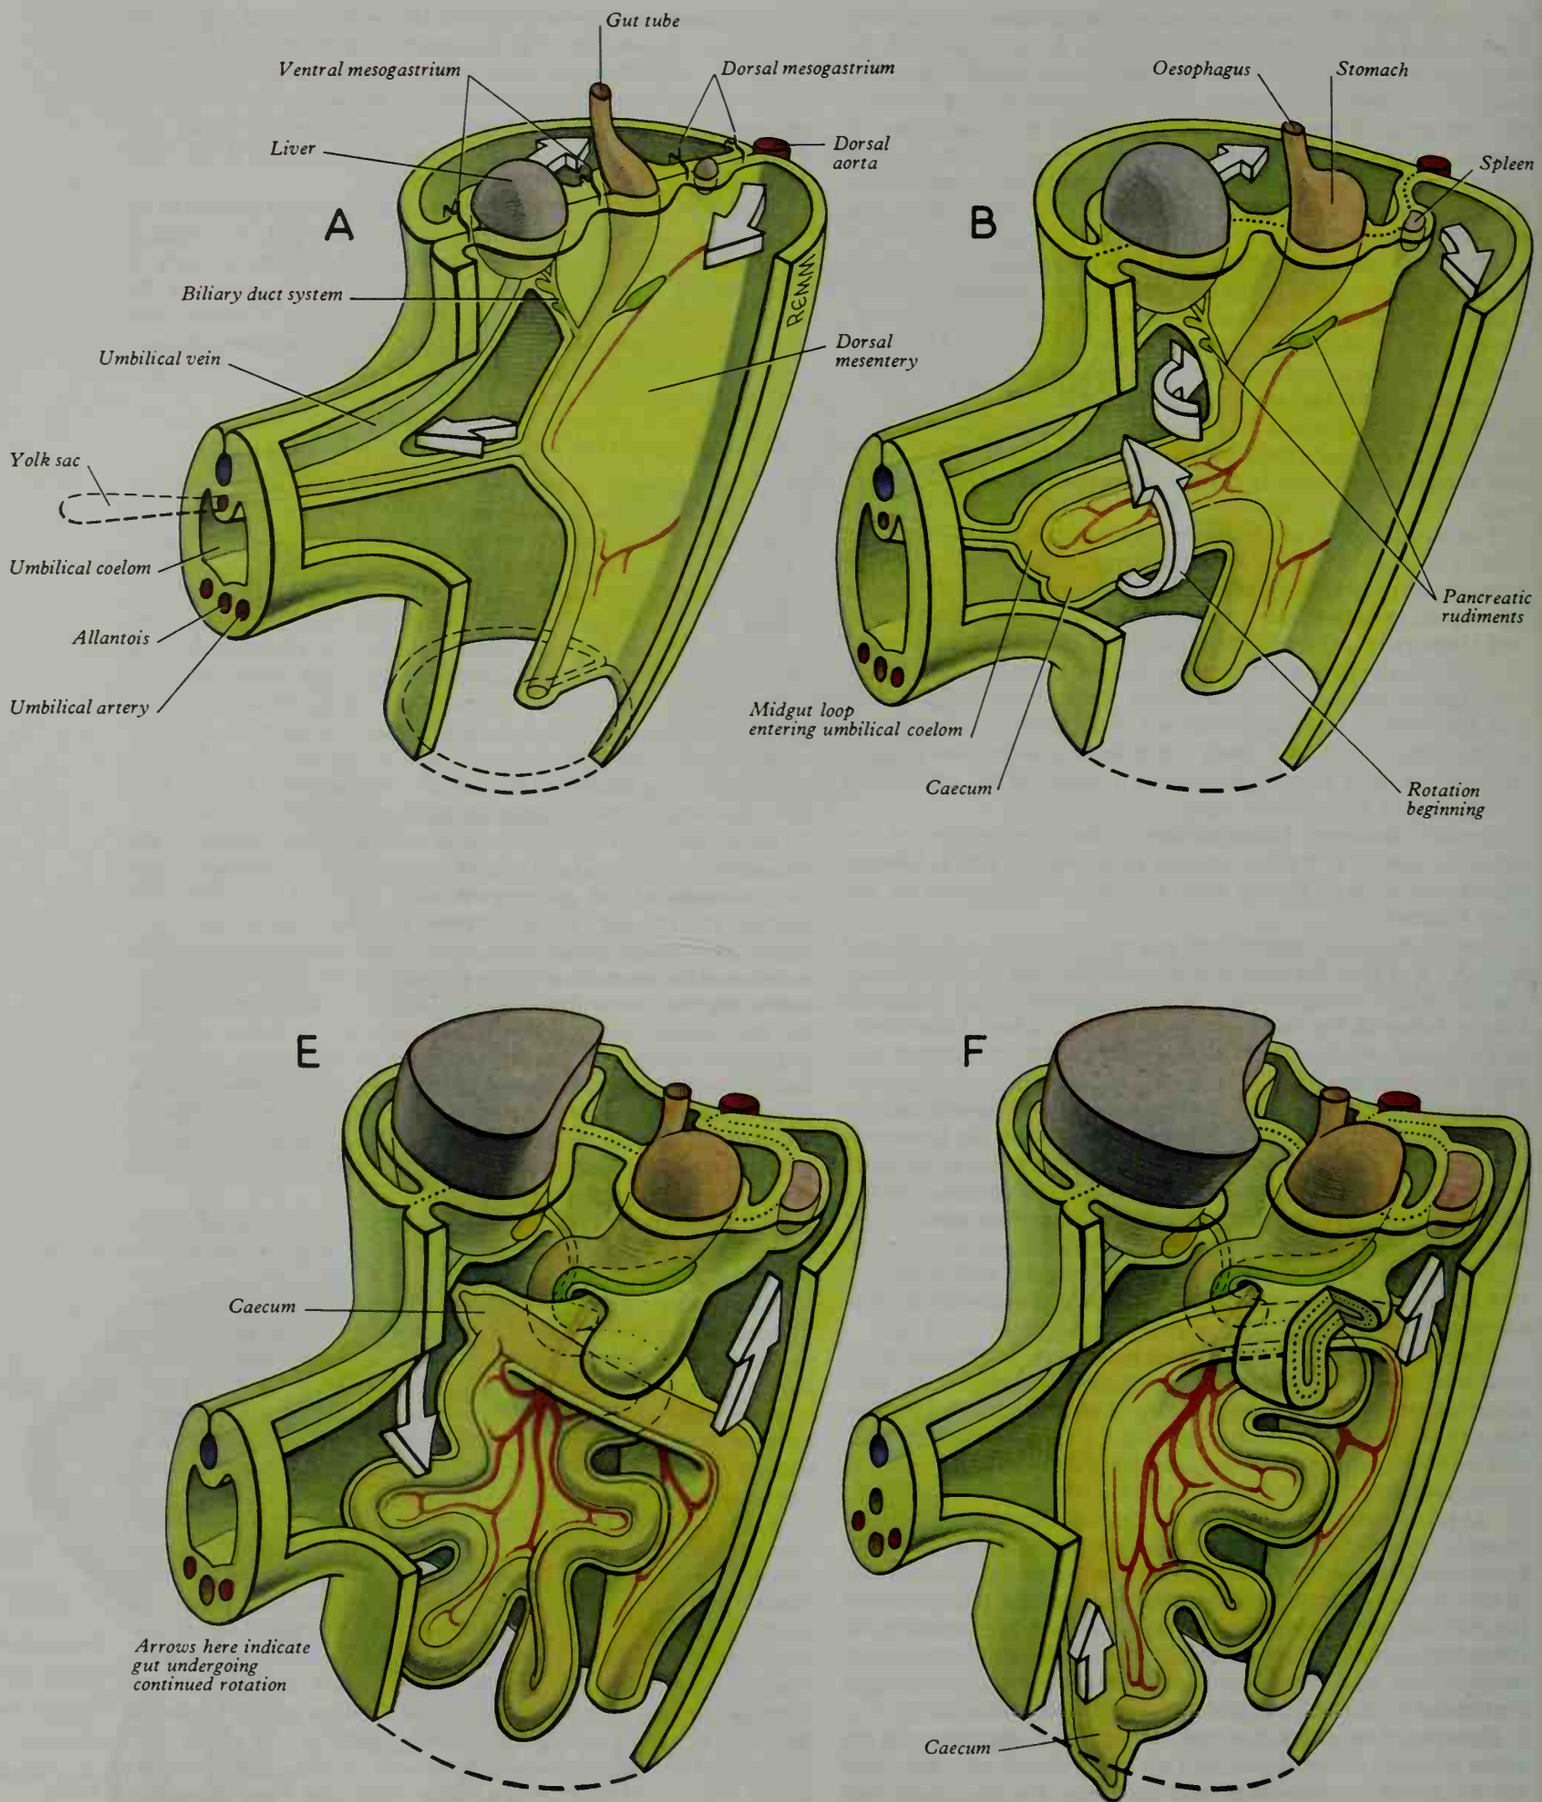
The yolk duct (p. 200) may remain patent as a constituent of the umbilical cord, or its proximal part may persist as an *ileal diverticulum* (of Meckel), which may or may not be anchored to the umbilicus by a fibrous band. In its simplest form this diverticulum is a short, saccular protrusion from the anti-mesenteric border of the ileum about 3 ft above the ileocaecal valve (p. 1345). It may be lined by patches of heterotopic gastric, jejunal, or colonic mucosa, and on occasion it may contain pancreatic tissue. Most commonly, however, it is lined by mucosa similar to that of the surrounding ileum. Postnatal persistence of the yolk duct results in an *ileo-umbilical fistula*; persistence of its distal part only giving an *umbilical* sinus; finally, persistence of its intermediate part may result in a fluid-filled *enterocystoma* suspended from the ileum and umbilicus by fibrous cords.

Rotation of the gut (p. 200) may fail to occur. In these cases the colon occupies the left lower portion of the abdominal cavity and has no connexion with the greater omentum: the duodenum may be spirally coiled and the superior mesenteric vessels pass either behind it or to its left side.

The caecum may retain its fetal form with an apical vermiform appendix. It may fail to complete its rotation, and then lies ventral to the right kidney in close relation to the visceral surface of the liver. Occasionally it is in the transverse mesocolon. (For an analysis of the normal and abnormal development of the vermiform appendix consult Balthazar and Gade 1976.)

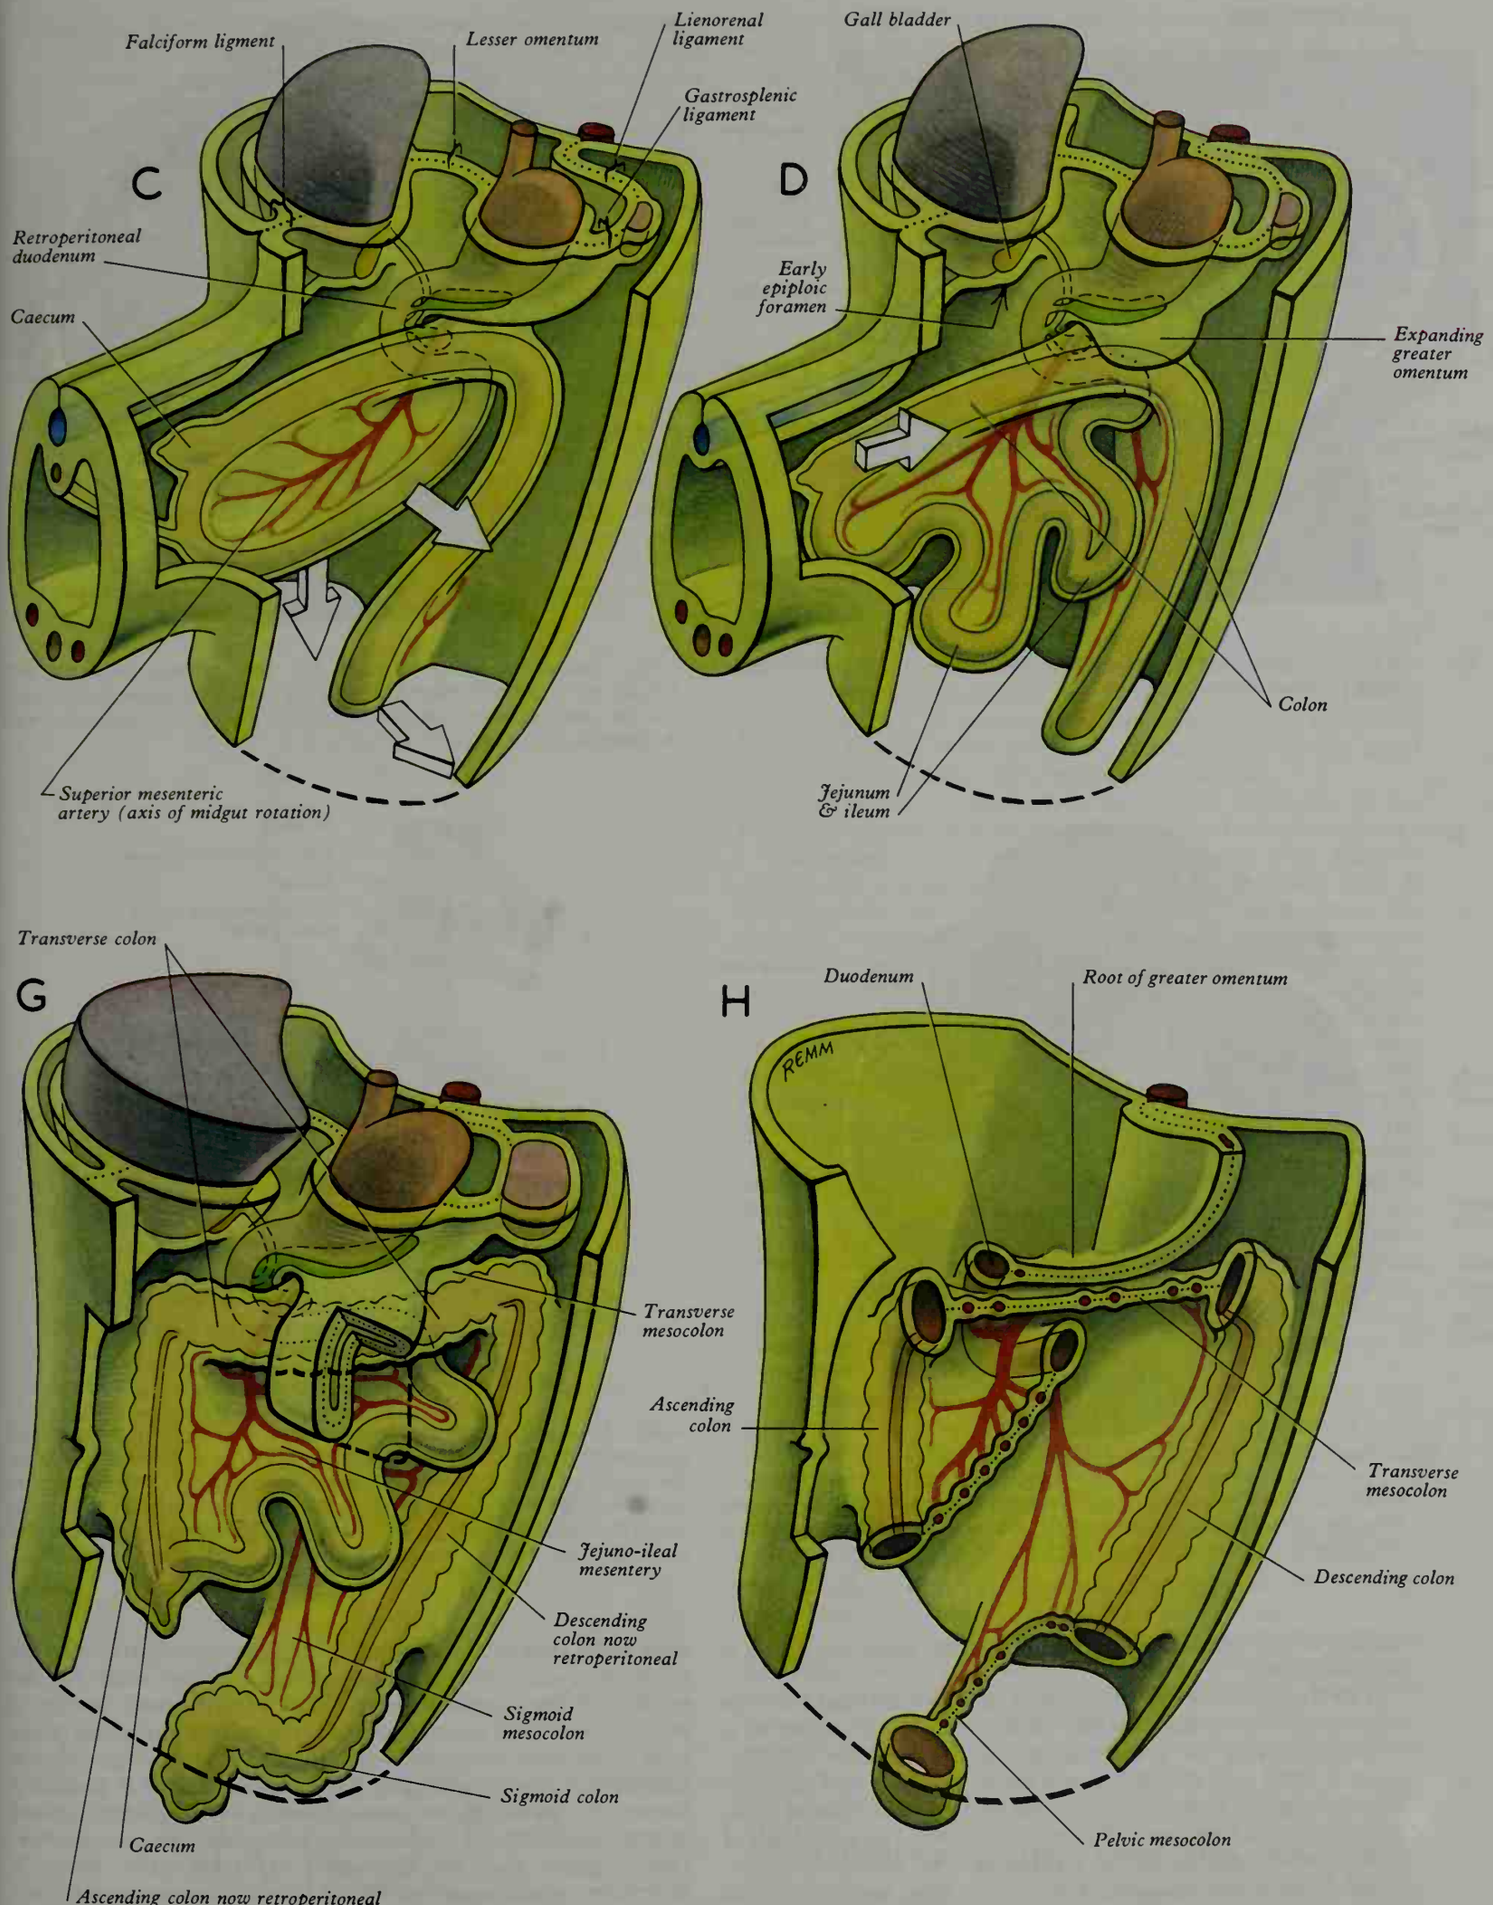
The separation of the endodermal cloaca into ventral and dorsal parts may be incomplete. The rectum then opens into the bladder, urethra or vagina and the anus is imperforate, a condition which may occur without other abnormalities. In some cases it is due to persistence of the anal membrane; in others, the colon may end blindly, considerably above the level of the pelvic floor. The proctodeum may or may not be present.

Because of its mode of development the anal canal is lined in its lower part by modified skin, and in its upper part by mucous membrane, which is endodermal in origin. Abrasions or tears of the wall of the lower part of the anal canal, such as occur in the condition known as anal fissure, are exceedingly sensitive and examination of them is acutely painful. On the other hand, lesions of the upper part of the anal canal are not associated with marked pain or tenderness (p. 1364).



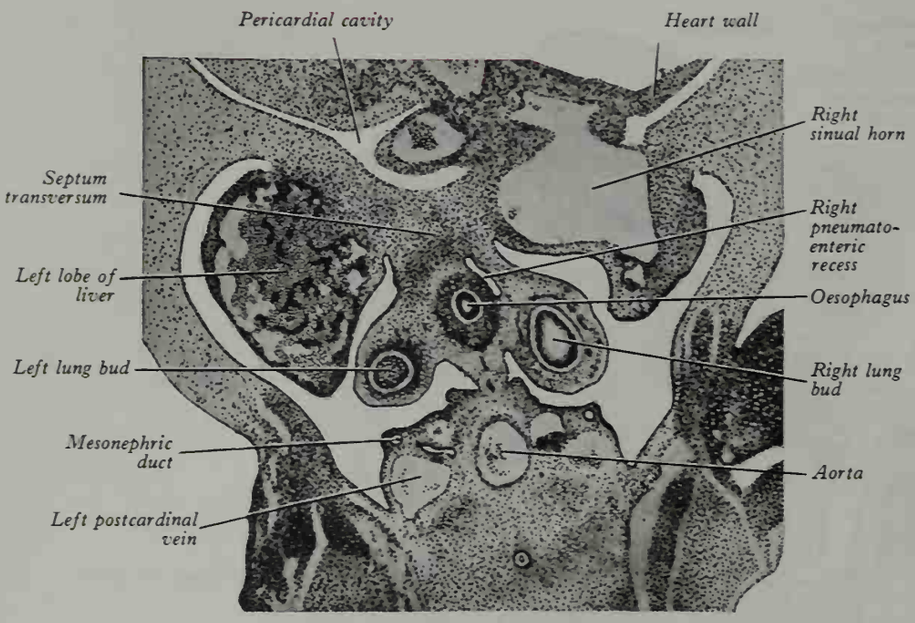
THE PERITONEUM AND THE OMENTAL BURSA

Before the stomach rotates, two peritoneal pockets, the *right* and *left pneumato-enteric recesses*, appear in each side of the dorsal mesogastrium. The left recess is transitory and soon disappears. The right recess communicates with the peritoneal cavity by a small opening to the right and extends cranially along the right side of the oesophagus (2.98A) towards the root of the right lung bud. The right wall of the recess is formed by a mesenteric fold termed the *caval fold* (Kanagasuntheram 1957) which may be derived from the septum transversum. Just below the right pneumato-enteric recess, and sharing with it a common aperture of communication with the peritoneal cavity, is a second recess which extends to the left in the dorsal mesogastrium (2.98B). This is the *pancreatico-enteric recess* (formerly called the *omental bursa*). Its mouth extends from the oesophageal end of the stomach to the duodenum; the cranial and caudal margins of this opening occupy the positions of the gastro-pancreatic folds of the adult and contain the left gastric and hepatic arteries. The pancreatico-enteric recess does not, at first, involve the mesoduodenum. The rotation of the stomach deepens this recess, which lies dorsal to it extending further to the left in the dorsal mesogastrium (2.97). At the caudal end of the pneumato-enteric recess another peritoneal recess extends ventrally and progressively separates the stomach and liver. This is termed the *hepato-enteric recess*. This comes to lie behind the ventral mesogastrium and is carried caudally behind the mesoduodenum. When the caudate lobe of the liver develops it invades the caval fold and then projects from it into the hepato-enteric recess.



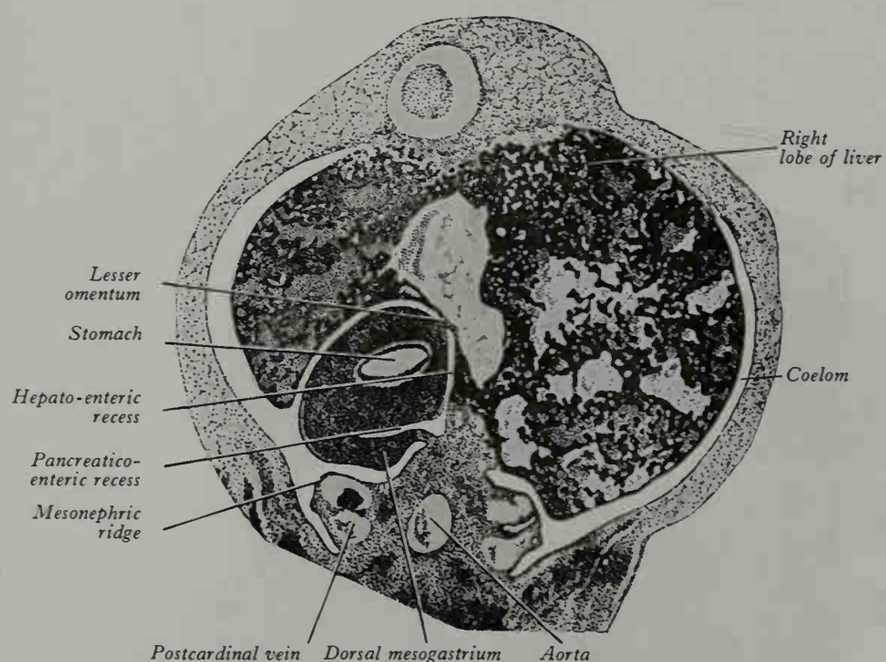
The cranial part of the pneumato-enteric recess is cut off by the development of the diaphragm and forms a small serous sac, the *infracardiac bursa*, within the right pulmonary ligament between the oesophagus and diaphragm. The remainder of this complicated system of peritoneal recesses together constitutes the adult *omental bursa* and the common communication with the peritoneal cavity is the *epiploic foramen*. The caudal part of the pneumato-enteric recess with the hepato-enteric recess form the superior part of the omental bursa in the adult, and the pancreatico-enteric recess gives rise to the inferior part of the omental bursa and its extensions.

As the stomach enlarges, the pancreatico-enteric recess keeps pace with it, and when the intestines return to the abdominal cavity they come to lie caudal and dorsal to its caudal part. In its cranial part the dorsal wall of the recess becomes pressed against the dorsal abdominal wall and the opposed peritoneal layers fuse (2.98D). Up to this time the dorsal mesogastrium is attached in the median plane, but as a result of the fusion the root of the mesogastrium acquires a new, curved attachment to the dorsal wall. From the oesophagus it passes caudally and to the left, becoming the *gastrophrenic* and *lienorenal (spleno-renal) ligaments* of the adult, and then turns to the right and runs somewhat caudally along the line of the pancreas (2.97).

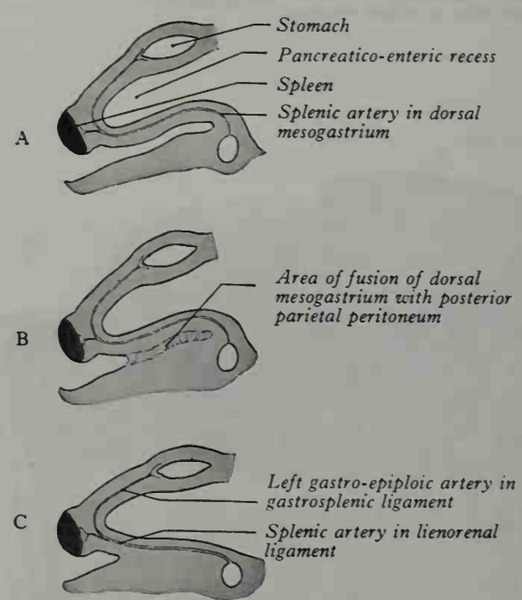


The development of the spleen in the cranial part of the dorsal mesogastrium (p. 207) divides that region of it into *lienorenal* and *gastrosplenic ligaments*. The caudal part of the dorsal wall of the recess remains free and grows caudally, overlapping the transverse colon and the underlying coils of small intestine, forming the greater omentum. Later the two layers of the transverse mesocolon become adherent to the overhanging dorsal

2.97 A three-dimensional schematization of the major developmental sequences of the subdiaphragmatic embryonic and fetal gut, together with its associated major glands, peritoneum and mesenteries, viewed from the left anterolateral aspect. The developmental sequence A–F spans 1½ months to the perinatal period. H denotes the general disposition of the



remaining viscera, mesenteric roots with their lines of attachment, and principal contained vessels, that approximate to the adult state for comparison. Some features of the sequence presented do not correspond to traditional descriptions—see text for further comment.

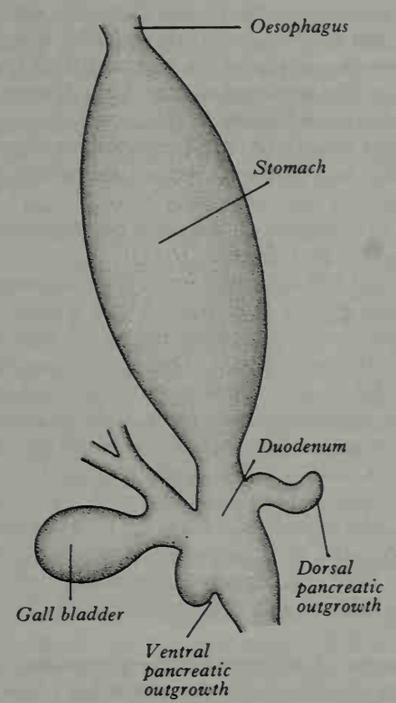


2.98A Transverse section of a human embryo, 8 mm long, showing the right pneumato-enteric recess.

2.98C Transverse section through the same embryo as 2.98B, but 150 μm more caudally. Compare with the preceding figure and observe that the omental bursa (pancreatico-enteric recess) communicates with the general peritoneal cavity at this level.

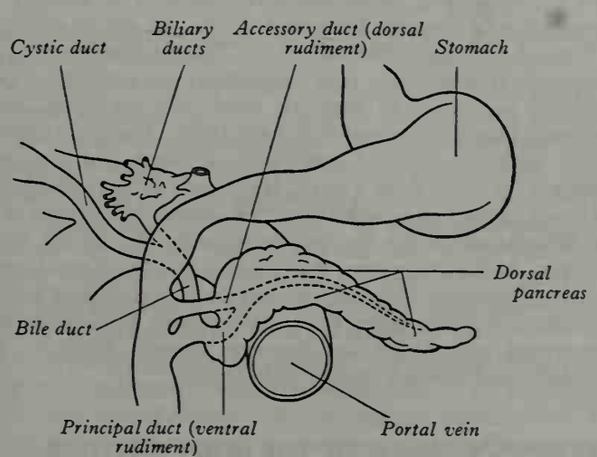
2.98B Transverse section through the same embryo as 2.98A but 530 μm more caudally. Note that rotation of the stomach has taken place and that the sinusoidal spaces in the liver communicate freely with one another.

2.98D Diagram to show the fusion of the proximal part of the dorsal mesogastrium with the peritoneum on the posterior abdominal wall. Note also the conversion of the dorsal mesogastrium into the gastrosplenic and lienorenal ligaments. A represents a transverse section of an embryo in which the dorsal mesogastrium is still at the stage shown in 2.98B. B and C represent transverse sections of older embryos made at the same level.



surface of the greater omentum, so that the adult condition is attained (2.97).

The liver arises in the fourth week as a diverticulum from the ventral surface of the foregut, close to the point where it is continuous with the yolk stalk (2.95A and B). This diverticulum is lined with endoderm, and grows ventrally and cranially into the septum transversum, giving off two solid buds of cells, which form the right and left lobes of the liver. The solid buds of cells develop into epithelial trabeculae, the *hepatic cylinders*, which branch and anastomose to form a close meshwork. The intervals of the meshwork become filled with blood *sinusoids*, and on section the organ has the appearance of a vascular sponge (2.98C). These vessels arise *in situ* as the result of the influence exercised by the endodermal cells of the liver on the potentially angiogenic cells of the mesenchyme of the septum transversum (Streeter 1942). The invasion of the vitelline veins by the epithelial trabeculae of the liver to form a sinusoidal system of vessels occurs only over a restricted area in a few mammals (Elias 1955). By the continued growth and ramification of the endodermal hepatic cylinders the mass of the liver is gradually formed, but its connective tissue stroma is derived from included mesenchymal cells of the septum transversum. Recent observations suggest that the formation of intrahepatic ducts is dependent upon contact between the developing embryonic liver mass and a preformed extrahepatic duct system (Elias 1967). The original diverticulum from the duodenum forms the *bile duct*, and from its distal part the cystic duct and gall bladder arise as an outgrowth, solid at first but later canalized. The bile duct first



opens into the ventral wall of the duodenum; later, it migrates to the left across the dorsal (originally right) surface of the duodenum to the position which it occupies in the adult on the medial (or mesenteric) border. The migration is ascribed to differing rates of growth in the duodenal walls and is aided by proliferation of the lining epithelium of the duodenum, which is most marked in this position (Kanagasuntheram 1960).

As the liver enlarges, it projects more and more into the abdominal cavity from the caudal surface of the septum transversum. In the process, mesenchyme of the septum becomes drawn out ventral to the liver to form the falciform ligament, and craniodorsally to form the coronary and triangular ligaments, and the lesser omentum. These peritoneal folds are collectively the *ventral mesogastrium*. At three months the liver almost fills the abdominal cavity, and its left lobe is nearly as large as its right. Later the relative development of the liver is less active, more especially that of the left lobe, which actually undergoes some degeneration and becomes smaller than the right; but until birth the liver remains relatively larger than in the adult.

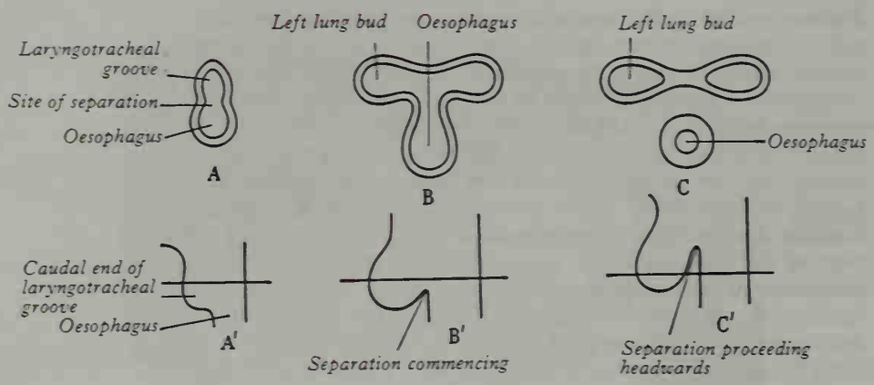
The pancreas (2.99A, B) is developed in *dorsal* and *ventral* parts. The former arises in the latter half of the fourth week as a diverticulum from the dorsal wall of the duodenum a short distance cranial to the hepatic diverticulum; growing craniodorsally in the mesoduodenum it enters that part of the dorsal mesogastrium which is forming the dorsal wall of the bursa omentalis. It forms the whole of the neck, body and tail of the pancreas and a part of the head. The *ventral* part grows out from the primitive bile duct at the point where the latter opens into the duodenum. This outgrowth is at first double, but the two soon fuse, and the resulting single mass grows round the gut into the mesoduodenum, where it enlarges to form the remainder of the head of the gland (Odgers 1930). The duct of the dorsal part the *accessory pancreatic duct*) therefore opens directly into the duodenum, while that of the ventral part (the *main pancreatic duct*) opens with the bile duct. Early in the seventh week the two-parts of the pancreas meet and fuse, and a communication is established between their ducts (2.99B). After this has occurred the terminal part of the accessory duct, i.e. the part between the duodenum and the point of meeting of the two ducts, undergoes little or no enlargement, while the duct of the ventral part increases in size and forms the terminal part of the main duct of the gland. The opening of the accessory duct into the duodenum is sometimes obliterated, and, even when it remains patent, it is probable that almost the whole of the pancreatic secretion is conveyed through the main duct.

2.99A Diagram of an early stage in the development of the pancreas in a human embryo, 7·5 mm long. (After Streeter.)

2.99B A later stage in the development of the pancreas in a human embryo, 14·5 mm long. (After Streeter.)

At first the body of the pancreas grows craniodorsally between the layers of the dorsal mesogastrium, in the dorsal wall of the bursa omentalis. When this wall fuses with the dorsal parietal peritoneum, the process extends tailwards as far as the caudal (inferior) border of the pancreas, and thus, finally, the gland becomes sessile on the dorsal wall of the abdomen.

For details of cytogenesis, exocrine and endocrine, of the human fetal pancreas consult Conklin (1962); Laitio *et al.* (1974).



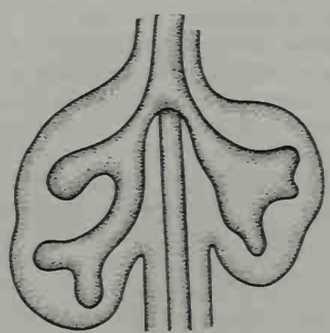
The spleen (2.97, 98D) is not a constituent part of the digestive system, but it is convenient to refer to its development here. It appears about the sixth week as a localized thickening of the coelomic epithelium of the dorsal mesogastrium near its cranial end, and the proliferating cells invade the underlying mesenchyme, which becomes condensed and vascularized. The process occurs simultaneously in several adjoining areas which soon fuse to form a lobulated spleen, derived in part from the coelomic epithelium and in part from the mesenchyme in the dorsal mesogastrium. As the organ enlarges it projects to the left so that its surfaces are covered by the peritoneum of the mesogastrium on its left aspect, thus forming a boundary of the greater sac. When fusion occurs between the dorsal wall of the lesser sac and the dorsal parietal peritoneum, the process does not extend so far to the left as the spleen (2.98D), which remains connected to the dorsal abdominal wall by a short lienorenal ligament, while its primitive connexion with the stomach persists as the gastro-splenic ligament. The earlier lobulated character of the spleen disappears, but is indicated by the presence of notches on its upper border in the adult.

The histogenesis of the spleen has attracted relatively little attention. For earlier accounts consult references (Sabin 1912; Holyoke 1936). The vascular reticulum is well developed at 8 to 9 weeks, with immature reticulocytes and numerous closely spaced thin-walled vascular loops. Differentiation of blood cells, macrophages, and of arteries, veins, capillaries and sinusoids has occurred by the eleventh to twelfth week. The capsule consists at first of cuboidal cells bearing cilia and microvilli (Weiss 1973). Later changes have not yet been described in detail.

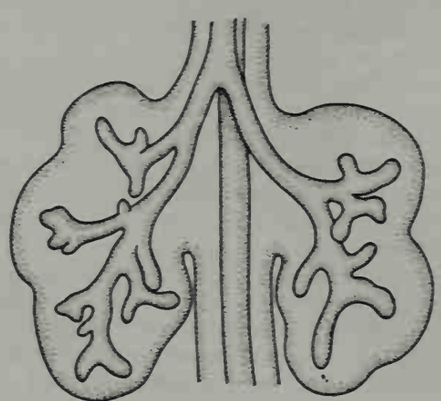
The spleen is subject to various anomalies of development, including complete agenesis, multiple spleens or polysplenia, isolated small additional spleniculi and persistent lobulation. Recently attention has been directed to association of cardiac, pulmonary and other abnormalities with asplenia or polysplenia (Rose *et al.* 1975).

DEVELOPMENT OF LARYNX TRACHEA AND LUNGS

The rudiment of the respiratory tree appears in the fourth week as a median *laryngotracheal groove* in the ventral wall of the pharynx. The groove deepens and its lips fuse to form a septum, converting the groove into a splanchnopleuric *laryngotracheal tube* (2.100A). The process of fusion commences at the caudal end of the groove



2.100A Diagrams to show the closure of the laryngotracheal groove and its separation from the oesophagus in the latter part of the fourth week. (After Streeter.) A, B and C represent transverse sections at the levels shown in A^1, B^1 and C^1, which are outline drawings of the oesophageal region in three closely following stages.



In A and A^1 the laryngotracheal groove communicates freely with the oesophagus.

In B^1 the lower end of the laryngotracheal groove has begun to close and to form right and left evaginations, which represent the earliest rudiments of the lung buds, seen in B.

In C′ the separation of the laryngotracheal groove from the oesophagus has proceeded further in a headward direction, and in C the primitive lung buds are now freed from the oesophagus.

2.100B The lung buds from a human embryo, 11·8 mm long, showing commencing lobulation. (After Streeter, *Contr. Embryol.*, **32**, 1948.)

2.100C The lungs of a human embryo (14·2 mm long) in the early part of the sixth week. (After Streeter.)

and extends cranially, but it does not involve the cranial end of the groove, where the lips remain separate, bounding a slit-like aperture, through which the tube opens into the pharynx. The tube is lined with endoderm, and from this the epithelial lining of the respiratory tract is developed. The cranial end of the tube forms the larynx, and its succeeding part the trachea, while from its caudal end two lateral outgrowths arise and form the stem bronchi and the right and left *lung buds*. These grow into the pleural coeloms and are therefore covered with splanchnic mesenchyme (**2.98A**), from which the connective tissue, cartilage, non-striated muscle and vasculature of the bronchi and lungs are developed.

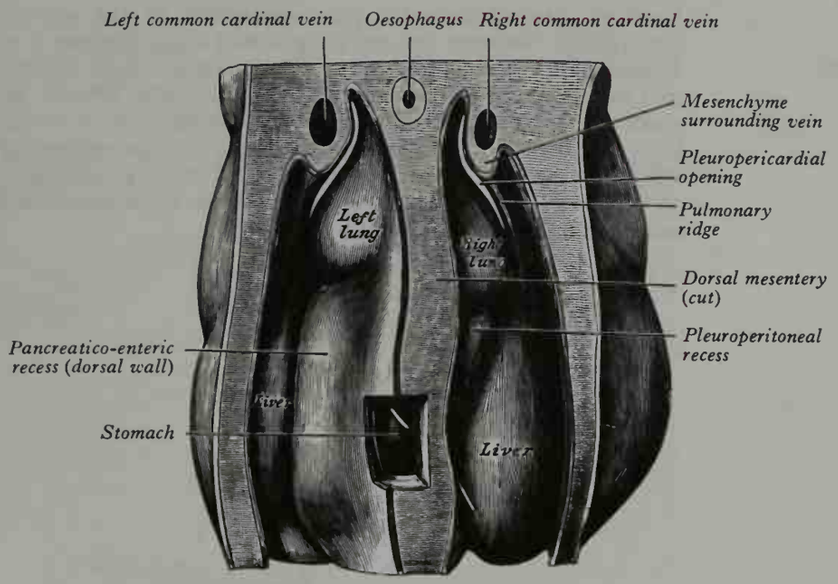
The first rudiment of the **larynx** is the cranial end of the laryngotracheal groove, bounded ventrally by the caudal part of the hypobranchial eminence (p. 197) and on each side by the ventral ends of the sixth arches. Two *arytenoid* swellings appear, one on each side of the groove (**2.92A, B**), and, as they enlarge, they become approximated to each other, and to the caudal part of the hypobranchial eminence (**2.92A, B**), from which the *epiglottis* is developed. The *opening* into the larynx is at first a vertical slit, which is converted into a T-shaped cleft by the enlargement of the *arytenoid swellings*; the vertical limb of the T lies between the two arytenoid swellings and its horizontal limb between them and the epiglottis. Soon after its appearance the epithelial walls of the cleft adhere to each other, and the aperture of the larynx remains occluded until the third month, when its lumen is regained. However, with the upgrowth of the arytenoid swellings and the deepening of the *primitive aryepiglottic folds* forming the walls of the *vestibule*, a new definitive aperture is formed above the level of the primitive aperture, and the latter now corresponds to the level of the *glottis*. The arytenoid swellings differentiate into the *arytenoid* and *corniculate cartilages*, and the folds joining them to the epiglottis become the *aryepiglottic folds*, in which the *cuneiform cartilages* are developed as derivatives of the epiglottis. The *thyroid cartilage* is developed from the ventral ends of the cartilages of the fourth, or fourth and fifth branchial arches; it appears as two lateral plates, each chondrified from two centres and united in the mid-ventral line by a fibrous membrane in which an additional centre of chondrification develops. The *cricoid cartilage* arises from two cartilaginous centres, which soon unite ventrally, and gradually extend and ultimately fuse on the dorsal surface of the tube (see also p. 151). For a recent compilation of literature on the early development of the larynx, consult O'Rahilly and Tucker (1973).

The right and left *lung buds* make their appearance before the laryngotracheal groove is converted into a tube. (An analysis of early pulmonary rudiment development in various mammals is provided by Hjortsjo 1950.) They grow out into the pleural passages caudal to the common cardinal veins and divide into lobules, three appearing on the right, and two in the left lung bud; these divisions are the first indications of the corresponding lobes of the lungs (**2.100B, C**). The buds undergo further subdivision and ramification, and ultimately end in minute expanded extremities—the *infundibula*. After the fifth to sixth month the *air sacs* begin to make their appearance as minute pouches of the infundibula. (For the detailed chronology of the branching, subdivision, phases, and differentiation of the bronchial tree, consult Reid (1976).

Three phases of differentiation—glandular, canalicular and alveolar—are described. In the *glandular phase*, the bronchial divisions are differentiated; their epithelial cells have a prominent Golgi apparatus, scattered RNA granules and glycogen, but few organelles (Leeson and Leeson 1964). In the *canalicular phase* the respiratory parts are delineated and establish an intimate relation with the expanding blood vascular system. The *alveolar phase* extends from 6 months, but new bronchi and alveoli continue to be formed after birth (Wilson 1928). The mechanism of alveolar distension is uncertain; fetal respiratory movements, possibly involving aspiration of amniotic fluid into the lungs, may be involved (Duenhoelter and Pritchard 1973). The main expansion occurs with the onset of respiration at birth, but may not be complete for some days. During the course of their development the lungs migrate in a caudal direction, so that by the time of birth the bifurcation of the trachea is opposite the fourth thoracic vertebra. As the lungs grow they project into the pleural passages and the splanchnic mesenchyme enveloping each lung rudiment expands on it and becomes the visceral pleura. For bibliographies concerning pulmonary development consult Boyden (1972); O'Rahilly and Boyden (1973); Reid (1976).

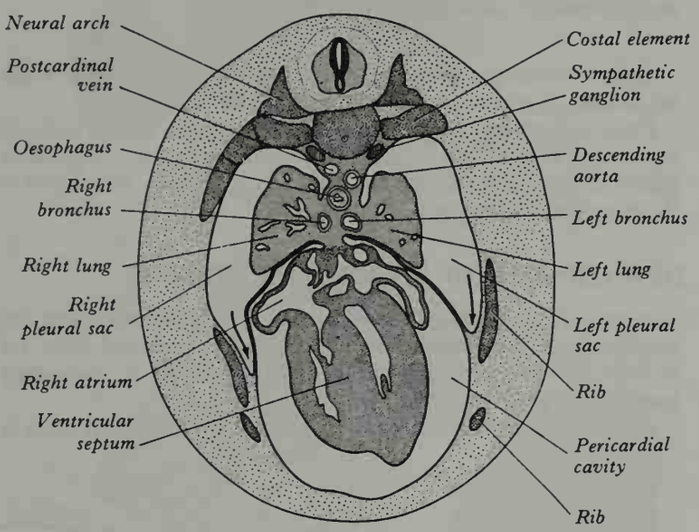
THE DEVELOPMENT OF THE BODY CAVITIES

The formation of the intra-embryonic coelom and its mode of communication with the extra-embryonic coelom have already



been described (p. 118). After the formation of the head fold the *pericardium* connects dorsally with the coelomic ducts, which open caudally into the peritoneal cavity. When the lung buds develop they project into the coelomic ducts, which may now be termed the *pleural coeloms*, and their communications with the pericardial and peritoneal coeloms, become the *pleuropericardial* and *pleuroperitoneal canals* respectively (**2**.98A, 100D).

A ridge of tissue, the *pulmonary ridge*, develops on the lateral side of the pleural coelom and partly encircles the pleuropericardial canal. The ridge is continuous dorsally with the septum transversum. The developing lung bud abuts on the ridge, which gives rise to two diverging membranes meeting at the septum transversum. One of these is cranially placed and is termed the *pleuropericardial membrane*; within its substance is the common cardinal vein and the phrenic nerve, which reach the septum transversum by this route. The other membrane is caudally placed and is termed the *pleuroperitoneal membrane*. As the apical part of the lung forms it invades the body wall and extends cranially on the *lateral aspect* of the common cardinal vein, carrying with it an extrusion of the pleural passage to form the definitive pleural sac. In this way the common cardinal vein and the phrenic nerve come to lie medially in the mediastinum. The pleuropericardial canal, which lies medial to the vessel, is gradually narrowed to a slit, which is soon obliterated by the apposition and fusion of its margins (**2**.101A). Its closure occurs early and is mainly effected by the growth and expansion of the surrounding viscera, the heart, lungs, trachea and oesophagus, and not by active growth of the pleuropericardial membrane across the opening to the root of the lung (**2**.101A).

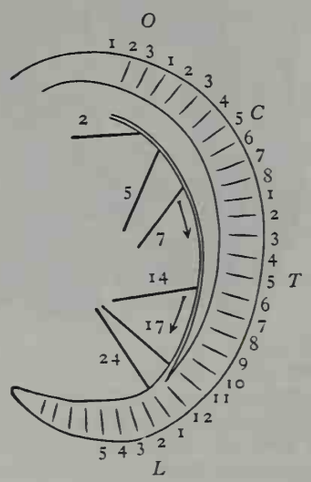


In addition to its extension in a cranial direction the lung enlarges ventrally and medially, and the pleura is therefore carried into the body wall over the surface of the pericardium, thus separating it from the lateral thoracic walls (**2**.101B).

The separation of the pleural and peritoneal cavities from each other is effected by the development of the diaphragm. The septum transversum at first forms a sheet of mesoderm, caudal to the pericardial cavity and extending from the ventral and lateral regions of the body wall to the foregut. Dorsal to it on each side is the pleuroperitoneal canal. The liver grows into the septum transversum, which now can be seen to consist of two parts. One, the *pars diaphragmatica*, is disposed in the transverse plane and lies over the convex cranial surface of the liver. The other, the *pars mesenterica*, lies in the median sagittal plane and is expanded by the developing liver. At this stage the liver is widely attached to the pars diaphragmatica and to the ventral abdominal wall. These attachments are the forerunners of the coronary and triangular ligaments and of the falciform ligament respectively. Medial to the pleuroperitoneal canals, are the oesophagus and stomach, with the dorsal mesentery, and at the root of the latter the dorsal aorta. Dorsolateral to the canals are the pleuroperitoneal membranes, which remain small; dorsally are the mesonephric ridges, suprarenals and gonads. Just as the enlargement of the pleural cavity cranially and ventrally is effected by a process of burrowing into the body wall, so its caudal enlargement is effected in the same way. The expanding pleural cavities extend into the mesoderm dorsal to the suprarenal glands, gonads and mesonephric ridges. This mesoderm is peeled off the dorsal body wall to form a substantial portion of the lumbar part of the diaphragm. The pleuroperitoneal canal is closed by the fusion of its edges, which are carried towards one another by the growth of the organs surrounding it and in particular of the suprarenal, which carries the dorsal margin ventrally to meet the pars diaphragmatica of the septum transversum (Wells 1954). The right pleuroperitoneal canal closes earlier than the left. It is therefore on the left that an abnormal communication between the pleural and peritoneal cavities more frequently occurs. The further development of the peritoneal cavity has already been described (p. 205).

While these changes are in progress, the septum transversum undergoes a progressive alteration in position. In a 2 mm human embryo, the dorsal border of the septum transversum lies opposite the second cervical segment but as the embryo grows, and the heart enlarges, it migrates in a caudal direction. At first the ventral border moves more rapidly than the dorsal, but after the embryo has attained a length of 5 mm it is the dorsal border which

2.101A A view, from the dorsal aspect, into the thoraco-abdominal part of the coelom of a human embryo 6·8 mm long, in the fifth week. Note that the dorsal body wall, including the spinal cord, developing vertebral column, the dorsal aorta and the mesonephroi, has been removed. A window has been made in the dorsal wall of the pancreatico-enteric recess to expose the posterior surface of the stomach and a wire has been passed through the epiploic foramen. (After Piper.)



2.101B Transverse section of a 21 mm human embryo, showing how the pleural sacs extend ventrally on each side of the pericardium and split the body wall. The arrows indicate the directions of growth of the two pleural sacs.

migrates more rapidly (**2**.102A). When the dorsal border of the septum transversum lies opposite the fourth cervical segment, the phrenic nerve (C 3, 4 and 5) and portions of the corresponding myotomes grow into it and accompany it in its later migrations. It is not until the end of the second month that the dorsal border of the septum transversum is opposite the last thoracic and first lumbar, segments, the final position occupied by the dorsal attachment of its derivative, the diaphragm.

The Development of the Diaphragm

The closure of the pleuroperitoneal openings completes a mesodermal partition which separates the thoracic from the abdominal viscera and which occupies the position of the future diaphragm. This partition has a composite origin. The sternal and costal parts are derived almost exclusively from the pars diaphragmatica of the septum transversum, with a very small dorsolateral contribution from the pleuroperitoneal membranes and from the thoracic wall (costal portion). Anterior to the oesophageal hiatus is a small contribution from the gastrohepatic

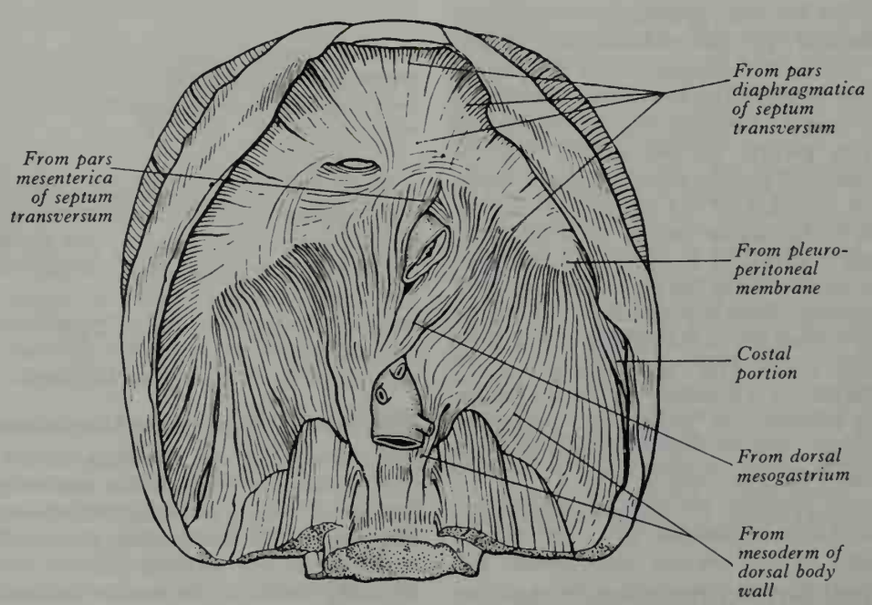
ligament, derived from the pars mesenterica of the septum transversum. Between the oesophageal and aortic hiatuses it is formed by the dorsal mesentery. The remainder of the lumbar part of the diaphragm is formed in the mesoderm around the abdominal aorta and more laterally in the mesoderm of the dorsal body wall behind the suprarenal, mesonephric ridge and gonad (Wells 1954). Some authorities consider that much greater areas of the adult diaphragm are derived from the pleuroperitoneal membranes and from the chest wall.

2.102A Schema showing stages in the descent of the septum transversum. The numerals on the heavy lines indicate the length of the embryo in mm, and the position of the occipitial, cervical, thoracic and lumbar segments is also shown. (After Mall.)

Gaps between the lumbar and costal portions of the diaphragm are usually due to under-development of the latter.

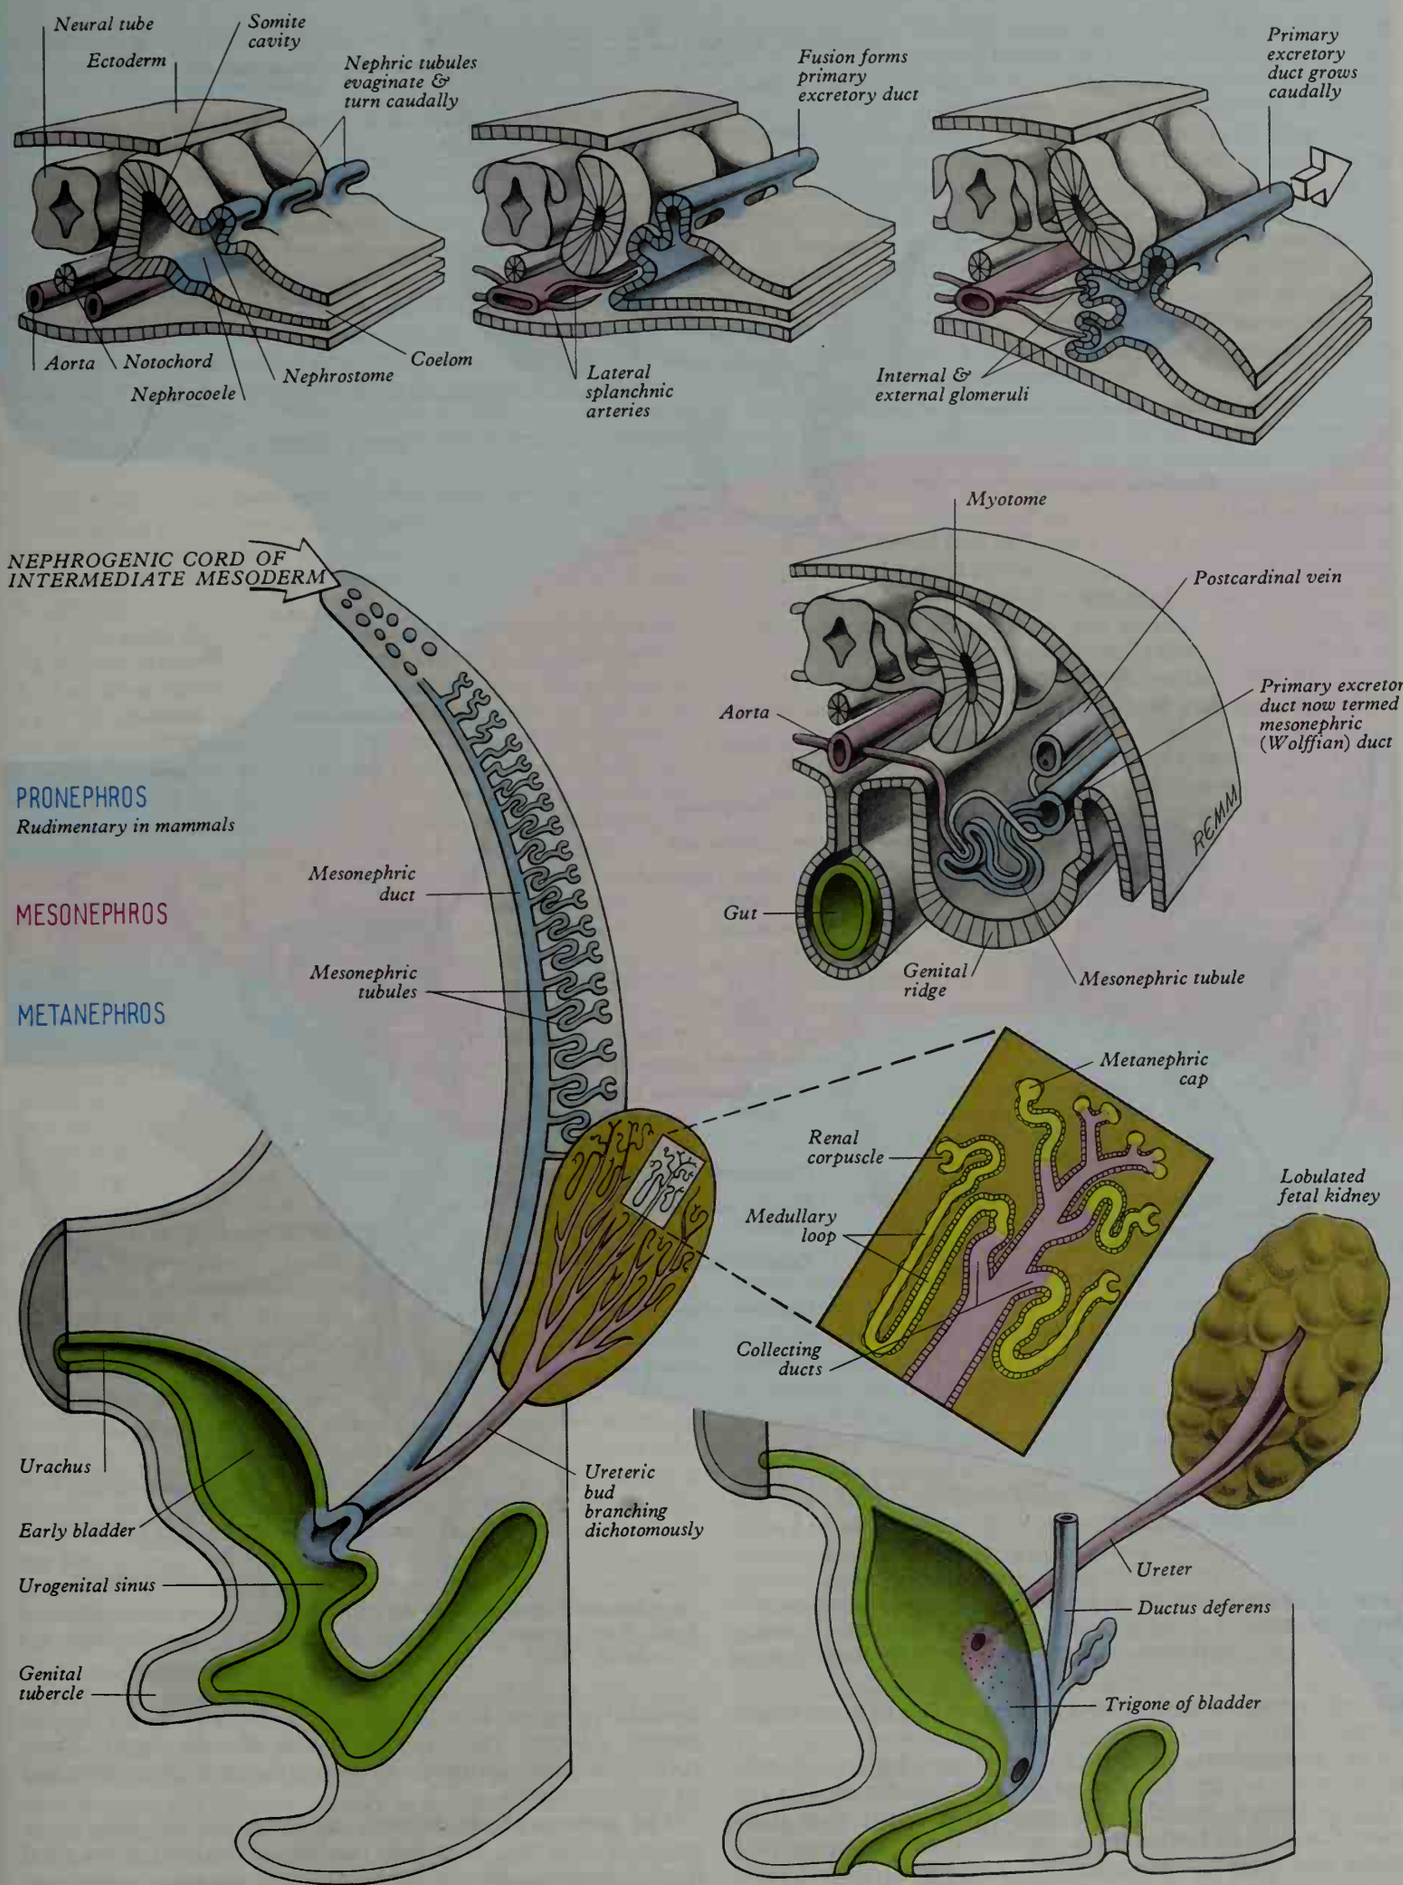
Premuscle tissue, derived principally from the fourth cervical myotomes, invades the septum transversum as already described and from there extends into the rest of the partition, giving rise to the muscular diaphragm (2.102B).

DEVELOPMENT OF UROGENITAL ORGANS



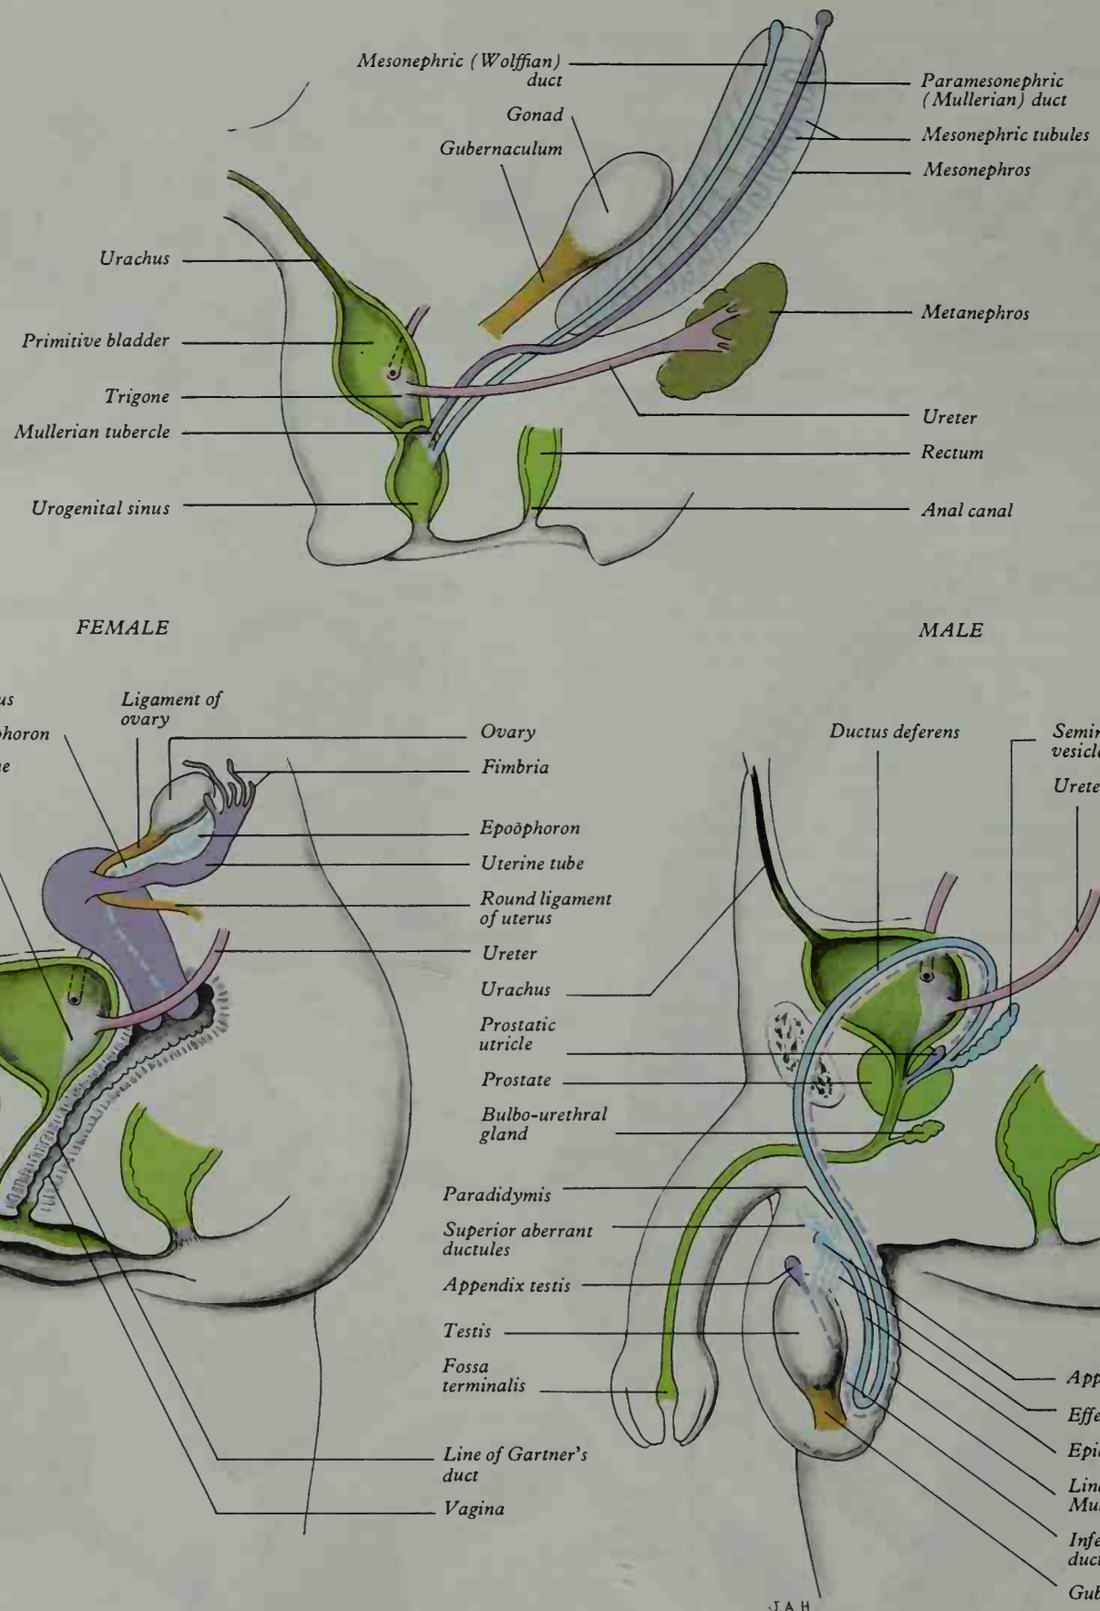
The urinary and reproductive organs are developed from the mesoderm of the *intermediate cell mass* (p. 117) and they are intimately associated with one another especially in the earlier stages of their development.

Typically, in lower vertebrates, the intermediate cell mass is divided into a series of segments, the *nephrotomes* (2.103A), each of which develops a cavity, a *nephrocoele*, which communicates with the coelom through a *peritoneal funnel*. In each segment the dorsal wall of the nephrotome is evaginated to form a *nephric tubule* communicating with the nephrocoele by means of a *nephrostome*. The outer ends of the earlier developed nephric tubules bend caudally and fuse to form a longitudinal *primary excretory duct*, which grows first caudally and then ventrally to open into the cloaca. The more caudally placed and later developed tubules open secondarily into this duct or into tubular outgrowths from it. The *glomeruli* arise from the ventral wall of the nephrocoele (*internal glomeruli*) or in the roof of the coelom adjacent to the peritoneal funnels (*coelomic* or *external glomeruli*) or in both situations (2.103A). These external glomeruli are usually transitory.



It has been customary to regard the renal excretory system as consisting of three organs, the *pronephros*, *mesonephros* and *metanephros*, which succeed one another in time and space. The last of these to develop is retained as the permanent kidney. It must be noted that it is impossible to provide reliable criteria that distinguish them as individual organs or to define their precise limits in the embryos of all animals. A pronephros cannot be distinguished as a separate organ in man; the earliest and most cranially situated nephric tubules are rudimentary and transient and are generally regarded as marking the pronephric region. This region merges caudally without a clear line of demarcation into the mesonephros.

In the human embryo the development of nephrotomes and their cavitation to form nephrocoeles which communicate with the coelom is confined to the levels of the most cranial somites. Caudal to about the level of the eighth somite the mesoderm of the intermediate cell mass is fused into an unsegmented *nephrogenic cord*. This is connected at irregular intervals with the coelomic epithelium. No nephric tubules are developed at the most cranial levels.



The *primary excretory duct* begins to develop in embryos of about 14 somites (23 to 24 days) as a solid rod of cells in the dorsal part of the nephrogenic cord. At this stage its cranial end is placed at about the level of the ninth somite and its caudal end merges with the undifferentiated mesoderm of the nephrogenic cord. It begins to differentiate before any nephric tubules and is at first unconnected with them. In older embryos it has lengthened and its caudal end becomes detached from the nephrogenic cord to lie immediately beneath the ectoderm. From this level it grows caudally, independently of the nephrogenic cord, and then curves ventrally to reach the wall of the cloaca. It becomes canalized progressively from its cranial end to form a

2.102B Inferior surface of the diaphragm showing the derivation of the different parts. (After L. J. Wells, *Contr. Embryol.*, **35**, 1954.)

2.103A Principal features of the primitive vertebrate nephric system for comparison with the development of the human nephric system. It should be appreciated that a considerable period of embryonic and fetal life has been necessarily compressed into a single, static diagram. (Modified from *Basic Human Embryology*, by Williams, Wendell-Smith and Treadgold, 1969.)

2.103B Disposition and fate of the mesonephric and paramesonephric ducts, mesonephric tubules, gonads and gubernaculum, primitive bladder and urogenital sinus, and ureters, as seen in the transformation from the indifferent stage to the condition in the two sexes. (Modified from *Basic Human Embryology*, by Williams, Wendell-Smith and Treadgold, 1969.)

duct which opens into the cloaca in embryos of 4 to 5 mm length (about 28 days).

The pronephros is first indicated as clusters of cells (rudimentary nephric tubules) in the nephrogenic cord (**2**.103 A, B). In regions cranial to the primary excretory duct these clusters develop no further. More caudally similar groups of cells appear and these become vesicular. The dorsal ends of these vesicles join the primary excretory duct, their central ends being connected with the coelomic epithelium by cellular strands probably representing rudimentary peritoneal funnels. Glomeruli are not developed in association with these cranially situated nephric tubules, which ultimately disappear. It is doubtful whether external glomeruli develop in the human embryo (Torrey 1954; O'Rahilly and Muecke 1972). These rudimentary nephric tubules constitute the pronephros described by earlier workers.

The mesonephros develops caudal to the foregoing rudiments (**2**.103, 104). It extends caudally to the level of the third lumbar segment, and its nephric tubules are more completely differentiated and distinct internal glomeruli are formed. As in the more cranial region, each tubule first appears as a mass of cells which becomes hollowed in the centre. One end of the vesicle grows towards and opens into the primary excretory duct, which may now be termed the *mesonephric duct*, whilst the other forms

the internal glomerulus. This becomes dilated and invaginated to form the *glomerular capsule*, the invaginated segment proliferating the tissue from which the glomerular capillaries are developed. These are supplied with blood through a lateral branch of the aorta (Streeter 1945). In all, it is estimated that about 70 to 80 tubules and a corresponding number of glomeruli develop, but these are not segmental in arrangement. All these tubules, however, are not present at the same time and it is rare to find more than 30 to 40 in any individual embryo, for the cranial tubules and glomeruli atrophy and disappear before the development of those which are situated more caudally. By the end of the sixth week the mesonephros forms an elongated spindle-shaped organ which projects into the coelomic cavity on each side of the dorsal mesentery from the septum transversum to the third lumbar segment. This projection is the *mesonephric ridge* (Wolffian body) and the genital gland is developed on its medial surface.

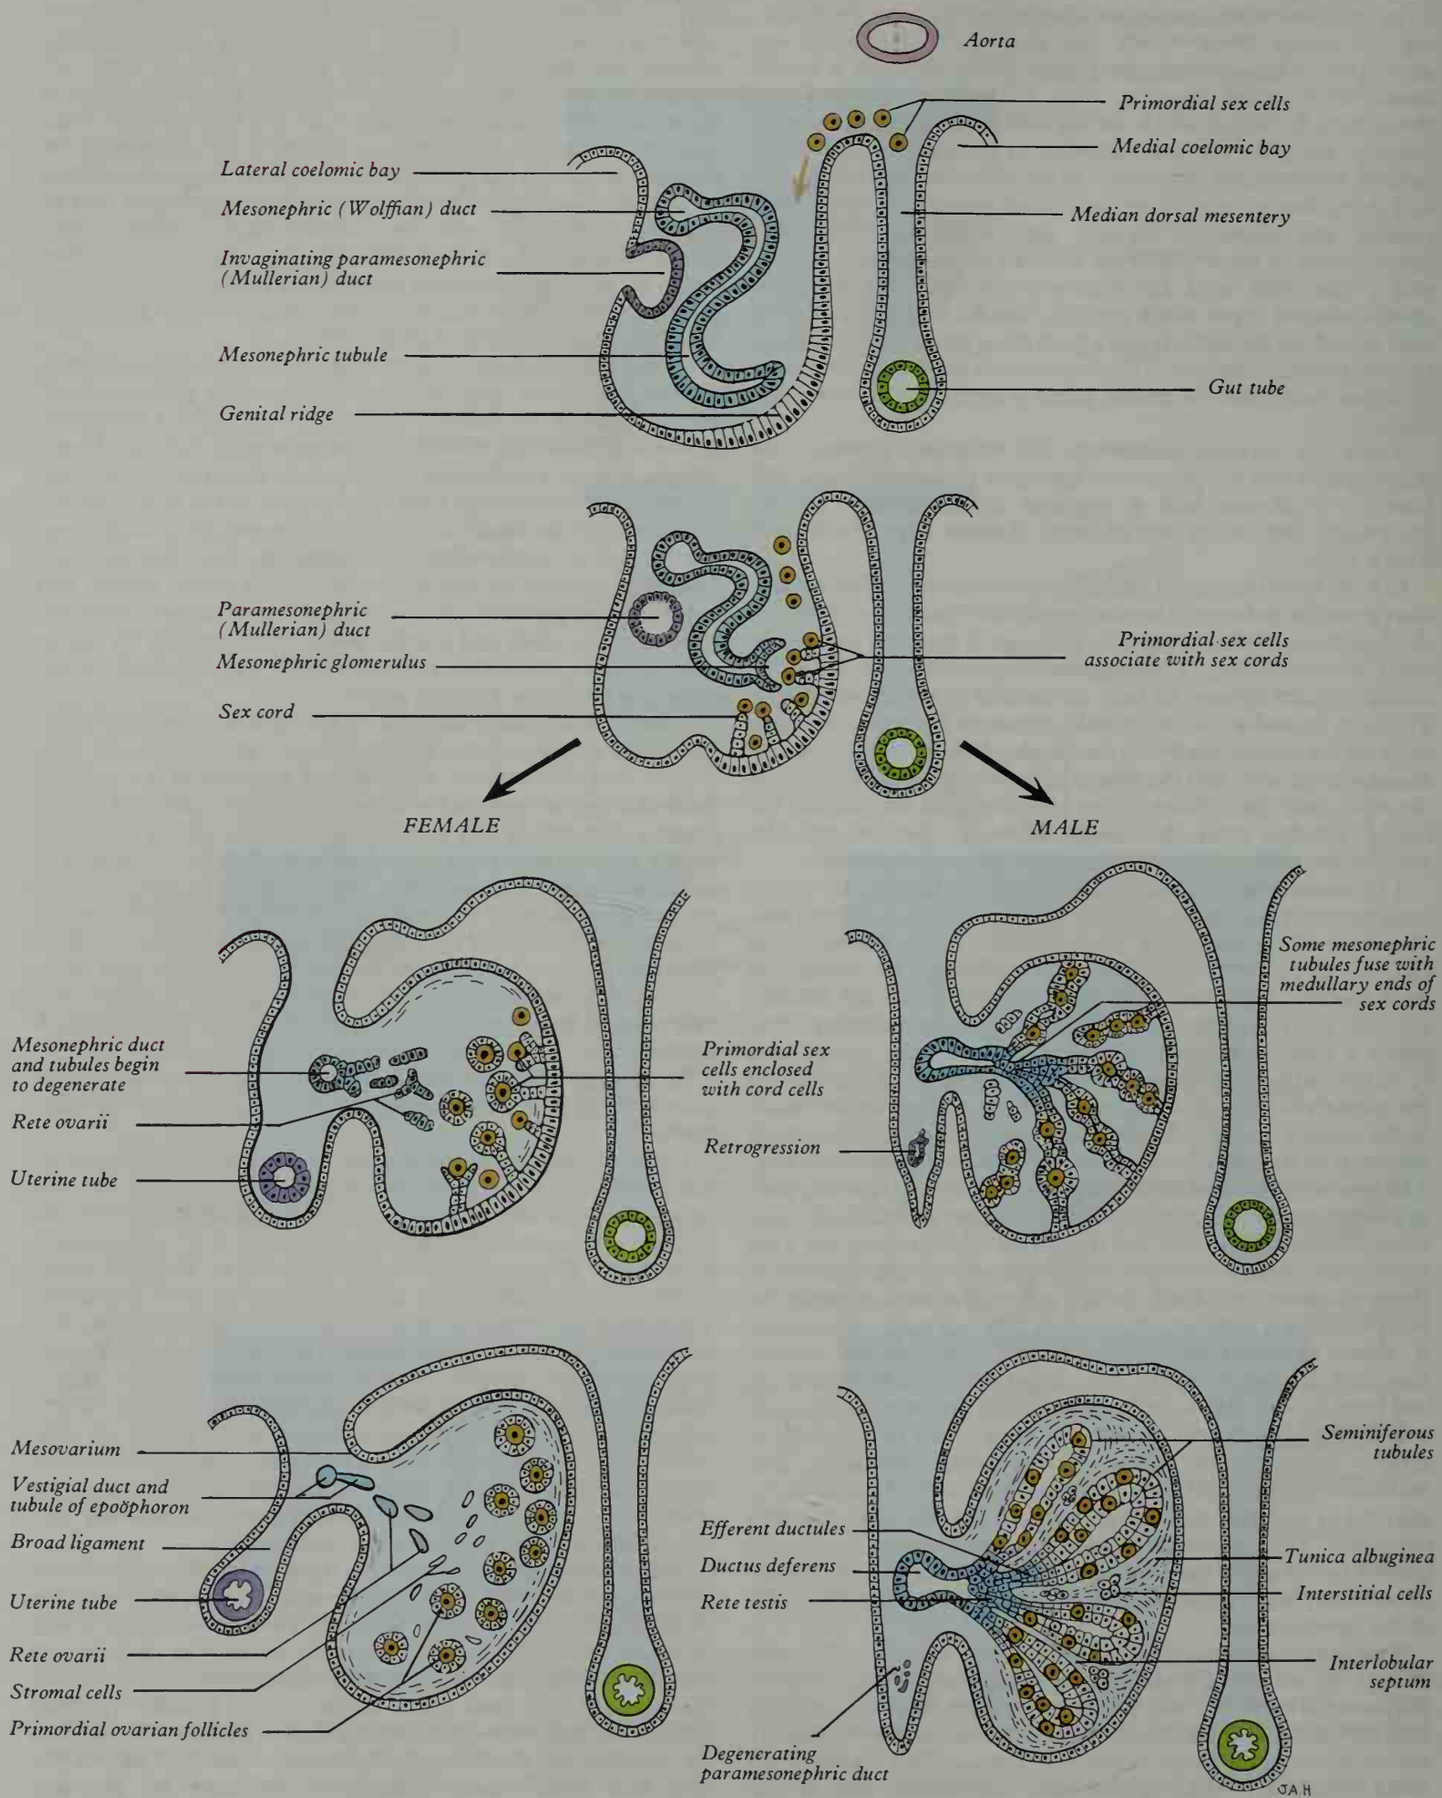
There are striking similarities in structure between the mesonephros and the permanent kidney or metanephros, but the former's nephrons lack a segment corresponding to the descending limb of the loop of Henle (Leeson 1957; Davies and Routh 1957).

In both sexes the cranial end of the mesonephros atrophies and disappears; in embryos of 20 mm length the organ is found only in the first three lumbar segments, although it may still possess as many as 26 tubules. (This massive degeneration of the more cranial tubules appears to have no parallel in other mammals.) The most cranial one or two tubules persist as the *rostral aberrant ductules*; the succeeding five or six tubules develop into the *efferent ductules of the testis* and the *lobules of the head of the epididymis* in the male, and the tubules of the *epoöphoron* in the female; the caudal tubules form the *caudal aberrant ductules* and the *paradidymis* in the male, and the *paroöphoron* in the female.

The *mesonephric duct* runs caudally in the lateral part of the mesonephric ridge, at the caudal end of which it is projected into the cavity of the coelom in the substance of a mesodermal fold (**2**.105A, C, D; 107A–F). As the ducts approach the urogenital sinus the two folds fuse with each other, between the bladder ventrally and the rectum dorsally, forming across the cavity of the pelvis a transverse partition which is termed the *genital cord* (**2**.105C). In the male the peritoneal fossa between the bladder and the genital cord becomes obliterated, but it persists in the female as the uterovesical pouch. The mesonephric duct itself becomes the canal of the *epididymis*, *ductus deferens* and *ejaculatory duct*. The *seminal vesicle* and the ampulla of the ductus deferens appear as a common swelling at the termination of the mesonephric duct around the end of the third and the start of the fourth month. This combined rudiment coincides in appearance with degeneration of the paramesonephric ducts, though no causal relation between the two processes is apparent. Separation into two rudiments occurs at about 125 mm crown–heel length. The seminal vesicle elongates, its duct becomes demarcated, and hollow diverticula bud from its wall. At about the sixth month (300 mm crown–heel length) the growth rate of both the vesicle and the ampulla is greatly increased, the cause of this being unknown. The acceleration may result from increased secretion of prolactin by the fetal or maternal hypophysis, or from the effects of placental hormones. The tubules of the prostate show a similar increase of growth rate at about the same time (Nilsson 1962). In the female the mesonephric duct is vestigial, becoming the longitudinal duct of the epoöphoron.

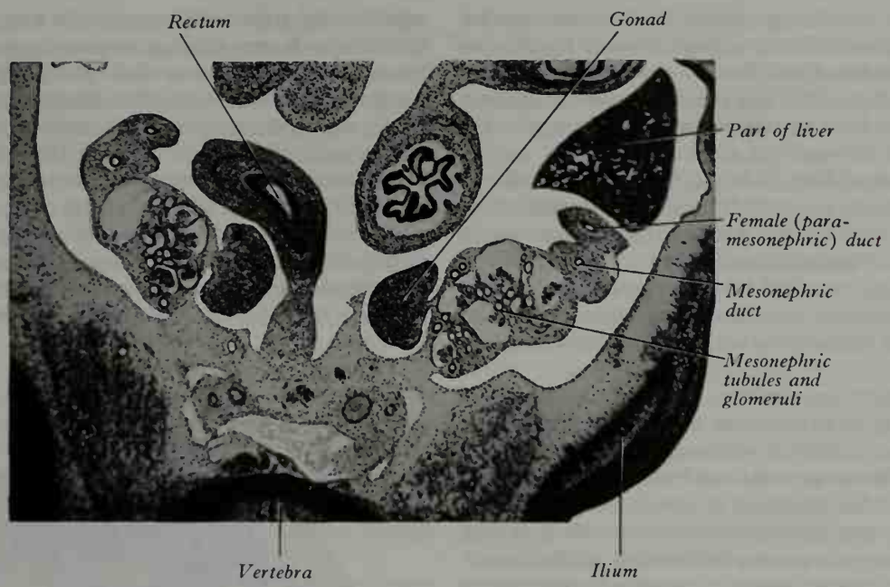
The metanephros, or permanent kidney, has a double origin (**2**.103). At about the 5 mm stage an outgrowth forms from the dorsomedial aspect of the mesonephric duct, near the point at which it opens into the cloaca. This is the *metanephric* (*ureteric*) *diverticulum*, and it grows dorsally at first and then cranially. Its blind extremity, which grows into the caudal end of the nephrogenic cord, becomes expanded and the adjoining mesoderm condenses around it to form the *metanephrogenic mass* or *cap* (**2**.103, 106). The presence of the actively growing extremity of the diverticulum may be regarded as an important factor in determining the differentiation of the mesoderm, and it may be noted that in cases where the ureter fails to develop, no metanephrogenic cap is formed. The stalk of the diverticulum becomes the *ureter*, and its expanded cranial end gives origin not only to the *pelvis* of the kidney and its *calices* but also to the *collecting tubules* of the kidney. The secreting and convoluted tubules and the renal corpuscles are all derived from the metanephrogenic cap in a manner similar to the development of the mesonephric tubules and glomeruli. The blood vessels of the glomeruli develop *in situ* from mesenchyme in the concavity of the glomerular capsule (Lewis 1958) and extend by repeated splitting of the lumina of the first-formed capillaries (Zamboni and de Martino 1968). The secretory tubules must establish communication with the ends of the collecting tubules; should they fail to do so, congenital cysts of the kidney will be formed. (For details of the tubulo-vascular relationships in the developing kidney consult Speller and Moffat 1977.)

From the expanded extremity of the ureter arise four collecting tubules of the first order and it itself forms the primitive renal pelvis. Each of the tubules ends in an ampullated extremity, from which collecting tubules of the second order bud out. These, in turn, give rise to collecting tubules of the third order, and so on. In some animals the four collecting tubules of the first order are absorbed into the renal pelvis, which then presents a single renal papilla and no subdivision into calices. In man, however, the collecting tubules of the first and second order persist and constitute, respectively, the major and minor calices, while the tubules of the third and fourth orders are taken into the minor calices which, therefore, directly receive the openings of the collecting tubules of the fifth order.



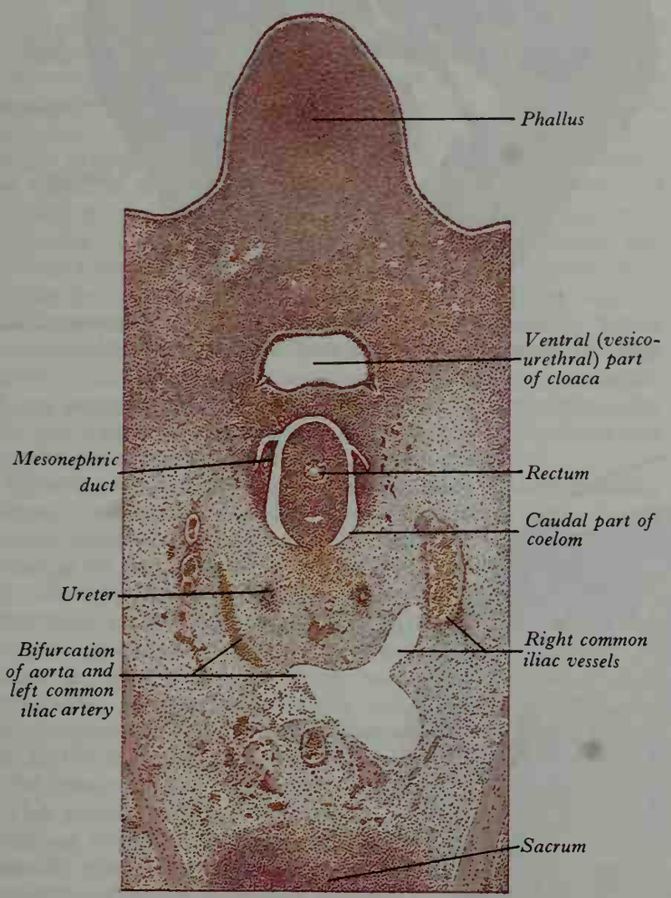
When it first appears, the renal rudiment is in the pelvic region, but, as the ureteric outgrowth lengthens, it grows cranially, and, by the time the embryo has attained a length of 13 mm, its expanded pelvis lies on a level with the second lumbar vertebra. During this period the developing kidney receives its blood supply from arteries in its immediate neighbourhood, the middle sacral and common iliac arteries, and the definitive *renal artery* is not recognizable until the beginning of the third month. It arises from the most caudal of the three suprarenal arteries, all of which represent persistent mesonephric or lateral splanchnic arteries (p. 191). Additional renal arteries are by no means uncommon. They may enter at the hilum or at the upper or lower pole of the gland, and they also represent persistent mesonephric arteries.

At an early stage the kidney is lobulated, a condition which persists through fetal life but disappears during the first year after birth.



Further development of the ureter has attracted little attention, but Ruano-Gil *et al.* (1975) examined it in 45 human embryos (5–55 mm), and they state that it is permeable at first (5 mm). Its lumen then becomes obliterated (13–22 mm), to be subsequently recanalized. Both processes were observed to begin at intermediate levels of the ureter and to proceed in both directions. The recanalization was not associated with metanephric function, but possibly with the rapid elongation of the ureter in conformity with embryonic growth. Two fusiform enlargements appear subsequently, affecting its lumbar and pelvic levels. The lumbar enlargement appears during the fifth month, the pelvic not until the ninth month, the latter being inconstant. As a result the ureter shows a constriction at its upper end and another as it crosses the pelvic brim. A third narrowing is always present at its lower end, and is caused by the growth of the bladder wall.

At first the ureter is connected to the dorsomedial aspect of the mesonephric duct but, owing to differences in rates of growth, the connexion becomes lateral to the duct. Thereafter the caudal end of the duct becomes incorporated in the developing bladder, and the orifice of the ureter opens into the bladder on the lateral side of the opening of the duct. Later the two orifices become separated still further and, although the ureter retains its point of entry into the bladder, the mesonephric duct opens into that part of the urogenital sinus which subsequently becomes the prostatic urethra.



The female ducts (paramesonephric or Müllerian ducts), play an important part in the development of the female reproductive system, but do not begin to develop until the embryo reaches a length of 10–12 mm (beginning of sixth week). Each commences as a groove-like invagination of the coelomic epithelium (the *female duct groove*) on the lateral aspect of the

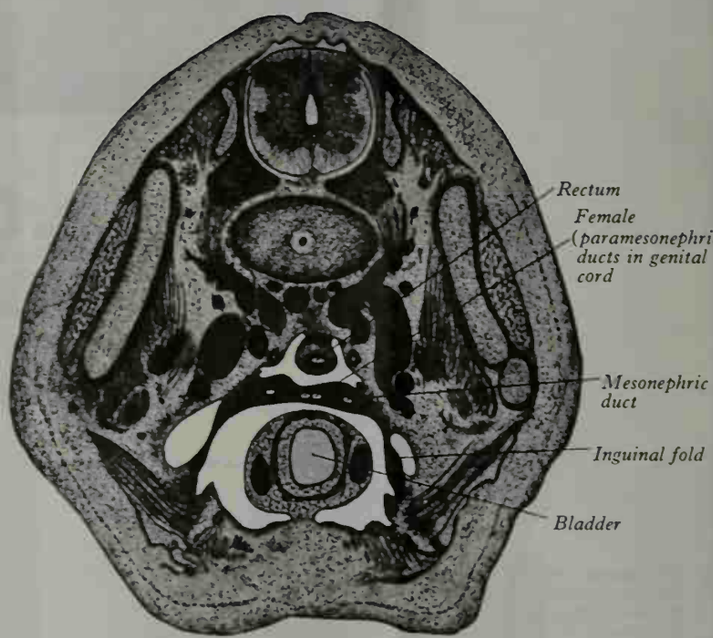
mesonephric ridge near its cranial end, and its blind end grows caudally in the ridge as a solid rod of cells which acquires a lumen as it lengthens. Throughout the extent of the mesonephros it is lateral to the mesonephric duct. At the caudal end of the mesonephros, which it reaches in the eighth week, the paramesonephric duct turns medially (2.103B) and crosses ventral to the mesonephric duct to enter the genital cord (2.105C, D), where it bends caudally in close apposition with its fellow of the opposite side. The two ducts reach the dorsal wall of the urogenital sinus during the third month, and their blind ends produce an elevation on it termed the *sinus* or *Müllerian tubercle* (2.103B). Each duct consists of vertical cranial and caudal parts with an intermediate horizontal region. The cranial part forms the uterine tube, and the original coelomic invagination remains as the pelvic opening of the tube, the fimbriae becoming defined as the cranial end of the mesonephros degenerates. The caudal vertical parts of the two ducts fuse with each other (2.107F) to form the *uterovaginal primordium*. This gives rise to the lower part of the uterus, and as it enlarges it takes in the horizontal parts to form the fundus and most of the body of the adult uterus. The stroma of the endometrium and the uterine musculature, the myometrium, are developed from the surrounding mesoderm of the genital cord.

At about the 60 mm crown–rump length stage an epithelial proliferation (the *sinuvaginal bulb*) arises from the dorsal wall of the urogenital sinus in the region of the sinus tubercle, and its origin marks the site of the future hymenal orifice. Whether the epithelium involved in the proliferation is from the sinus (Bulmer 1957), or epithelium of the mesonephric duct which has extended over the Müllerian tubercle (Vilas 1932; Meyer 1938; Forsberg 1963) is uncertain. The proliferation gradually extends cranially as a solid, anteroposteriorly flattened plate, inside the tubular mesodermal condensation of the uterovaginal primordium which will eventually become the fibromuscular vaginal wall. The caudal tip of the female duct epithelium recedes until, at about the 140 mm stage, its junction with the sinus proliferation lies in the cervical canal.

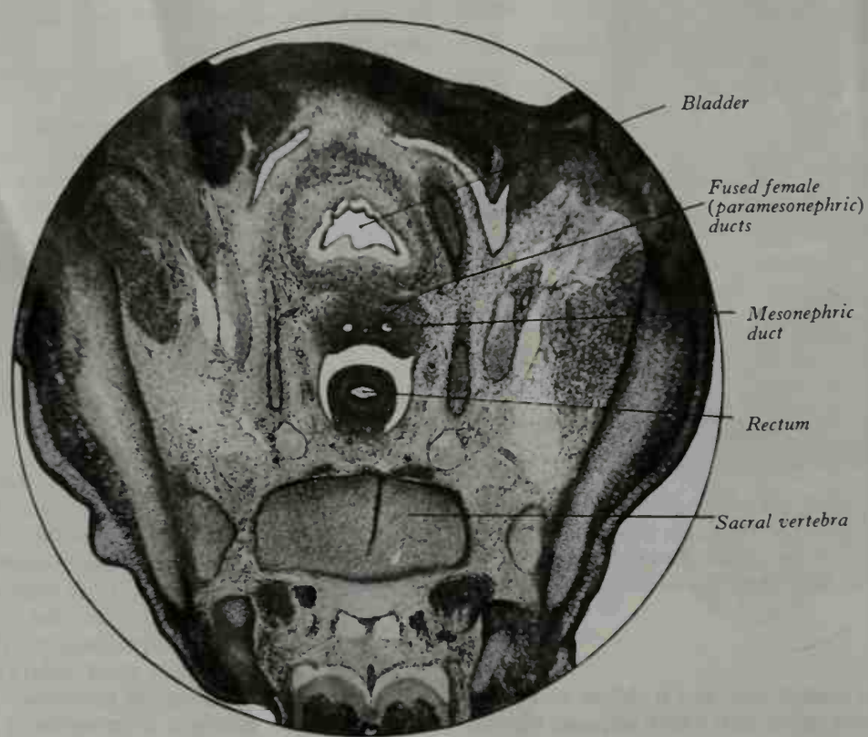
Commencing from the lower end, and gradually extending cranially through its whole extent, the solid plate formed by the sinus proliferation enlarges into a cylindrical structure and the central cells desquamate to establish the vaginal lumen. According to one view, the paramesonephric ducts do not directly contribute to the formation of the vagina (Frutiger 1969), but it has also been suggested that the mesonephric and paramesonephric ducts are both concerned (Linkevich 1969). As the upper end of the vaginal plate enlarges it grows up into the mesoderm around the cervix to produce the vaginal fornices. As the lower end enlarges it invaginates the dorsal wall of the urogenital sinus around the hymeneal orifice, trapping a thin layer of mesoderm around the orifice to form the hymen (2.108). The hymen is lined on its upper surface by vaginal epithelium, which, despite its origin, is clearly distinct from the sinus epithelium on

the under surface. In the later stages, however, the lower surface of the hymen and a large part of the vestibule become lined by an epithelium indistinguishable from that of the vagina (Bulmer 1959). The urogenital sinus undergoes relative shortening in a craniocaudal direction to form the vestibule, which opens on the surface through the cleft between the genital folds.



During the later months of fetal life the vaginal epithelium is enormously hypertrophied, apparently under the influence of maternal hormones, but after birth it assumes the inactive form of childhood (Fraenkel and Papanicolaou 1938).

The differing embryonic origins of the vaginal epithelium and uterine epithelium have been correlated with their dissimilar responses in adult life to stimulation with oestrogenic hormones (Zuckerman 1940).



In the male the paramesonephric (female) duct mostly atrophies, but a vestige of its cranial end persists as the *appendix testis* (p. 1410). The fused terminal portions of the two ducts are connected to the wall of the urogenital sinus by a solid cord of cells, the *utricular cord*. In this position it soon merges with a proliferation of sinus epithelium, the *sinu-utricular cord*, similar to, but less extensive than, the sinus proliferation in the female. This proliferating epithelium is claimed to be an intermingling of the endoderm of the urogenital sinus with the lining epithelia of the mesonephric and paramesonephric ducts, which have extended on to the surface of the sinus tubercle. As the sinu-utricular cord grows, so the utricular cord recedes from the tubercle. In the second half of fetal life the composite cord acquires a lumen and dilates to form the *prostatic utricle*, the lining of which consists of hyperplastic stratified squamous epithelium. The sinus tubercle becomes the *colliculus seminalis* (Vilas 1933; Glenister 1962).

The primordial germ cells, from which the definitive germ cells are derived, are segregated very early in embryonic development. This has been demonstrated as early as the 2-somite stage in the chick (Clawson and Domm 1969). They are large cells, in comparison with most somatic cells, being from 12 to 20 μm in diameter, and they are characterized by vesicular nuclei with well-defined nuclear membranes, and by a tendency to retain yolk inclusions long after these have disappeared from somatic cells. (For the ultrastructure of human primordial germ cells consult Fukuda 1976, Fujimoto *et al.* 1977.) It is not yet established whether the primordial germ cells are derived from particular blastomeres during cleavage, or constitute a clonal line from a single blastomere, or are the product of a progressive concentration of the germinal plasma of the fertilized ovum by unequal partition of this at successive mitoses (Buonoure 1939).

The germ cells can be identified in human embryos at the 13-somite stage (fourth week), in the endoderm at its caudal end and in the adjacent part of the yolk sac (Witschi 1948, and Fujimoto 1978). At this stage the number of cells is probably not more than 20 to 30 (Hardisty 1967). When the tail fold has formed they appear in the endoderm and the splanchnic mesoderm of the hindgut as well as in the adjoining region of the wall of the yolk sac. By amoeb-

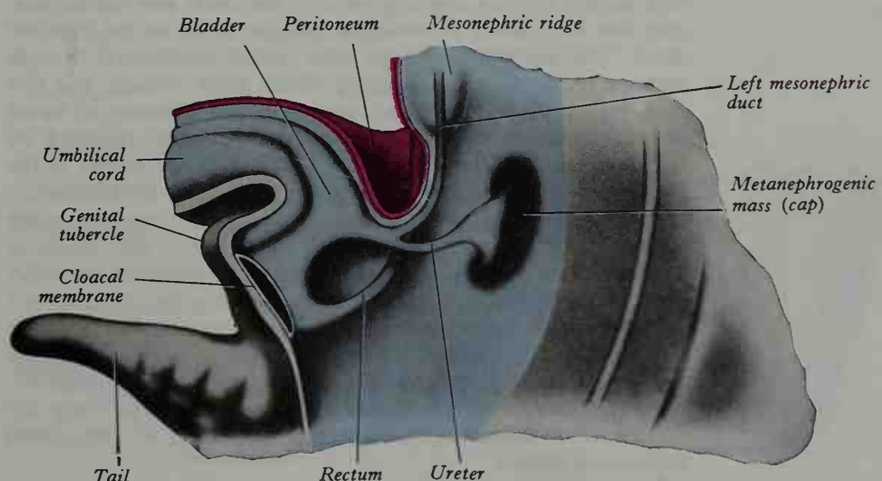
oid movements and by growth displacement they migrate dorsocranially in the mesentery, passing around the dorsal angles of the coelom to reach the medial sides of the mesonephric ridges—the developmental sites of the gonads. In most vertebrates mitosis in the germ cells is arrested after their early segregation, to be renewed only when they reach the genital primordia. However, in mammals there is no such arrest, and the cells proliferate both during and after migration to the mesonephric ridges; cells which do not complete this migration degenerate. After segregation the primordial germ cells are often termed *primary gonocytes*, which in turn divide to form *secondary gonocytes*. The distinction between the two generations is clear in most vertebrates, but the absence of mitotic arrest in mammals leads to a merging of the two stages.

The early association of primordial germ cells with the endoderm suggests that they are in fact derived from primitive endodermal cells or perhaps from common stem cells (Franchi *et al.* 1961). Alternatively, the endoderm may exert an inductive effect on their development and differentiation without being their actual source. For a discussion of this problem and citation of pertinent references consult Carlon and Stahl (1973).

While sexual differences in germ cell numbers occur in some vertebrate species, it is uncertain whether this represents an original difference at segregation or results from earlier and more rapid proliferation in one sex or the other. No connexion between numbers of primordial germ cells and fertility has been detected, but there is evidence that gross deficiency in number may affect individual fecundity (Hardisty 1967).

The formation of the gonads is first indicated by the appearance of an area of thickened epithelium on the medial side of the mesonephric ridge in the fifth week (**2**.104). Elsewhere on the surface of the ridge the coelomic epithelium is one or two cells thick, but over this genital area it is many-layered. The thickening rapidly extends in a longitudinal direction until it covers nearly the whole of the medial surface of the ridge. The thickened epithelium continues to proliferate, displacing the renal corpuscles of the mesonephros in a dorsolateral direction, and forming a projection into the coelomic cavity, the *gonadal ridge*. Surface depressions form along the limits of the ridge which is thus connected to the mesonephros by an originally broad mesentery, the *mesogenitale*. In this way the mesonephric ridge becomes subdivided into a lateral part containing the mesonephric and paramesonephric ducts, which may be termed the *tubal fold*, and a medial part, termed the *gonadal fold*. The tubal fold contains the nephric tubules and glomeruli at its base.

Up to the seventh week the gonad possesses no differentiating feature. The proliferating epithelium now forms a number of cellular *gonadal cords*, separated by mesenchyme. These cords remain at the periphery of the primordium to form a cortex; more centrally a proliferation of the mesenchyme of the mesonephros constitutes a medulla. In the male all the progenitors of the definitive gonocytes become incorporated in the cords, but in the female a large number remain behind under the surface epithelium. At this stage in the male, an extension of the mesenchyme cuts off the gonadal cords from the surface and rapidly thickens to form the *tunica albuginea*. This also develops in the female but to a lesser extent and at a later stage.



The testis (**2**.104). The cellular cords lengthen partly by additions from the coelomic epithelium and encroach on the medulla, where they unite with the network derived from the mesenchyme which ultimately becomes the *testicular rete*. The primordial germ cells are incorporated in the cords, which later become enlarged and canalized to form the *seminiferous tubules*. (*See* Fukuda and Hedinger 1975.) The cells derived from the surface of the gonad form the *supporting cells* (of Sertoli). The *interstitial cells* of the testis are derived from the mesenchyme and possibly also from coelomic epithelial cells which do not become incorporated into the tubules. The cords of the testicular rete, which canalize later, become connected to the glomerular capsules in the cranial end of the persisting part of the mesonephros, and the glomerular tufts concerned become atrophied. The rete cords thus become connected to the mesonephric duct by the five to twelve most cranial persisting tubules and these become exceedingly convoluted and form the lobules of the head of the epididymis. The mesonephric duct, which was the primitive 'ureter' of the mesonephros, becomes the canal of the *epididymis* and the *ductus deferens* of the testis. The seminiferous tubules do not acquire lumina until the seventh month, but the tubules of the testicular rete do so somewhat earlier.

The ovary (**2**.104). In its earliest stages, the ovary closely resembles the testis, although it is slower to differentiate its characteristically female features. Few, if any, of the gonadal cords invade the medulla, the majority remaining in the cortex, where they may be joined by a second proliferation from the epithelium covering the gonad. In sections of the ovary in the third and subsequent months the cords appear as clusters of cells which may or may not contain primitive germ cells. These clusters are separated by fine septa of undifferentiated mesenchyme. An *ovarian rete* arises in the medulla and some of its cords may form a junction with mesonephric glomeruli. The medulla regresses and connective tissue and blood vessels from this region invade the cortex to form the stroma of the ovary. As this invasion proceeds the cell clusters break up into individual groups which surround the *primordial ova*, now *primary oöcytes*, which have entered the prophase of the first meiotic division. These cells have been derived from a mitotic division of the primordial germ cells (*naked oögonia*). Their epithelial capsules (*pregranulosa cells*) consist of flattened cells derived from the proliferations of coelomic epithelium (Gillman 1948). The ovary now has its full complement of primary oöcytes. The majority undergo atresia at various stages during the course of their development, but the remainder resume development by completing the first meiotic division shortly before ovulation (Zuckerman 1951, 1956). The capsular cells at the same time enlarge and multiply to form the stratum granulosum, and as they do so they become surrounded by thecal cells which differentiate from the stroma.

Organ culture of human fetal ovaries confirms the above, but it was considered that the primary oöcytes had progressed to the leptotene stage. Strands of epithelial cells containing oögonia developed during culture (Baker and Neal 1974).

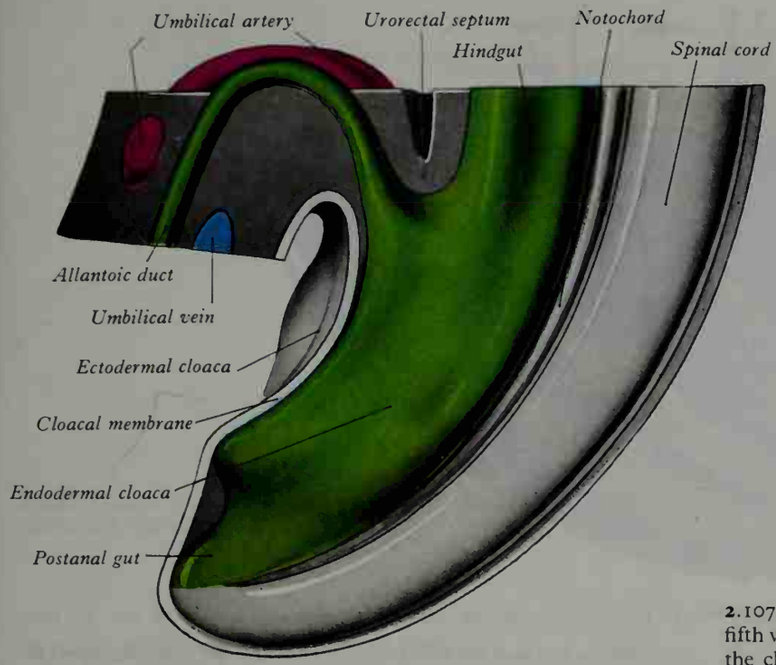
Only the middle part of the gonadal ridge produces the ovary. Its cranial part is sterile and becomes the *suspensory ligament of the ovary* (infundibulopelvic fold of peritoneum). Its caudal region, also sterile, is incorporated in the *ovarian ligament*.

The descent of the testis is not merely a simple migration. At first it lies on the dorsal abdominal wall, but, as it enlarges, its cranial end degenerates, and the organ therefore assumes a more caudal position. It is attached to the mesonephric fold by a peritoneal fold, the *mesorchium* (**2**.105A), the *mesogenitale* of the undifferentiated gonad, which contains the testicular vessels and nerves and a quantity of undifferentiated mesenchyme. In addition, it acquires a secondary attachment to the ventral abdominal wall, which has a considerable influence on its subsequent movements. At the point where the mesonephric fold

2.106 Schema, based on **2**.107D, to show the formation of the pelvis of the kidney and the metanephrogenic mass or cap.

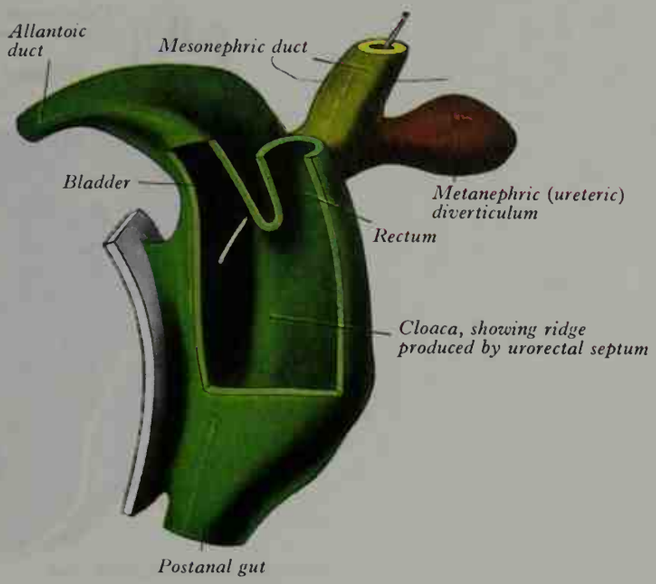
bends medially to form the genital cord (p. 213), it becomes connected to the lower part of the ventral abdominal wall by an *inguinal fold* of peritoneum (**2**.105C). The mesenchymal cells included in the inguinal fold form a cord, extending from the skin which will later form the scrotum through the inguinal fold and the mesorchium to the caudal pole of the testis. It traverses the site of the future inguinal canal, which is formed around it by the muscle of the abdominal wall as they become differentiated. At the end of the second month the caudal part of the ventral abdominal wall is horizontal but, after the return of the intestines to the peritoneal cavity (p. 201), it grows in length and becomes vertical. As a result the umbilical artery pulls up a falciform peritoneal fold, as it runs ventrally from the dorsal to the ventral wall, and this forms the medial boundary of a peritoneal fossa into which the testis projects. This fossa is termed the *saccus vaginalis* or *lateral inguinal fossa* (p. 1410) and its lower end protrudes down the inguinal canal along the gubernaculum, as the *processus vaginalis*. The caudal pole of the testis is retained in apposition with the deep inguinal ring by the gubernaculum until the seventh month, when it suddenly and rapidly passes through the inguinal canal and gains the scrotum. As it descends it is necessarily accompanied by its peritoneal covering, and the adjoining peritoneum from the iliac fossa is drawn down into the processus vaginalis. The distal end of the processes vaginalis, into which the testis projects, forms the *tunica vaginalis testis*, but the portion associated with the spermatic cord in the scrotum and in the inguinal canal normally becomes obliterated. The fascial coverings of the testis and spermatic cord, including the cremaster, are developed from the gubernaculum testis (Backhouse and Butler 1958).

The actual mechanism of the descent of the testis is still uncertain. It has been ascribed, by different investigators, to shortening and active contraction of the gubernaculum, to increased intra-abdominal pressure, to a simple growth process, and to the effect on the convex surface of the gland of the active contraction of the lower fibres of the internal oblique muscle, squeezing it through the canal. None of these explanations is entirely convincing. Whatever contribution the gubernaculum makes to the process, it cannot be by muscular contraction, because it contains no muscle, remaining a soft, mesenchymatous mass through its existence (Forssner 1928; Backhouse and Butler 1960). It precedes the testis both spatially and in rate of growth, forming a tapering column of soft tissue, with the diminutive testis at its cranial pole. It continues to grow until the seventh month, by which time its caudal part has filled the future inguinal canal and has begun to expand the developing scrotum. In this it also precedes the processus vaginalis, but does not develop attachments to skin, nor is there any evidence that it produces the radiating extensions into the suprapubic, perineal and femoral sites, which are often used as explanations for the various forms of ectopia testis. By its soft consistency the gubernacular tissue may offer a route of low resistance to the descending testis, and the cessation of its growth in the last two months of gestation, coupled with an accelerating rate of growth in the testis and epididymis, may also be a factor in testicular descent as far as the inguinal canal. The mechanism of the final, rapid intrascrotal descent remains unidentified. Endocrine effects seem certain, but this does not explain the actual agency. This account is based principally upon events as observed in porcine material by Backhouse and Butler (1960). A more recent discussion of the problems of testicular descent and maldescent by Backhouse (1964) should be consulted. He has reviewed the literature since Hunter's original description (1762). Apparently the cremaster muscle develops in gubernacular mesenchyme, and this may explain the development of the concept of the gubernaculum as a 'fibromuscular' ligament. The processus vaginalis also develops in close association with the soft, mucoid tissue of the gubernaculum and follows it into the genital swelling. Ultimately, as the testis and epidymis fill the scrotum, or genital swelling, the gubernacular mesenchyme is incorporated into the associated connective tissues.



Various abnormalities may occur in connexion with testicular descent and obliteration of the processus vaginalis (p. 1416). The testis may remain in the abdomen, or it may fail to reach the scrotum and may then lie in any of the following situations: (1) in the perineum, (2) at the root of the penis, (3) at the superficial inguinal ring (p. 1367), (4) in the upper part of the thigh. These malpositions have been traditionally associated with certain additional extensions of gubernacular tissue. The largest extension normally passes to the scrotum while lesser extensions have been described as gaining attachment to the perineum, the root of the penis, the pubis, the inguinal ligament, and the neighbourhood of the saphenous opening. The testis must follow the processus vaginalis, and should the latter for any reason follow any but the scrotal extension of the gubernaculum, malposition of the testis will result. It should be appreciated, however, that considerable doubt has now been expressed concerning these lesser expansions (previously the so-called 'tails of Lockwood'): possibly they reflect premature and abnormal fibrous partitioning of the gubernacular mesenchyme.

The processus vaginalis may remain completely patent, or its obliteration may be incomplete. When it retains a connexion with the general peritoneal cavity it provides a preformed sac for a potential oblique inguinal hernia. It may be occluded at its upper end and may be shut off from the tunica vaginalis and yet remain patent in the intervening section. The patent portion may become distended with fluid, constituting an encysted hydrocoele of the spermatic cord.



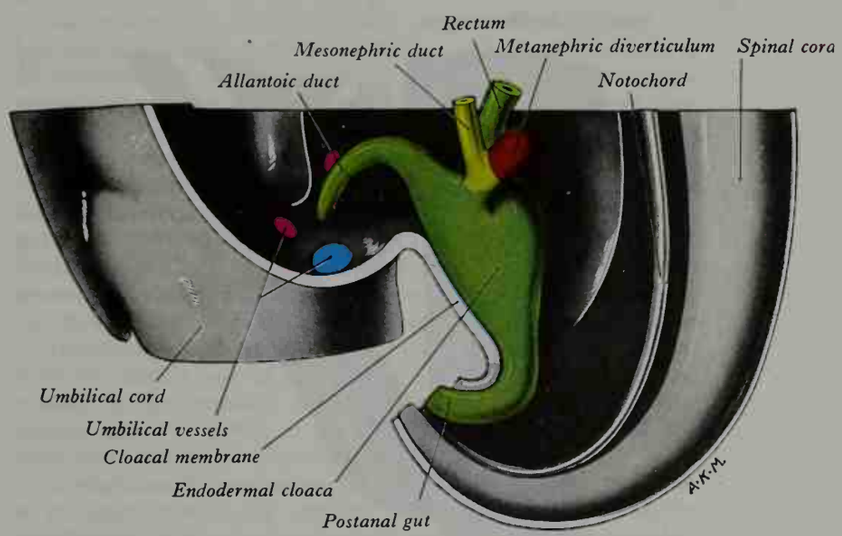
The descent of the ovary is less extensive. Like the testis, the ovary ultimately reaches a lower level than it occupies in the early months of fetal life, but it does not leave the pelvis to enter the inguinal canal save under abnormal conditions. Connected to the medial portion of the mesonephric fold by the *mesovarium*, which is homologous with the mesorchium, the ovary is also attached to the ventral abdominal wall through the medium of the inguinal fold. In this fold the mesenchymatous gubernaculum develops and, as it traverses the mesonephric fold, it acquires an additional attachment to the lateral margin of the uterus near the entrance of the uterine tube; its lower part, caudal to this attachment, becomes the *round ligament of the uterus* and the part cranial to this *the ovarian ligament*, these two structures together being homologous with the gubernaculum testis in the male. This new attachment restricts the extent of ovarian descent. At first the ovary is attached to the medial side of the mesonephric fold, but owing to the way in which the two mesonephric folds unite to form the genital cord (p. 213) its connexion is finally to the posterior layer of the broad ligament of the uterus. The gubernaculum thus persists in the female, unlike the male, as two fibrous bands or ligaments.

The *saccus vaginalis* also appears in the female; its prolongation into the inguinal canal (sometimes termed the canal of Nuck in the female) normally undergoes complete obliteration, but may remain patent and form the sac of an oblique inguinal hernia (p. 1367). At birth the ovary and the lateral end of the corresponding uterine tube lie above the pelvic brim, and they do not sink into the lesser pelvis until it enlarges sufficiently to contain both of them and the other pelvic viscera, including the bladder.

The urinary bladder (**2**.107A–E) is derived partly from the endodermal cloaca and partly from the caudal ends of the mesonephric ducts (**2**.103, 107, 109). After the separation of the rectum from the cloaca (p. 202), the ventral part of the latter becomes divided into three regions: (1) a cranial *vesico-urethral canal*, continuous with the allantoic duct—into this part the mesonephric ducts open; (2) a middle, narrow channel, the *pelvic portion*; and (3) a caudal, deep, *phallic* section, closed externally by the *urogenital membrane* (**2**.107D, E). The second and third parts together constitute the *urogenital sinus*. The ureter and the mesonephric duct come to open separately into the vesico-urethral part (p. 213). The termination of the mesonephric duct then moves caudally to open into that part which will form the prostatic urethra. This occurs by the formation of a caudally directed loop of the duct behind the urogenital sinus, followed by absorption of the apposed walls. In this way the mesonephric duct contributes to the trigone of the bladder and dorsal wall of the prostatic urethra. The remainder of the vesico-urethral part forms the body of the bladder and part of the prostatic urethra; its apex is prolonged to the umbilicus as a narrow canal, termed the *urachus*. In post-natal life the urachus is drawn downwards as the

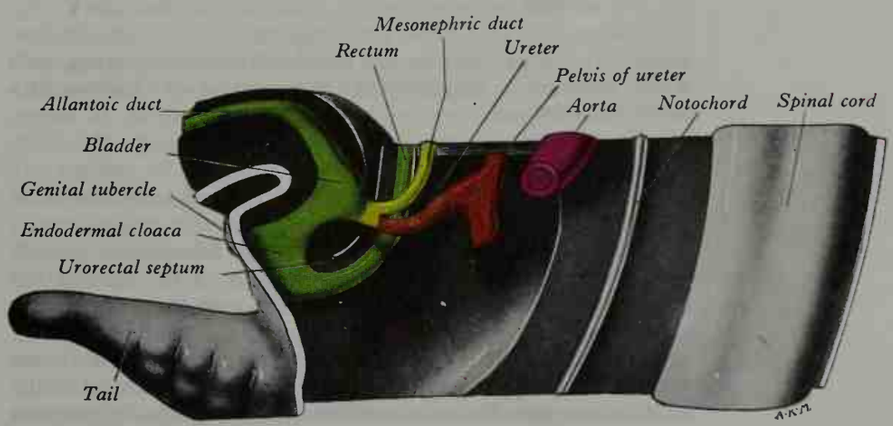
2.107A The tail end of a human embryo, about four weeks old. The model has been dissected to show the left lateral aspects of the spinal cord, notochord and endodermal cloaca. (After Keibel.)

2.107B The endodermal cloaca of a human embryo, near the end of the fifth week. A wire has been passed along the right mesonepheric duct into the cloaca, and a part of the left wall of the cloaca, including the left mesonephric duct, has been removed, together with the adjoining portions of the walls of the developing bladder and rectum. A piece of the ectoderm around the cloacal membrane has been left *in situ* and is uncoloured. (After Keibel.)



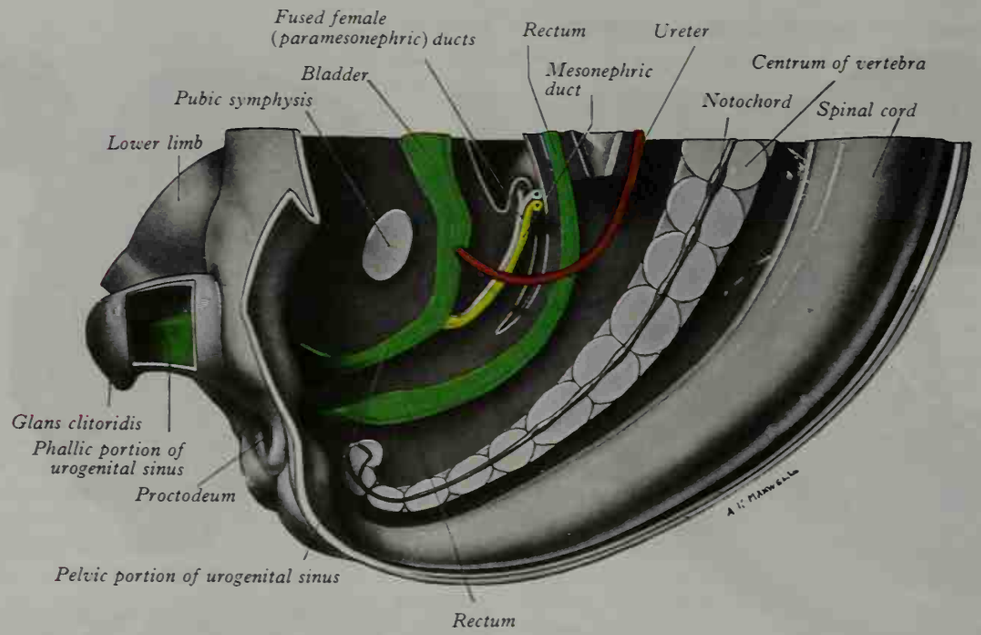
bladder descends, but its blind upper end remains connected to one or both of the obliterated umbilical arteries. Its lumen persists throughout life, and its lower end frequently communicates with the bladder near its apex (Begg 1930).

The prostate arises during the third month from the proximal part of the urethra. The earlier outgrowths, some fourteen to twenty in number, arise from the endoderm around the whole circumference of the tube, but mainly on the lateral aspect and excluding the dorsal wall above the utricular plate. These outgrowths give rise to the outer glandular zone of the prostate (p. 1420). Later outgrowths from the dorsal wall above the mesonephric ducts arise from the epithelium of mixed urogenital, mesonephric and possibly paramesonephric origin covering the cranial end of the sinus tubercle. These produce the internal zone of glandular tissue. The outgrowths, which are at first solid, branch, become tubular and invade the surrounding mesenchyme, which is being differentiated into muscular tissue.



Similar outgrowths occur in the female, but remain rudimentary. The urethral glands correspond to the mucosal glands around the upper part of the prostatic urethra and the paraurethral glands to the true prostatic glands of the external zone (Glenister 1962).

The *bulbo-urethral glands* in the male, and *greater vestibular glands* in the female, arise as diverticula from the epithelial lining of the urogenital sinus.



The external genital organs, like the gonads, pass through an undifferentiated state before distinguishing sexual characters appear (**2**.110). A surface elevation, the *genital tubercle*, appears at the cranial end of the cloacal membrane and lengthens to form the *phallus* (**2**.105B). Within it is a longitudinal endodermal mass, the *urethral plate* (**2**.109, 110), which grows forwards from the walls of the cloaca and urogenital sinus towards the tip of the organ. The lower aspect of the plate is in contact with ectoderm lining a median groove, the *primary urethral groove*, which has meanwhile developed along the caudal surface of the phallus. The raised margins of the groove are the *genital folds* (**2**.110). Proximally they surround the urogenital membrane and terminate in a transverse ridge immediately ventral to the anus. The rupture of the urogenital membrane provides a common perineal orifice for the genital and urinary organs at the base of the phallus, bounded at the sides by the genital folds. Meanwhile disintegration of the cells of the urethral plate and contiguous ectoderm occurs, commencing at the base of the phallus and resulting in a

2.107C The caudal end of a human embryo, about five weeks old. (Drawn from a model by Keibel.)

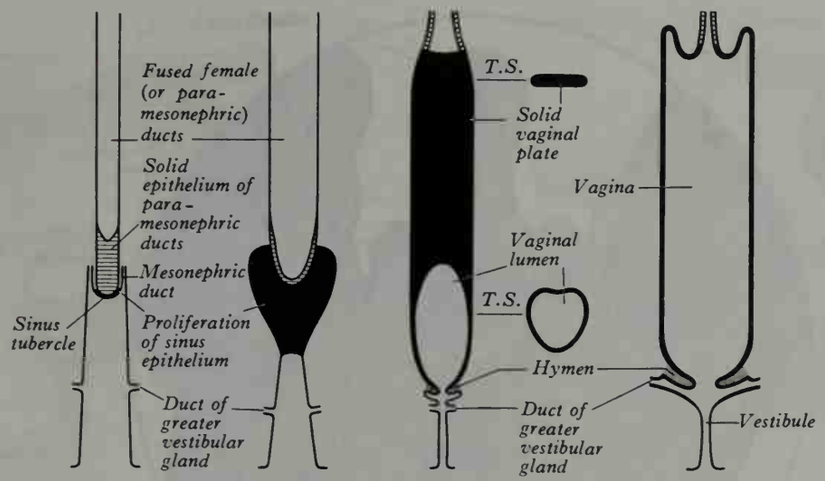
2.107E The tail end of a female human fetus, eight and a half to nine weeks old. The model has been dissected from the left side to show the structures in and near the median plane. Note that the cloaca has now been separated into urogenital and intestinal segments. (After Keibel.)

2.107F Part of the vesico-urethral portion of the endodermal cloaca of a female human fetus, eight and a half to nine weeks old. (Drawn from a model by Keibel.)

deepening of what can now be termed the *definitive urethral groove*.

While these changes are in progress two *labioscrotal (genital) swellings* have appeared, one on each side of the base of the phallus; these extend caudally, separated from the genital golds by distinct grooves (**2.110**).



The male phallus enlarges to form the penis, its apex being the glans. The genital swellings meet each other ventral to the anus and unite to form the scrotum. The genital folds fuse with each other from behind forwards enclosing the phallic part of the urogenital sinus behind to form the bulb of the urethra; similarly, the folds close the definitive urethral groove in front to form the greater part of the spongiose urethra. Fusion of the folds results in the formation of a median raphe, and occurs in such a way that the lining of the urethra is mainly, if not wholly, endodermal in origin (Glenister 1954). Thus, as the phallus lengthens, the urogenital orifice is carried onwards until it reaches the glans. At the tip of the glans an ingrowth of surface epithelium has occurred to meet the anterior extremity of the urethral plate, and the disintegration of this gives rise to a groove which is entirely ectodermal in origin; closure of this creates the terminal part of the urethra contained within the glans.

The glans and shaft of the penis are hence recognizable by the third month. The prepuce begins to develop in the third month, when the urethra still exhibits its primary orifice at the base of the glans. A ridge consisting of a mesodermal core covered by epithelium appears proximal to the neck of the penis and extends forwards over the glans. Deep to this ridge is a solid lamella of epithelium which extends backwards to the base of the glans. The ventral extremities of the ridge curve backwards to become continuous with the genital folds at the margins of the urethral orifice. As the urethral folds meet to form the terminal part of the urethra the ventral horns of the ridge fuse to form the frenulum. Over the dorsum and sides of the glans, the epithelial lamella breaks down to form the preputial sac and thus free the prepuce from the surface of the glans. Thereafter the prepuce grows as a free fold of skin covering the terminal part of the glans. The preputial sac may not be complete until 6 to 12 months or more after birth and, even then, the presence of some connecting strands may still interfere with the retractability of the prepuce.

The mesodermal core of the phallus is comparatively undifferentiated in the first two months, but during the third month the blastemata of the corpora cavernosa become defined. Nerves are present in the differentiating mesenchyme from the seventh week (Dail and Evan 1974).

The female phallus, which exceeds the male in length in the early stages, becomes the clitoris. The genital swellings remain separate as the labia majora and the genital folds also remain separate, forming the labia minora. The perineal orifice of the urogenital sinus is retained as the cleft between the labia minora, above which the urethra and vagina open. The prepuce of the clitoris develops in the same way as the homologous structure in the male.

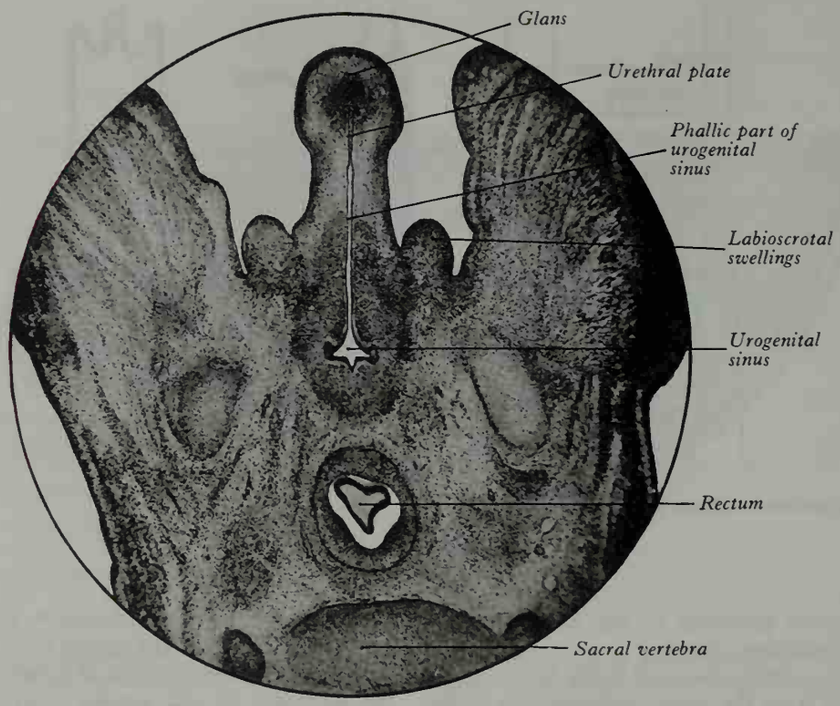
The urethra, in the *female* is derived entirely from the vesico-urethral region of the cloaca (p. 218). It is homologous with the

2.108 Diagrams to show the successive stages in the development of the uterus and vagina.

part of the prostatic urethra proximal to the orifices of the prostatic utricle and the ejaculatory ducts.

In the *male*, the prostatic urethra proximal to the orifice of the prostatic utricle is derived from the vesico-urethral part of the cloaca and the incorporated caudal ends of the mesonephric ducts (Bengmark 1958). The remainder of the prostatic part, the membranous part and probably the part within the bulb, are all derived from the urogenital sinus (p. 213). The succeeding section, as far as the glans, is formed by the fusion of the genital folds, while the section within the glans is formed in the way described above.

The homologies of the various parts of the urogenital system in the male and the female (**2**.103B, 110) can be summarized as follows:



Undifferentiated	*Male*	*Female*
Gonad	Testis	Ovary
Gubernacular cord	Gubernaculum testis	Ovarian and Round ligaments
Mesonephros (Wolffian body)	Appendix of epididymis(?)	Appendices vesiculosae (?)
	Efferent ductules	Epoöphoron
	Lobules of epididymis	
	Paradidymis	Paroöphoron
	Aberrant ductules	
Mesonephric duct (Wolffian duct)	Duct of epididymis	Duct of epoöphoron
	Ductus deferens	
	Ejaculatory duct	
	Part of bladder and prostatic urethra	Part of bladder and urethra
Female (paramesonephric or Müllerian) duct	Appendix of testis	Uterine tube
		Uterus
	Prostatic utricle	Vagina(?)
Allantoic duct	Urachus	Urachus
Cloaca: dorsal part	Rectum and upper part of anal canal	Rectum and upper part of anal canal
ventral part	Most of bladder, part of prostatic urethra	Most of bladder and the urethra
urogenital sinus	Prostatic urethra distal to utricle	
	Bulbo-urethral glands	Greater vestibular glands
	Rest of urethra	Vestibule
Genital folds	Ventral penis	Labia minora
Genital tubercle	Penis	Clitoris

Congenital anomalies Defects of the urethra, due to arrests of development, are not uncommon in the male. The urethra may open on the ventral aspect of the penis at the base of the glans, and the part of the urethra which is normally within the glans is absent. This constitutes the simplest form of *hypospadias*. In more severe cases the genital folds fail to fuse, and the urethra opens on the ventral aspect of a malformed penis just in front of the scrotum. A still greater degree of this malformation is accompanied by failure of the genital swellings to unite with each other. In these cases the scrotum is divided and, since the testes are also frequently undescended, the resemblance to the labia majora is very striking. Male children suffering from this deformity are often mistaken for girls.

Maldevelopment of the cloacal or urogenital membranes is a less common condition, but two varieties can be distinguished. (1) In *extroversion of the bladder* (ectopia vesicae) the lower part of the anterior abdominal wall is occupied by an irregularly oval area, covered with mucous membrane, on which the two ureters open (Wyburn 1937). Around its periphery this extroverted area, covered by transitional epithelium, becomes continuous with the skin. (2) In *extroversion of the cloaca* the condition is very similar, but is complicated by the presence of intestinal openings in the median plane. In (2) the cloacal membrane is probably abnormally elongated and ruptures prematurely and throughout its whole extent, prior to the formation of the urorectal septum. In (1) the maldevelopment occurs after the separation of the ventral from the dorsal part of the cloaca. The urogenital membrane extends further cranially than it does in normal cases and the genital tubercle forms at its *caudal* limit. Rupture of the membrane throws the bladder open to the exterior.

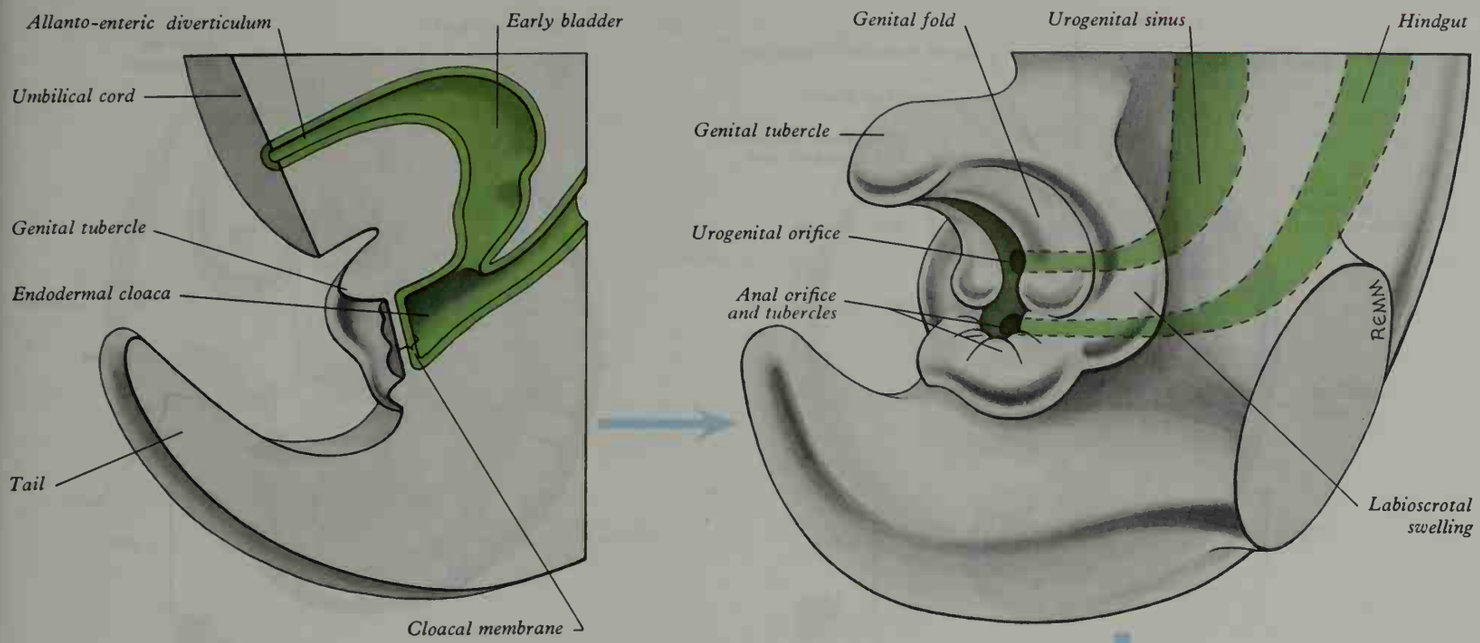
In *epispadias* the urethra opens on the dorsal aspect of the penis at its junction with the anterior abdominal wall. No entirely satisfactory explanation has yet been suggested for this anomaly. For a genetic and epidemiological study of urinary tract malformations consult Bois *et al.* (1975).

Differentiation of the genital organs (Burns 1955; Price and Jost 1957; Moore 1947) is primarily directed by genetic factors (p. 103) which may mediate their effects through endocrine controls, notably the cortex of the suprarenal gland. The differentiation of the gonad may be modified by several factors including chromosomal constitution (p. 102), degree of ripeness of the ovum at fertilization, the number and distribution of the primordial germ cells, and endocrine influences. A reduction in the number of primordial germ cells, believed to be associated with over-ripeness of the ovum at fertilization, exercises a masculinizing effect on genetic females. It is suggested that this is due to a failure of normal development of the superficial or cortical zone of the ovary, thus allowing the deep or medullary zone, which is the essentially male element, to dominate subsequent differentiation. The zones are not well marked in man but it is considered that they play an important role in the differentiation not only of the gonad but also of the genital ducts, mesonephric and paramesonephric, cloaca, external genitalia, and eventually of the secondary sexual characters. During their development the accessory sexual organs also pass through an indifferent or potentially bisexual stage.

2.109 Transverse section through the lower part of the pelvis of a nine-week-old human fetus.

The part played by hormones in the differentiation of the reproductive organs is not clear, but both androgens and oestrogens may profoundly modify this process, as instanced by work on the freemartin in cattle (Jost 1961). In twin pregnancy, where the fetuses are of opposite sex and their placental circulations anastomose, the male often exerts a masculinizing effect on its female twin. This has been attributed to the action of hormones elaborated in the interstitial tissue of the medullary zone in the testes of the male fetus. The gonad in turn affects the differentiation of the genital ducts, cloaca and external genitalia. It seems that the fate of the accessory organs, and particularly of the ducts, is determined largely by the presence or absence of a male factor, possibly hormonal, elaborated by the testes. The different parts of the accessory genital organs are most susceptible to this masculinizing effect over limited but differing periods.

Prenatal Growth in Form and Size



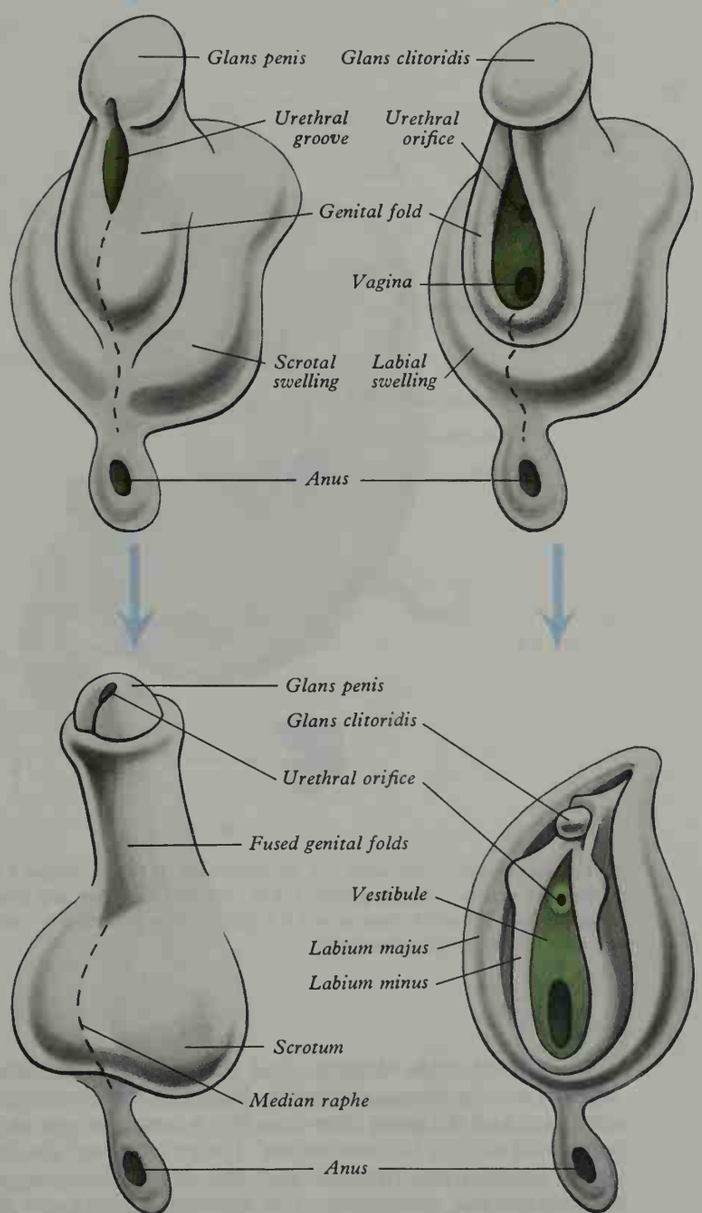
The absolute size of neither embryo nor fetus affords a reliable indication of either its true age or stage of structural organization, even though graphs based on large numbers of observations have been constructed to provide averages. All such data suffer from the difficulty of equating dimensions and degree of differentiation with the actual time of conception, which can rarely, if ever, be established with complete exactness. The life of the individual really commences with fertilization, but the date of this cannot be exactly determined in mankind. It has long been customary to compute the age, whether in a normal birth or an abortion, from the last menstrual period of the mother, but since ovulation usually occurs near the fourteenth day of a period, this 'menstrual age' is about two weeks too much. Where a single coitus can be held to be responsible for conception, a 'coital age' can be established, and the 'fertilization age' cannot be much less than this, because of the limited viability of both gametes, though it is usually held that the difference may be several days—a highly significant interval in the earlier stages of embryonic development. Even if the time of ovulation and coitus were known in instances of spontaneous abortion, not only would some uncertainty still persist with regard to the time of fertilization, but also there would remain an indefinable period between the cessation of development and the actual recovery of the conceptus. With the legalization of abortion in some countries the latter source of inaccuracy may be expected to become less important.

To overcome these difficulties early embryos have been graded or classified, on the basis of both internal and external features, into developmental stages or 'horizons' (**2**.111 A–H). Classical contributions in this field have been made by Lillie (1917), Streeter (1942–51), Hamilton (1944), Hertig *et al.* (1956), Heuser and Corner (1957), and O'Rahilly (1973). Although it has become customary to describe these developmental levels as *stages*, the earlier descriptions are still accepted. However, Stages 1 to 9, covering the first three weeks of development, have been given a more reliable basis by O'Rahilly (1973), who has also gathered together the pertinent literature.

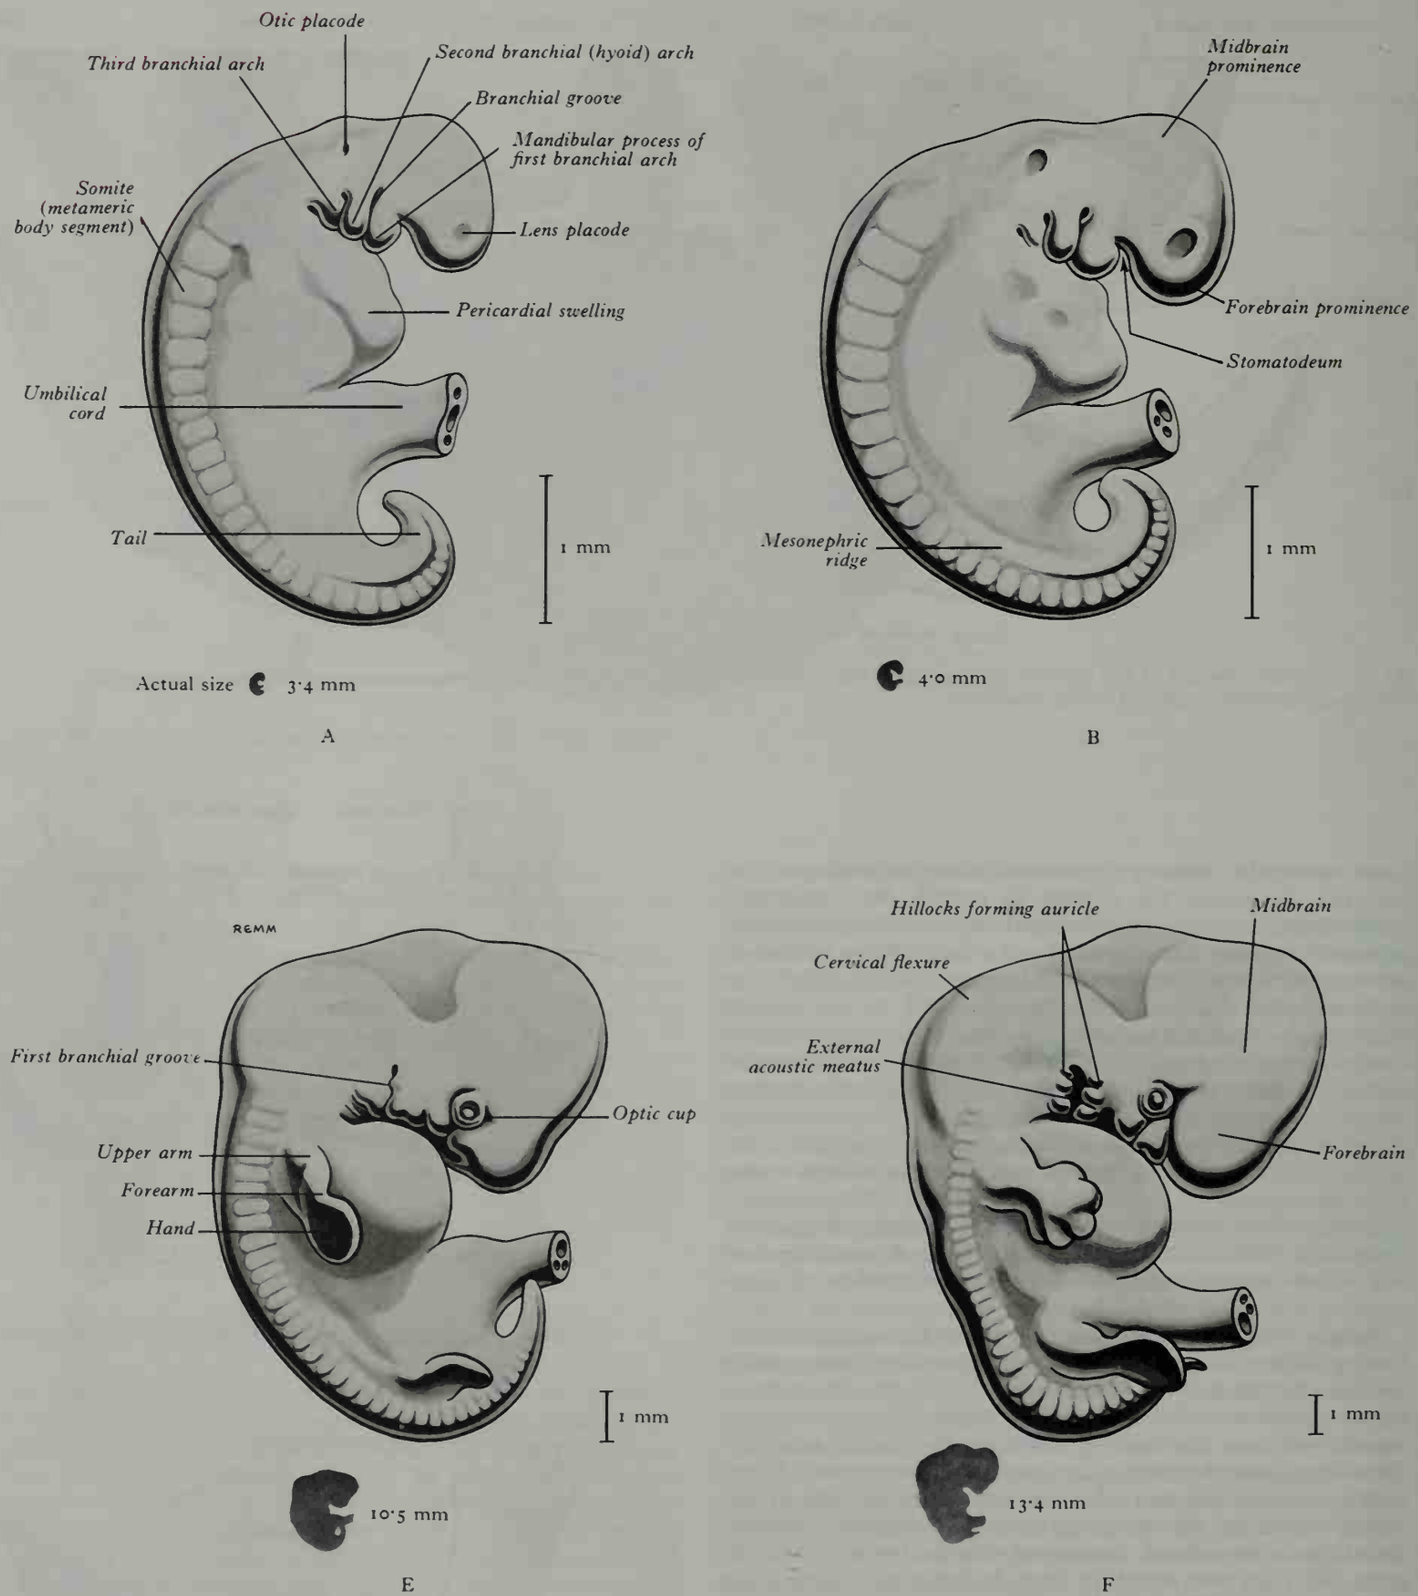
Stages 1 to 3 occupy the first 4 to 5 days after fertilization of the oöcyte in the ampulla of the uterine tube. The initial 24 hours (Stage 1) are occupied by fertilization, the dominant feature of which is the fusion of the male and female pronuclei. This is followed by the first mitotic division, which is the onset of segmentation, or cleavage, and is arbitrarily regarded as the transition from Stage 1 to Stage 2. Stage 2 is characterized by the continuation of cleavage, starting with two blastomeres and ending with about twelve. During this stage the developing morula moves along the uterine tube, by mechanisms still not wholly understood, a journey occupying about 4 days. During the fourth day a segmentation cavity appears within the cell mass, and this is taken as initiating Stage 3, which thus corresponds to the establishment of a free blastocyst.

Although comparatively few human embryos representing Stages 1 to 3 have been recovered (*see* pp. 103–5 and consult O'Rahilly 1973), a considerable degree of agreement exists and, moreover, the recent observations of *in vitro* fertilization between human spermatozoa and ova (**2**.18 A–H) support the earlier descriptions.

Stages 4 to 6 are concerned with the endometrial attachment of the blastocyst, trophoblastic development, implantation, further development of the blastocyst and the appearance of the primitive streak. Stage 4 corresponds to the fifth and sixth post-fertilization days. The blastocyst, now in the uterine cavity, loses its zona pellucida (**2**.19, 20) and it begins the rapid but complex activities of orientation in respect of the endometrium—adhesion, penetration and the cellular proliferation of trophoblastic growth. This establishment of dependence on the maternal circulation for nutritional requirements is far more rapid in primates than in



2.110 The development of the external genitalia from the indifferent stage to the definitive male and female conditions.

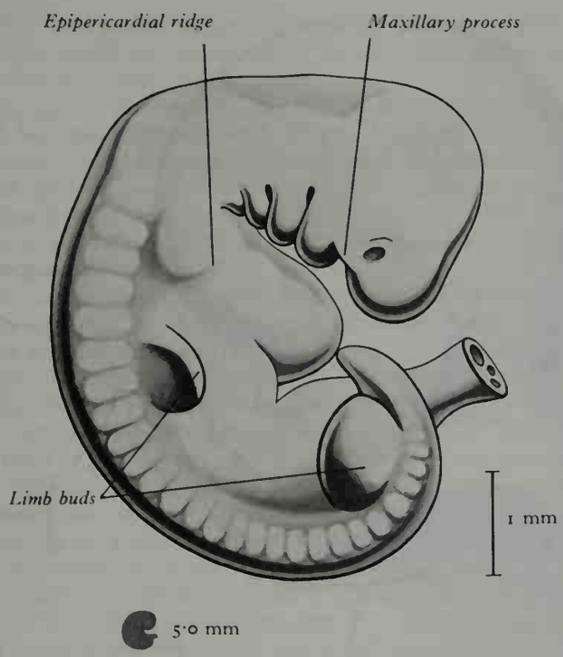


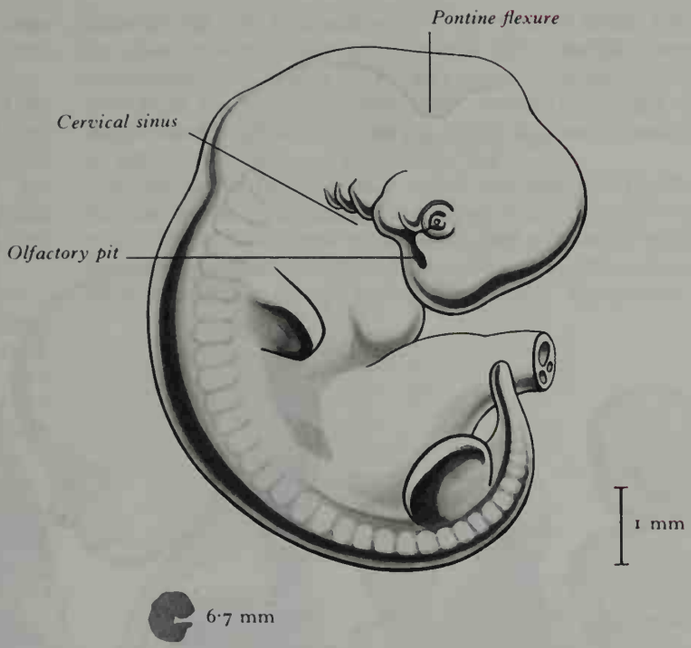
other mammals. Stage 5 is reached when implantation has occurred, occupying the seventh to twelfth days; syncytiotrophoblastic and cytotrophoblastic strata have differentiated, the proamniotic cavity has appeared, and a labyrinthine system of intercommunicating trophoblastic lacunae through which the maternal blood ebbs and flows, has developed. A little later in Stage 5 the exocoelomic membrane has been identified. In Stage 6 chorionic villous stems become defined and begin to develop side branches almost at once, producing an increasingly complex intervillous space. A little later the primitive streak becomes apparent and differentiation of the embryonic area has commenced, and may now be distinguished from the various extra-embryonic tissues.

Because of the complexity of the events in Stages 5 and 6, both have been subdivided by some authorities. A much greater number of human embryos have been recovered which represent Stages 4 to 6.

Stages 7 to 9 are characterized by basic embryogenic changes. During Stage 7 (sixteenth to eighteenth days) the primitive streak develops further and the notochordal ('head') process appears, together with the other mesodermal strata. The chorion and amnion continue to develop, villous stems being generally distributed over the former, but are more pronounced at the embryonic pole. Haemopoetic foci appear in the wall of the definitive yolk sac, and the cloacal membrane and allanto-enteric diverticulum are defined. Associated with the latter promordial germ cells have been noted. In Stage 8 (eighteenth to twentieth days) the prechordal plate, the primitive pit, the neural groove and the notochordal and neurenteric canals are all definable. By Stage 9 (twentieth to twenty-second days) the neural groove is deepening and the first somites begin to appear about midway along it. The cranial half of the groove, representing developing brain, is beginning to develop a cephalic flexure, optic primordia become visible, and the appearance of head and tail folds has commenced, as Stage 10 is approached. The foregut is becoming defined, and indications of early pharyngeal pouches may be identifiable. The embryo is now 1·5 to 2·0 mm in length.

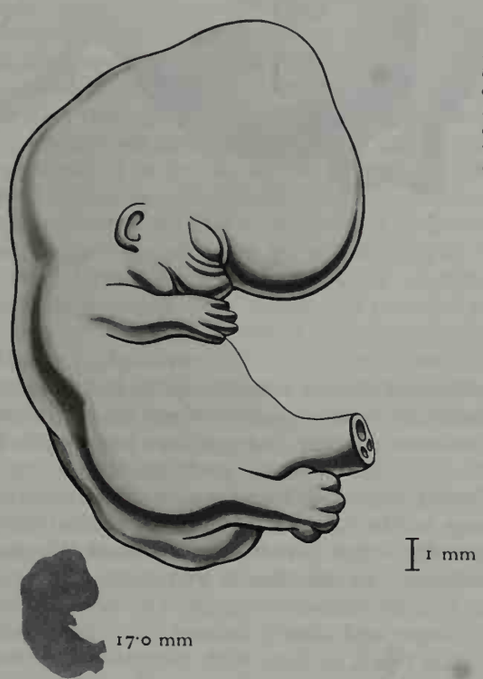
Stages 10 to 12, occupying days 22 to 26, feature continued formation of somites, and during this, the fourth week, the head and tail folds are completed, the neural groove closes, and the primary cerebral vesicles appear. The cervical flexure can now be recognized, the optic vesicles form and the lens and otic placodes appear and become vesicular. The branchial arches are appearing,



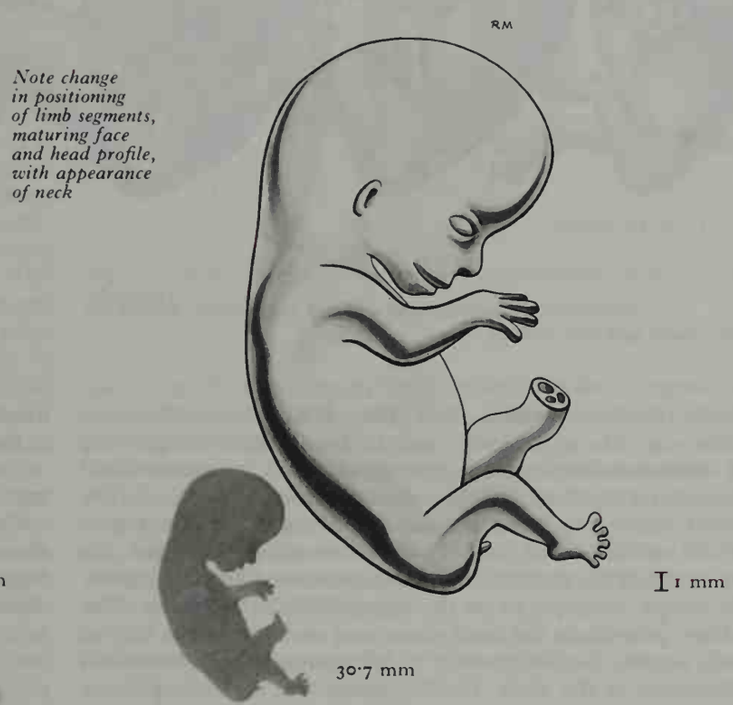


2.111 A–H A series showing the development of the principal external features of embryos ranging from 3·4 to 30·7 mm crown–rump length ($3\frac{1}{2}$ to $9\frac{1}{2}$ weeks). To assist comparison a 1 mm scale is included in each case; the small silhouette is actual size.

head and tail folds develop, and the cloacal membrane and hindgut are becoming definable. Rudimentary limb buds are appearing and the heart tubes fuse into a common loop in which contractile activity is commencing. The primordia of the thyroid gland, lungs, liver, pancreas and mesonephric tubules are all identifiable and developing. The embryo is about 4·0 mm in length.

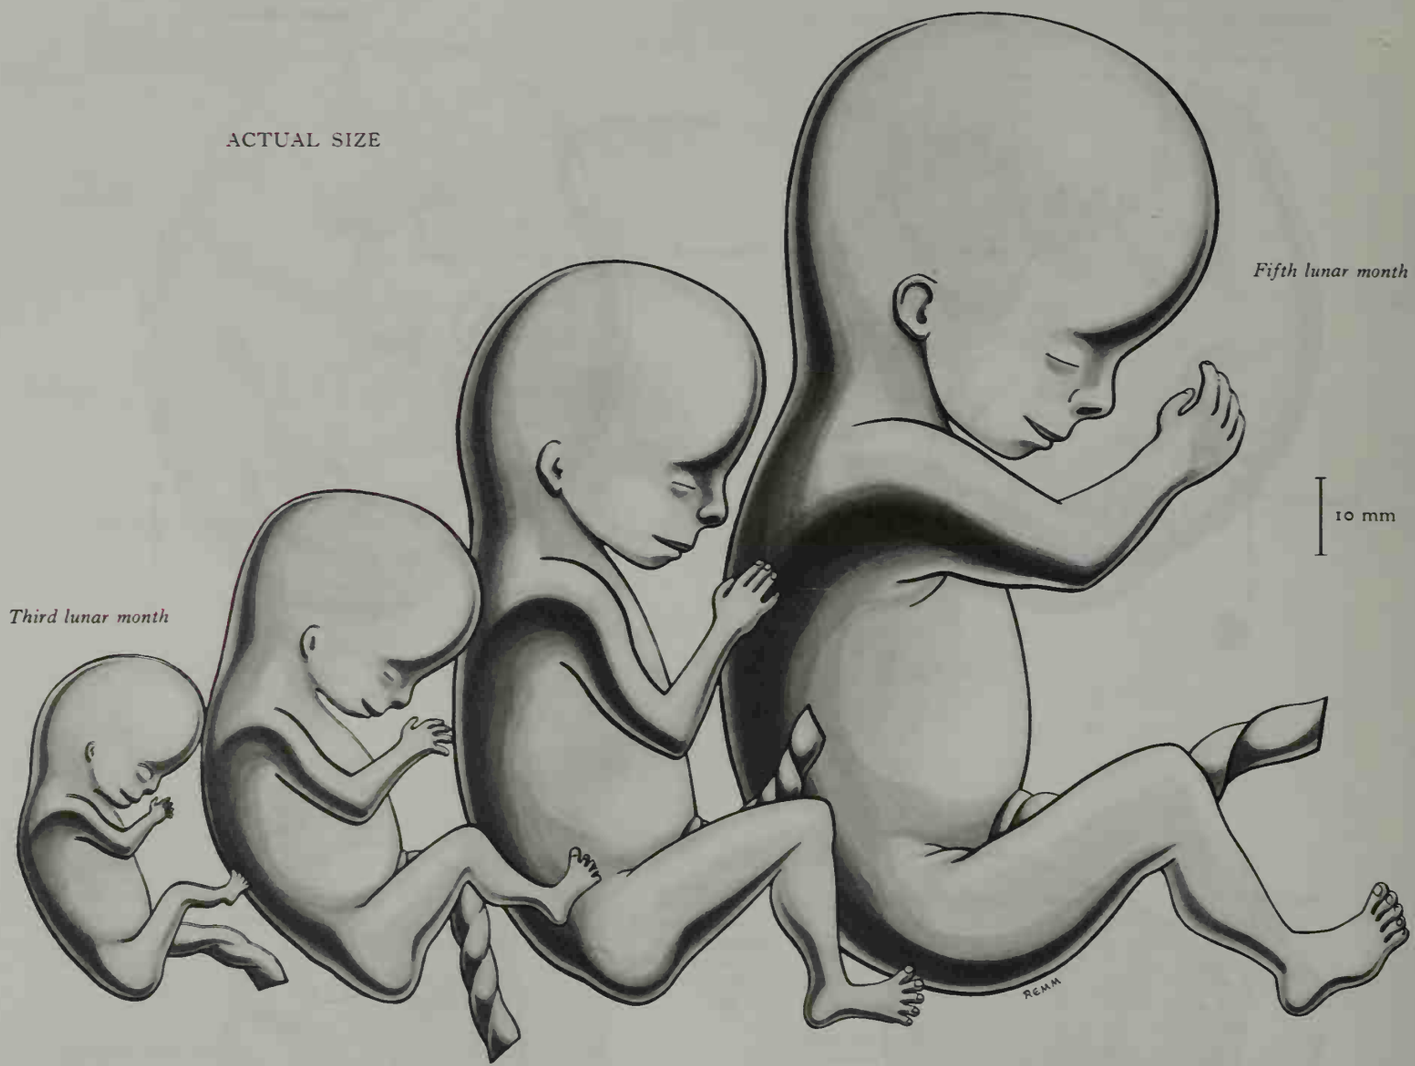


Stages 13 to 16 correspond approximately to the fifth week of development, during which the embryo grows from about 4·0 to 8·0 mm. It becomes markedly curved and its junction with the yolk sac relatively constricted. The cervical flexure is increased and the mesencephalic flexure is appearing. The dorsolateral (alar) and ventrolateral (basal) laminae are differentiating, and the sites of the corpus striatum and thalamus are marked by proliferating cells. The cranial and spinal nerves are developing, together with their ganglia, from the associated placodes and



C

D



G

H

neural crest elements. The limb buds are elongating, displaying joint flexures, and the hands and feet are differentiating. The olfactory placodes, maxillary processes, frontonasal elevations, tongue primordia, and the hypophysial pouch (of Rathke) are all appearing. The tubotympanic recesses are defined, and the primordia of the thymus and parathyroid glands can be identified. In the developing heart the septum primum appears, and the foramen primum follows. The mesonephric ducts reach the cloaca, and subsequently the metanephric (ureteric) buds appear and extend to the metanephrogenic masses of mesoderm. The gonadal ridges, urorectal septum and genital tubercle are also developing.

Stages 16 to 20 are roughly equivalent to the sixth week, by the end of which the embryo has a length of about 13 to 15 mm. Its curvature has further increased, and its head and relatively long tail are in contact with the developing umbilical stump. The

2.112 The progressive changes in fetal size and proportions during the third, fourth and fifth months.

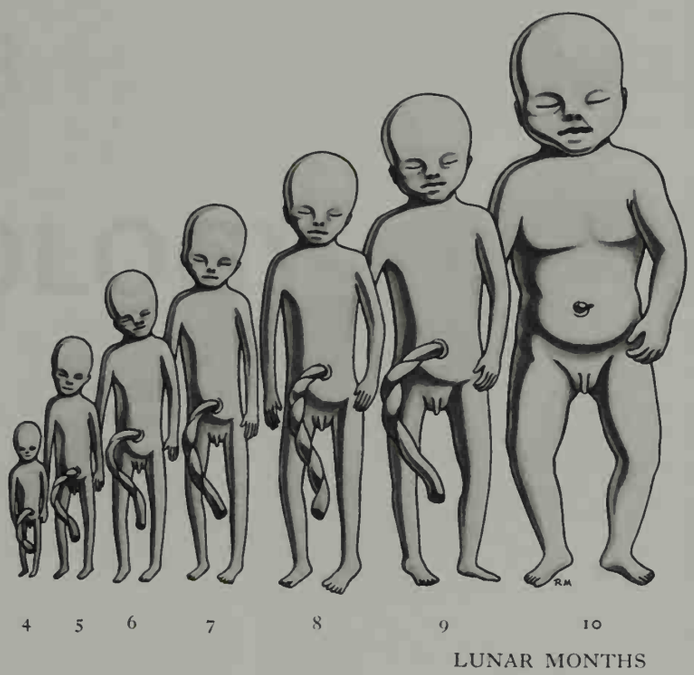
pontine flexure, cerebral hemispheres and cerebellum are developing. The upper limbs and the facial region are growing and differentiating rapidly; the palatal and primitive nasal processes are apparent, and the oronasal membrane ruptures. The liver produces a surface prominence between the cardiac region and the umbilical cord. Into the latter the midgut herniates as a loop in which the appendix and caecum become distinguishable. The spleen develops, as do the female (Müllerian) ducts. The foramen primum in the heart closes and septation of the bulbus cordis occurs. Cardiac muscle is differentiating. Haemopoiesis commences in the liver. Chondrification of skeletal elements begins and ossification commences in mesenchymatous bones, the mandible and clavicles.

Stages 21 to 23 complete the series, extending to about day 47. This represents the major part of the seventh week, and with the eighth week, the *formative* or *embryonic period* is regarded as coming to an end. This is a period during which *patterned differentiation* with consequent *organogenesis* tends to overshadow the growth which accompanies these events. Very considerable increase in size has, however, occurred; from a single cell about 0·14 mm in diameter the embryo has become a most complex and functioning creature, consisting of millions of cells and with a length of about 30 mm or more, and it has increased in weight many thousands of times. During the *fetal period*, which occupies the third to tenth lunar months (**2**.112, 113), the accent is upon growth rather than differentiation, but, of course, the latter continues through this period and to a lesser degree after birth (and in some tissues, throughout life). During this period the rate of growth in length is greater, but not markedly so; from the fourth to sixth weeks the rate is about 1 mm per day, with a maximum of about 2 mm, during the fourth month. The increase in length in the fetal period is from 30/40 to about 500 mm, and the increase in weight from perhaps 2 or 3 gm to more than 3,000 gm.

During the *seventh* and *eighth weeks* there is a remarkable change in the external appearance of the embryo, for at the beginning of this period the individual still appears markedly 'embryonic', though clearly a primate, whereas at the end, the form is most definitely human. The head is less flexed and the neck longer and clearly defined. The development of the face proceeds much further, with completion of the upper lip and nostrils, though the latter are plugged and the palate still incomplete. Enamel organs are developed from the dental laminae. The external ears and the eyelids are developing, and the limbs elongate considerably, approaching much nearer to their ultimate proportions and displaying well-formed hands and feet with separated digits. Early in this period the interventricular septum is completed. Skeletal and visceral muscle tissues begin to differentiate about this time, and generalized ossification occurs in enchondral bones. In the metanephrogenic mass vesicles appear and the remainder of the nephrons and the collecting tubules of the kidneys are defined. The ovaries or testes are distinguishable and the female (Müllerian) ducts are fusing to form the primordia of uterus and vagina. The external genitalia are further advanced and show sexual differentiation by the beginning of the eighth week. The cloacal membrane becomes perforate, and the tail is retrogressing. By the end of the period the embryo possesses almost all the structural features, internal and external, characteristic of the human mammal, and it now passes into the fetal period. During this there is much growth in the dimensions

of the established organs, extensive changes in proportions brought about by variations of growth rate, and widespread maturation in differentiating cells.

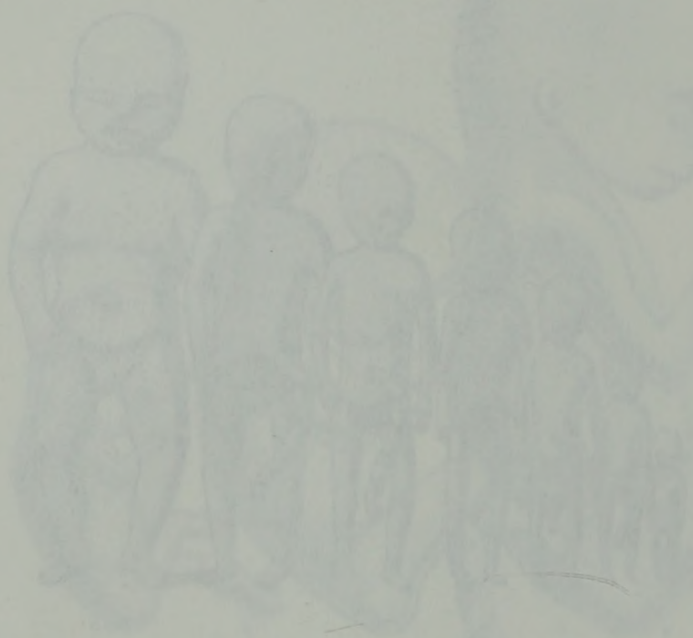
During the *third month* head flexion decreases further and the neck becomes proportionately longer. The eyelids meet and fuse and will remain temporarily united until the sixth lunar month. Nails appear on the digits and the limbs in general are comparatively accelerated in development. The umbilical protrusion of the gut is reduced by a proportionate augmentation of abdominal volume.



During the *fourth month* the primary covering of hair appears—the *lanugo* (p. 1223). As in the previous month, the head and upper limbs are still disproportionately large, and although the trunk and lower limbs begin to catch up by increased rates of growth during the rest of uterine life, the same disproportion is present after birth and to a diminishing degree throughout childhood into the years of puberty (p. 236). By the end of the fourth month the eyes have moved even further into an anteriorly directed position, but they are still relatively wide apart. The external ear is beginning to attain its characteristic form and it is nearer its ultimate position, at the side of the head and no longer in the upper part of the neck. The total fetal length, including the lower limb, is now of the order of 230 mm. Its weight at the end of the *fifth month* is about 300 gm, which will be increased more than tenfold during the second half of intrauterine life. Towards the end of this period sebaceous glands become active, and the sebum secreted blends with desquamated epidermal cells to form a cheesy covering to the skin, the *vernix caseosa*, which is usually considered to protect the former from maceration by the amniotic fluid. During this month the mother becomes conscious of fetal movements, the so-called 'quickening'.

The *sixth month* witnesses a further general change of bodily proportions and facial appearance towards those of the infant at birth. The lanugo darkens and the skin becomes markedly wrinkled, presumably through a disparity in the growth rates of cutaneous and subcutaneous tissues. The eyelids and eyebrows are now well developed. The vernix caseosa is more abundant. The length of the fetus is about 300 mm by the end of this month.

During the *seventh month* the hair of the scalp is lengthening and the eyebrow hairs and the eyelashes are well-developed. The eyelids themselves separate and the pupillary membrane disappears. The body becomes more plump and rounded in its contours and the skin loses its wrinkled appearance due to increased deposition of subcutaneous fat. Towards the end of this month the fetus is viable and may in fact be successfully raised if born prematurely. Its length has increased to about 350 mm and it weights about 1·5 kg.

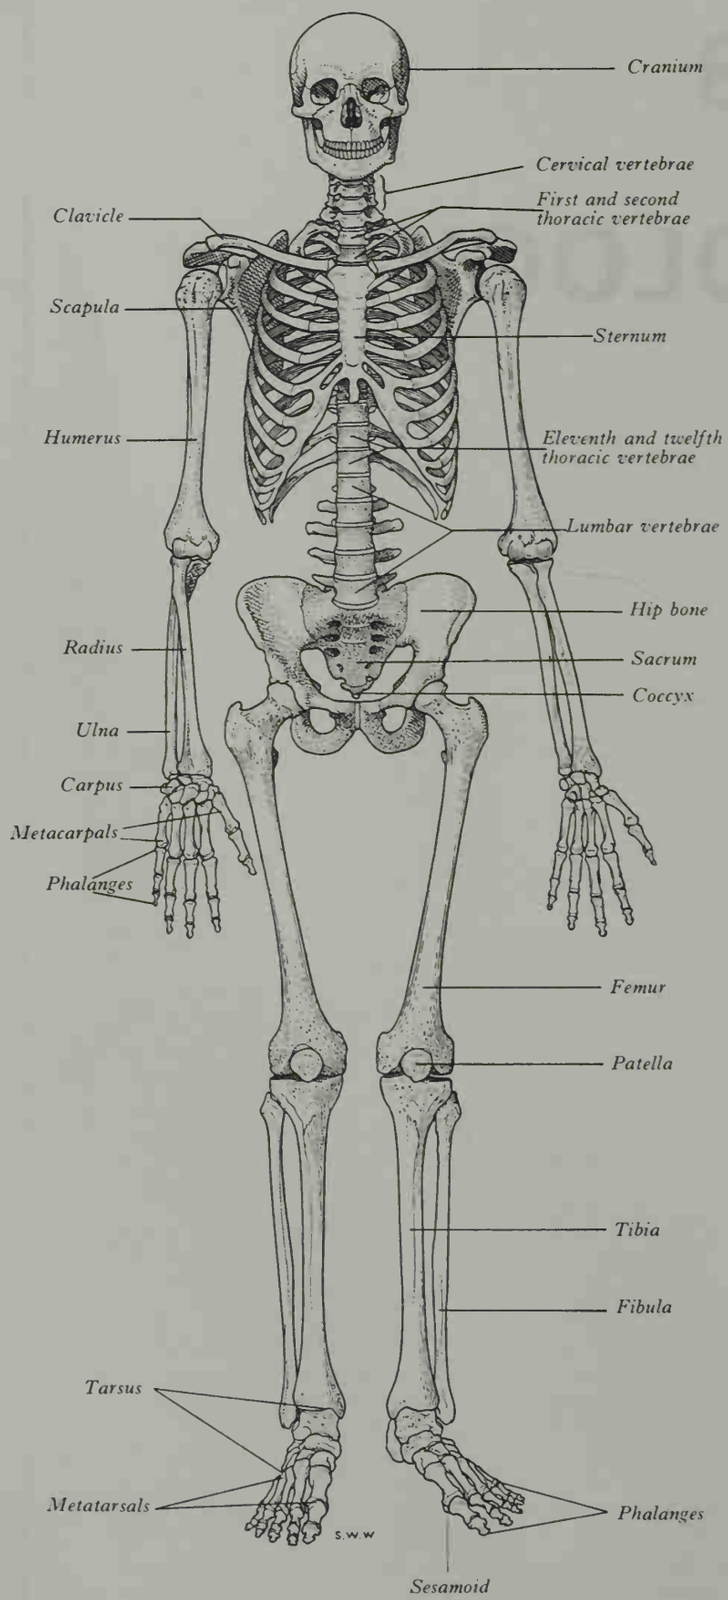


Throughout the remaining three lunar months of normal gestation the covering of vernix caseosa is prominent. There is a progressive loss of lanugo, except for the hairs on the eyelids, eyebrows and scalp. The bodily shape is becoming more infantile, but despite some acceleration in its growth the leg has not quite equalled the arm in length even at the time of birth. The thorax broadens relative to the head, and the infra-umbilical area of the abdominal wall shows a relative areal increase, so that the umbilicus gradually becomes more centrally situated. Average lengths and weights for the eighth, ninth and tenth months are 40, 45 and 50 cm and 2, 2·5 and 3 to 3·5 kg.

At the end of the *tenth lunar month*, just before birth, the lanugo has almost disappeared, the umbilicus is central, and the testes, which begin to descend with the vaginal process of peritoneum during the seventh month and are approaching the scrotum in the ninth month, are usually scrotal in position. The ovaries are not yet in their final position at birth; though they have attained their final relationship to the uterine folds, they are still above the level of the pelvic brim.

2.113 Changes in *relative* size and bodily proportions at the fetal ages indicated.

The length of the *period of gestation* is regarded as nine calendar months in obstetric practice—approximately 270 days. It is usually about 266 days—ten lunar months less 14 days. Legally, the infant is regarded as viable if born after the end of seven calendar months, but considerably more premature infants have been successfully reared.



3

OSTEOLOGY

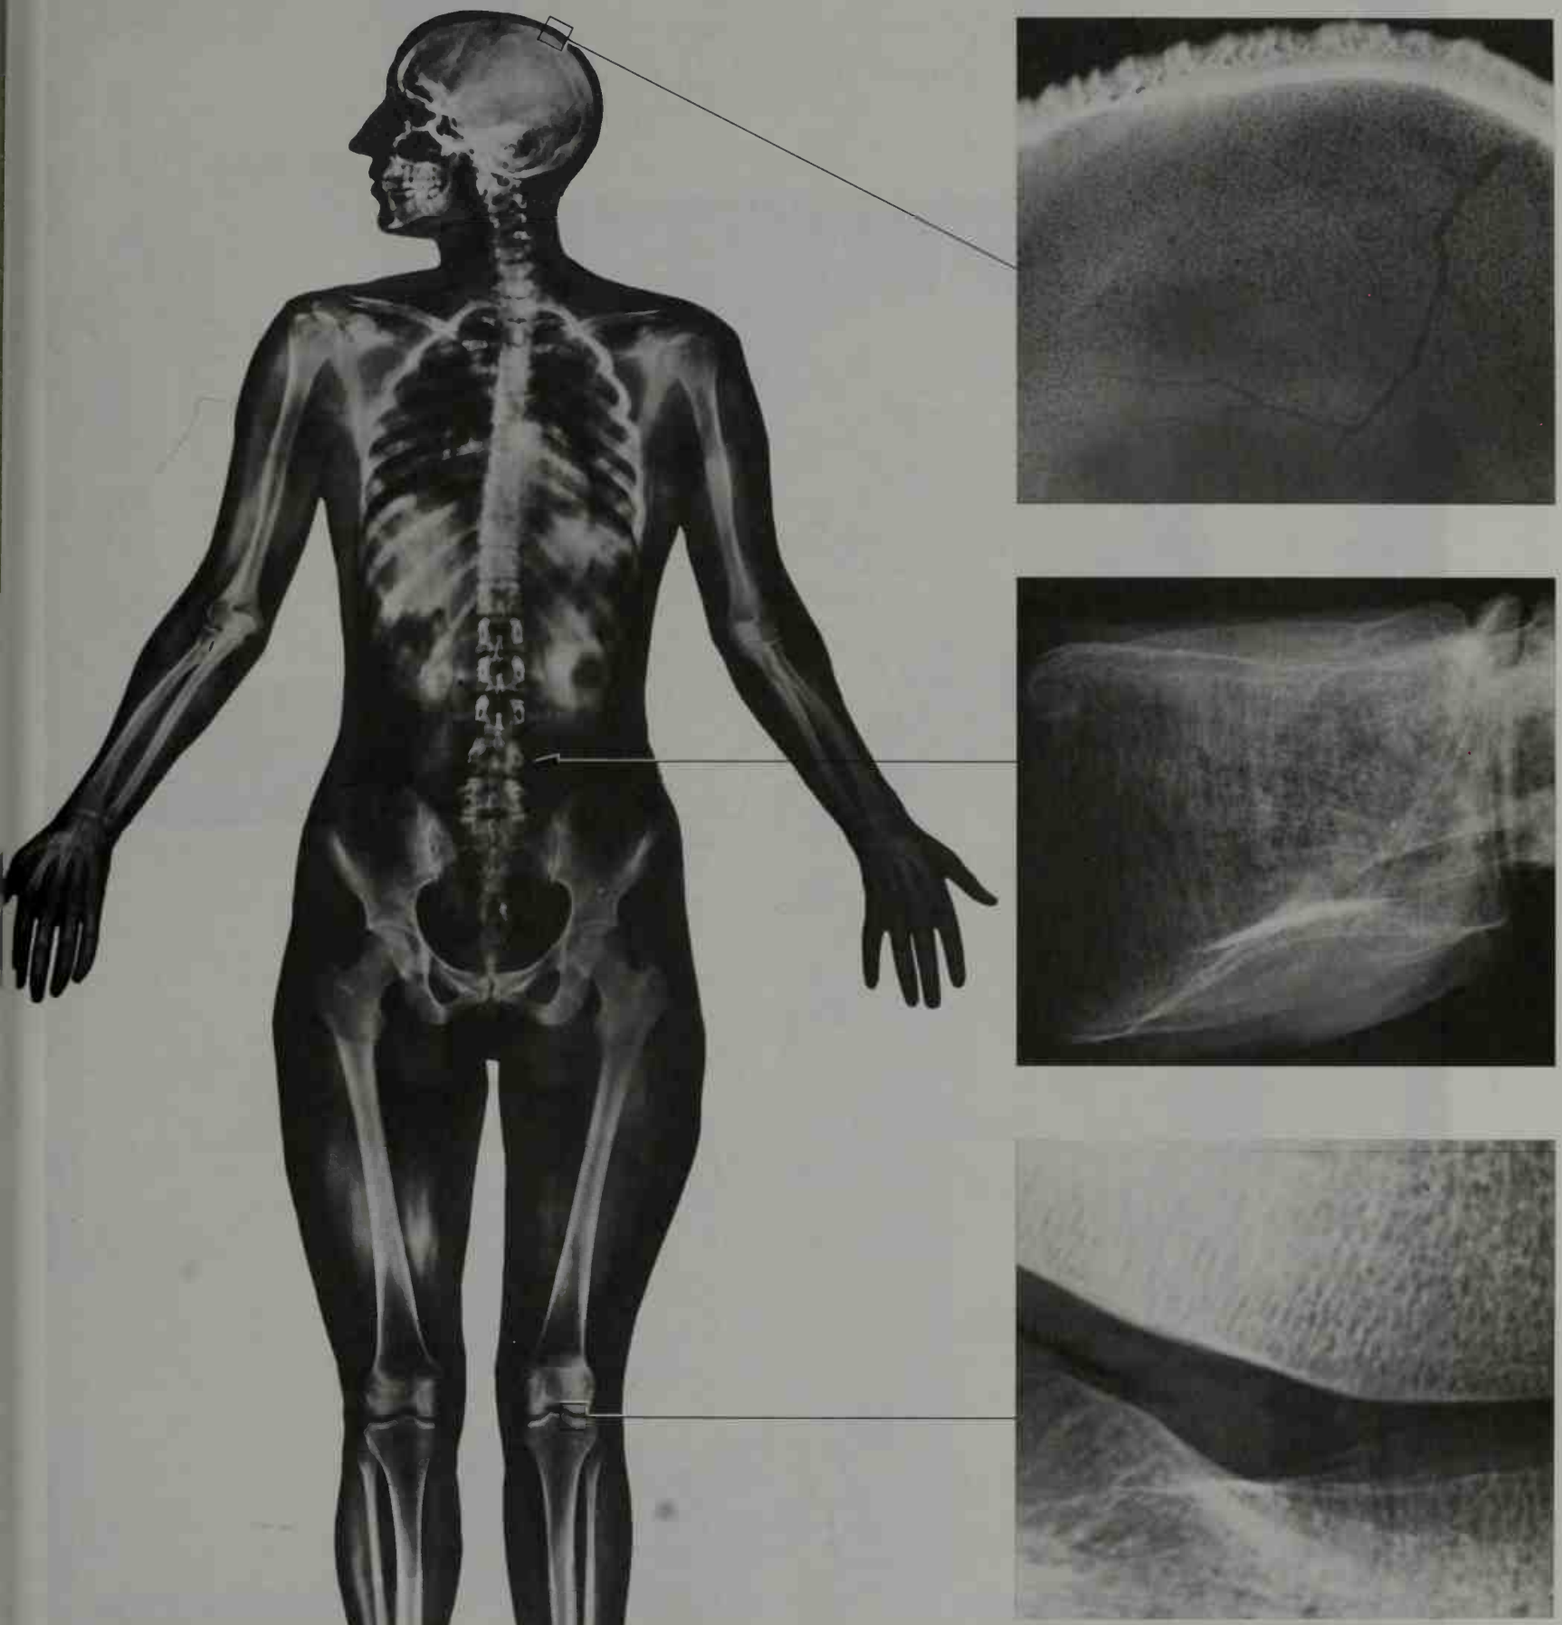
MORPHOLOGY OF THE HUMAN SKELETON

Introduction

The general shape of the human body accords with the bilaterally symmetrical pattern of its skeleton (3.1A, B). As in any typical vertebrate this consists of an axis, divided into segments to allow the flexibility necessary for movement, and of two paired appendages, or limbs, pectoral and pelvic in position, which are also divided into jointed parts for their basic activities in locomotion, grasping, etc. To these must be added the expanded and highly modified cranial end of the axis, the skull, and also a variable series of osseo-cartilaginous nodules, the sesamoid bones, which develop in some tendons and ligaments. All these elements are implied in the collective term 'skeleton'.

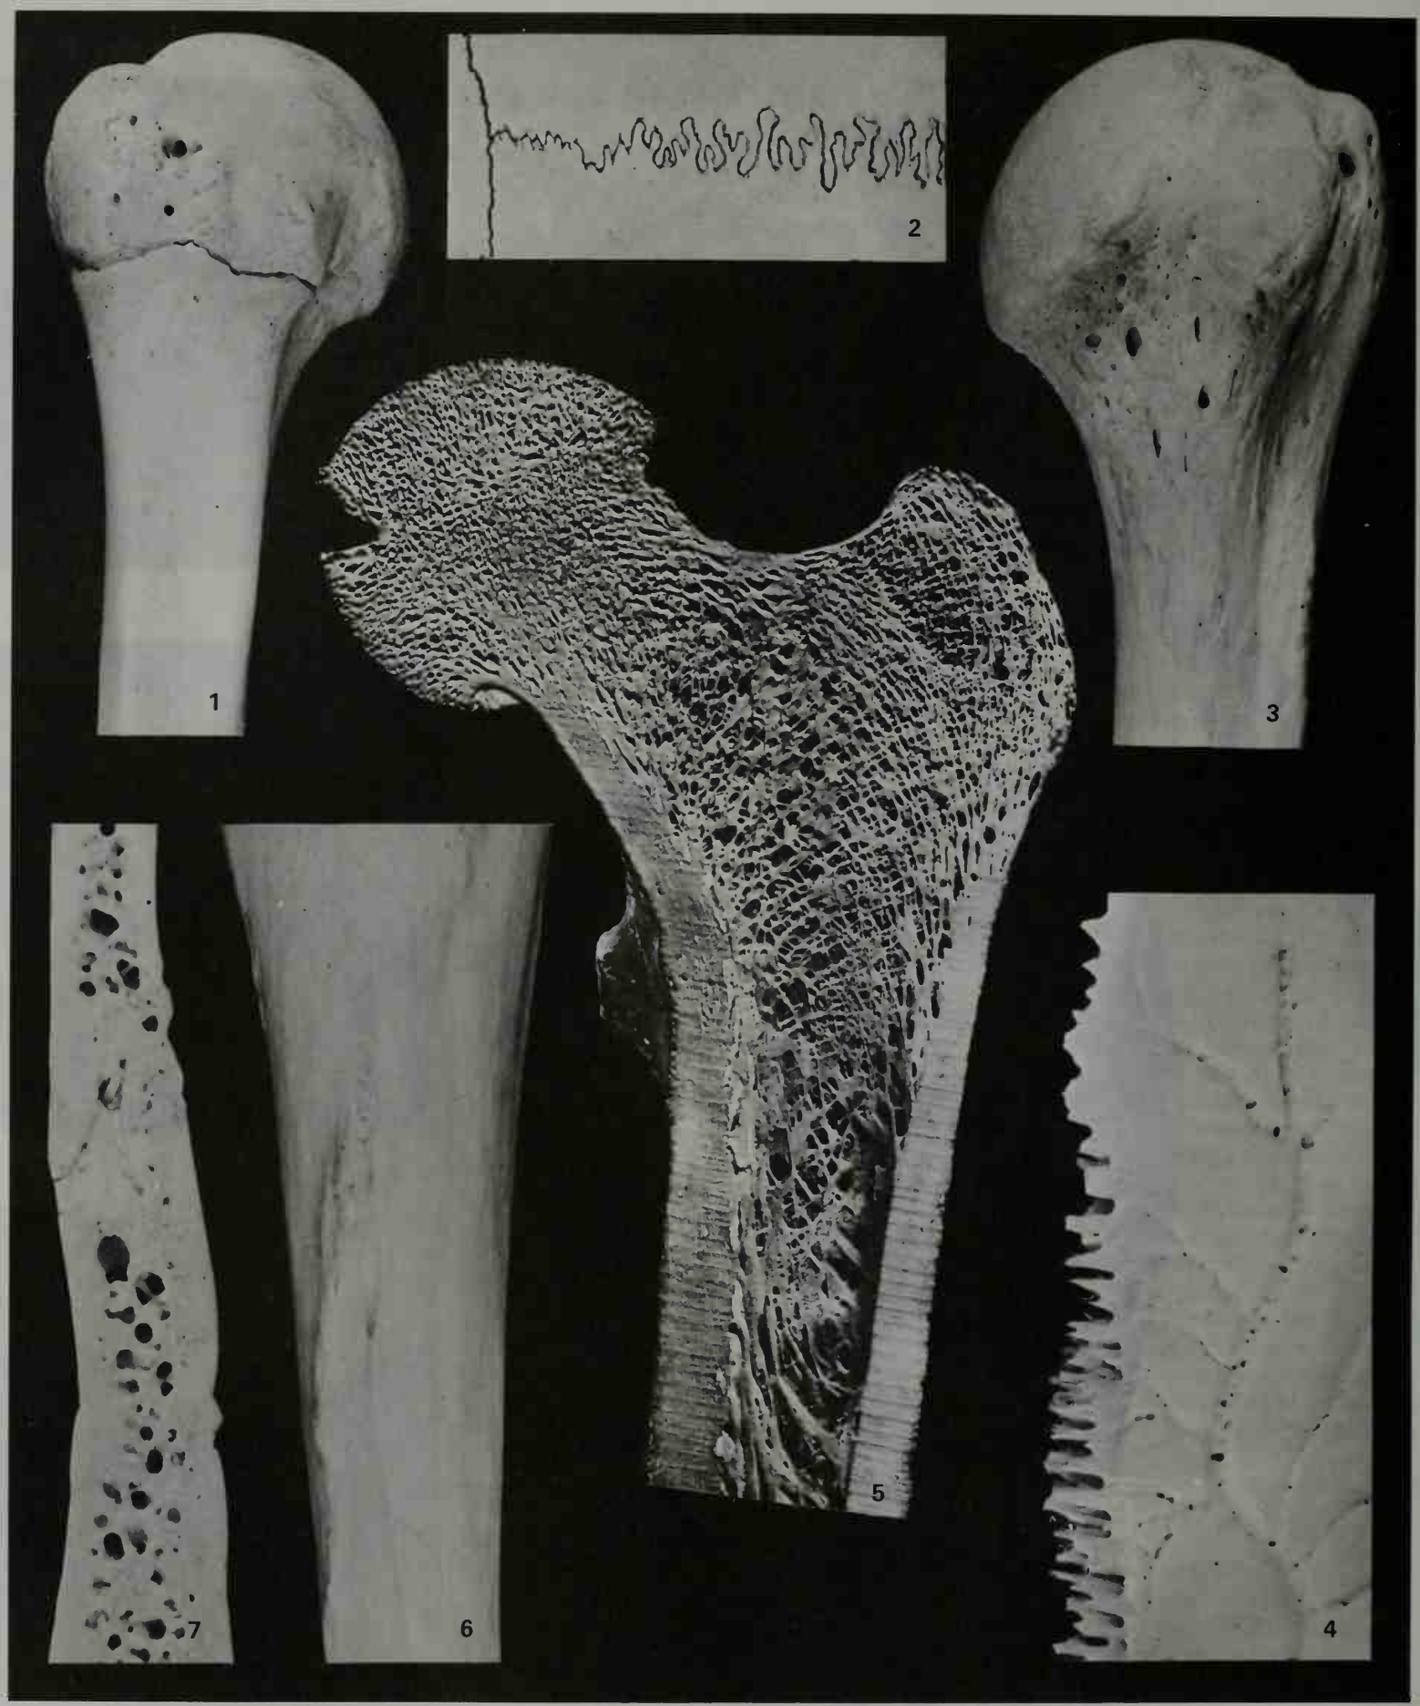
3.1A Anterior aspect of the male skeleton. The right hand is in the prone, the left in the supine position.

The human skeleton, as in other vertebrate animals, is internal to the muscles with which it has evolved in intimate functional integration. It is an *endoskeleton*, in sharp contrast with the *exoskeleton* characteristic of many invertebrates, such as the *Insecta*, whose muscles are attached to the internal aspects of jointed elements of chitin, a rigid material which also offers considerable protection from external mechanical forces. The same defensive quality is usually ascribed to many features of the human endoskeleton, and often with an excess of emphasis sufficient to obscure the primary association of skeletal elements, osseous or cartilaginous, with muscle in the more effective production of movement. Perhaps only in the case of the vault of the skull may the protective role be said to be uppermost, and even here muscle attachments obtrude upon the scene. The superficial situation of these particular bones is in line with their evolutionary origin, as is generally accepted, from the dermal bony armour of many groups of earlier vertebrates, including fish, amphibians and reptiles, both extinct and extant. Of the latter the ossified dermal carapace of the tortoise is a familiar example. Not only the cranial vault but also the maxilla, mandible, clavicle, as well as nails and the dentine of teeth, are dermal derivatives; collectively these structures are the vestiges in mankind of the much more extensive systems of dermal bones from which they have been modified. They constitute the human 'exoskeleton'.



The skeletal elements of the branchial apparatus of fish also contribute a *visceral* component to the skeleton of higher vertebrates, including man. Much modified, these elements now appear as ear ossicles, perhaps a part of the mandible, and as the styloid process and hyoid bone. The more caudal branchial arches have persisted as the cartilaginous skeleton of the larynx, but it is not customary to include these as members of the human skeleton; much less has this concept been extended to the supportive visceral cartilages of the trachea and bronchi, though these, as stiffeners to maintain the respiratory lumen, subserve much the same function as the bones and cartilages of the nasal cavities.

In some ungulates bone develops in the connective tissue of the cardiac 'skeleton' as an *os cordis*, and an *os penis* occurs in many mammals. Even without these, the human skeleton is clearly a complex of components, derived from original endoskeleton, from exoskeletal dermal elements, from modified branchial arches, and extraskeletal ossification in structures such as tendons.



The Skeleton in Life

During life the skeleton may also be regarded as including other, non-osseous, but intimately related structures which are removed in the process of *maceration* by which bones are prepared for study and preservation. Not only the attached muscles, ligaments and periosteum, but also cartilages are stripped away. Costal cartilages, somewhat arbitrarily, are grouped with the bony skeleton without question; but articular cartilages, an equally integral part of most living bones, are excluded, as are ligaments and all other joint cartilages, including intervertebral discs. After maceration, therefore, a skeleton is completely disjointed into separated elements which, while convenient for individual examination, have lost much of their functional implications. The drying out of macerated bones also entails disappearance of the contained marrow, and a slowly progressive loss of the mechanical properties, such as elasticity, proper to living bone (Smith and Walmsley 1959).

The morphological properties of living bone have been studied extensively (Thompson 1942; Bell 1956), at macroscopic, microscopic and ultrastructural levels, in relation to the

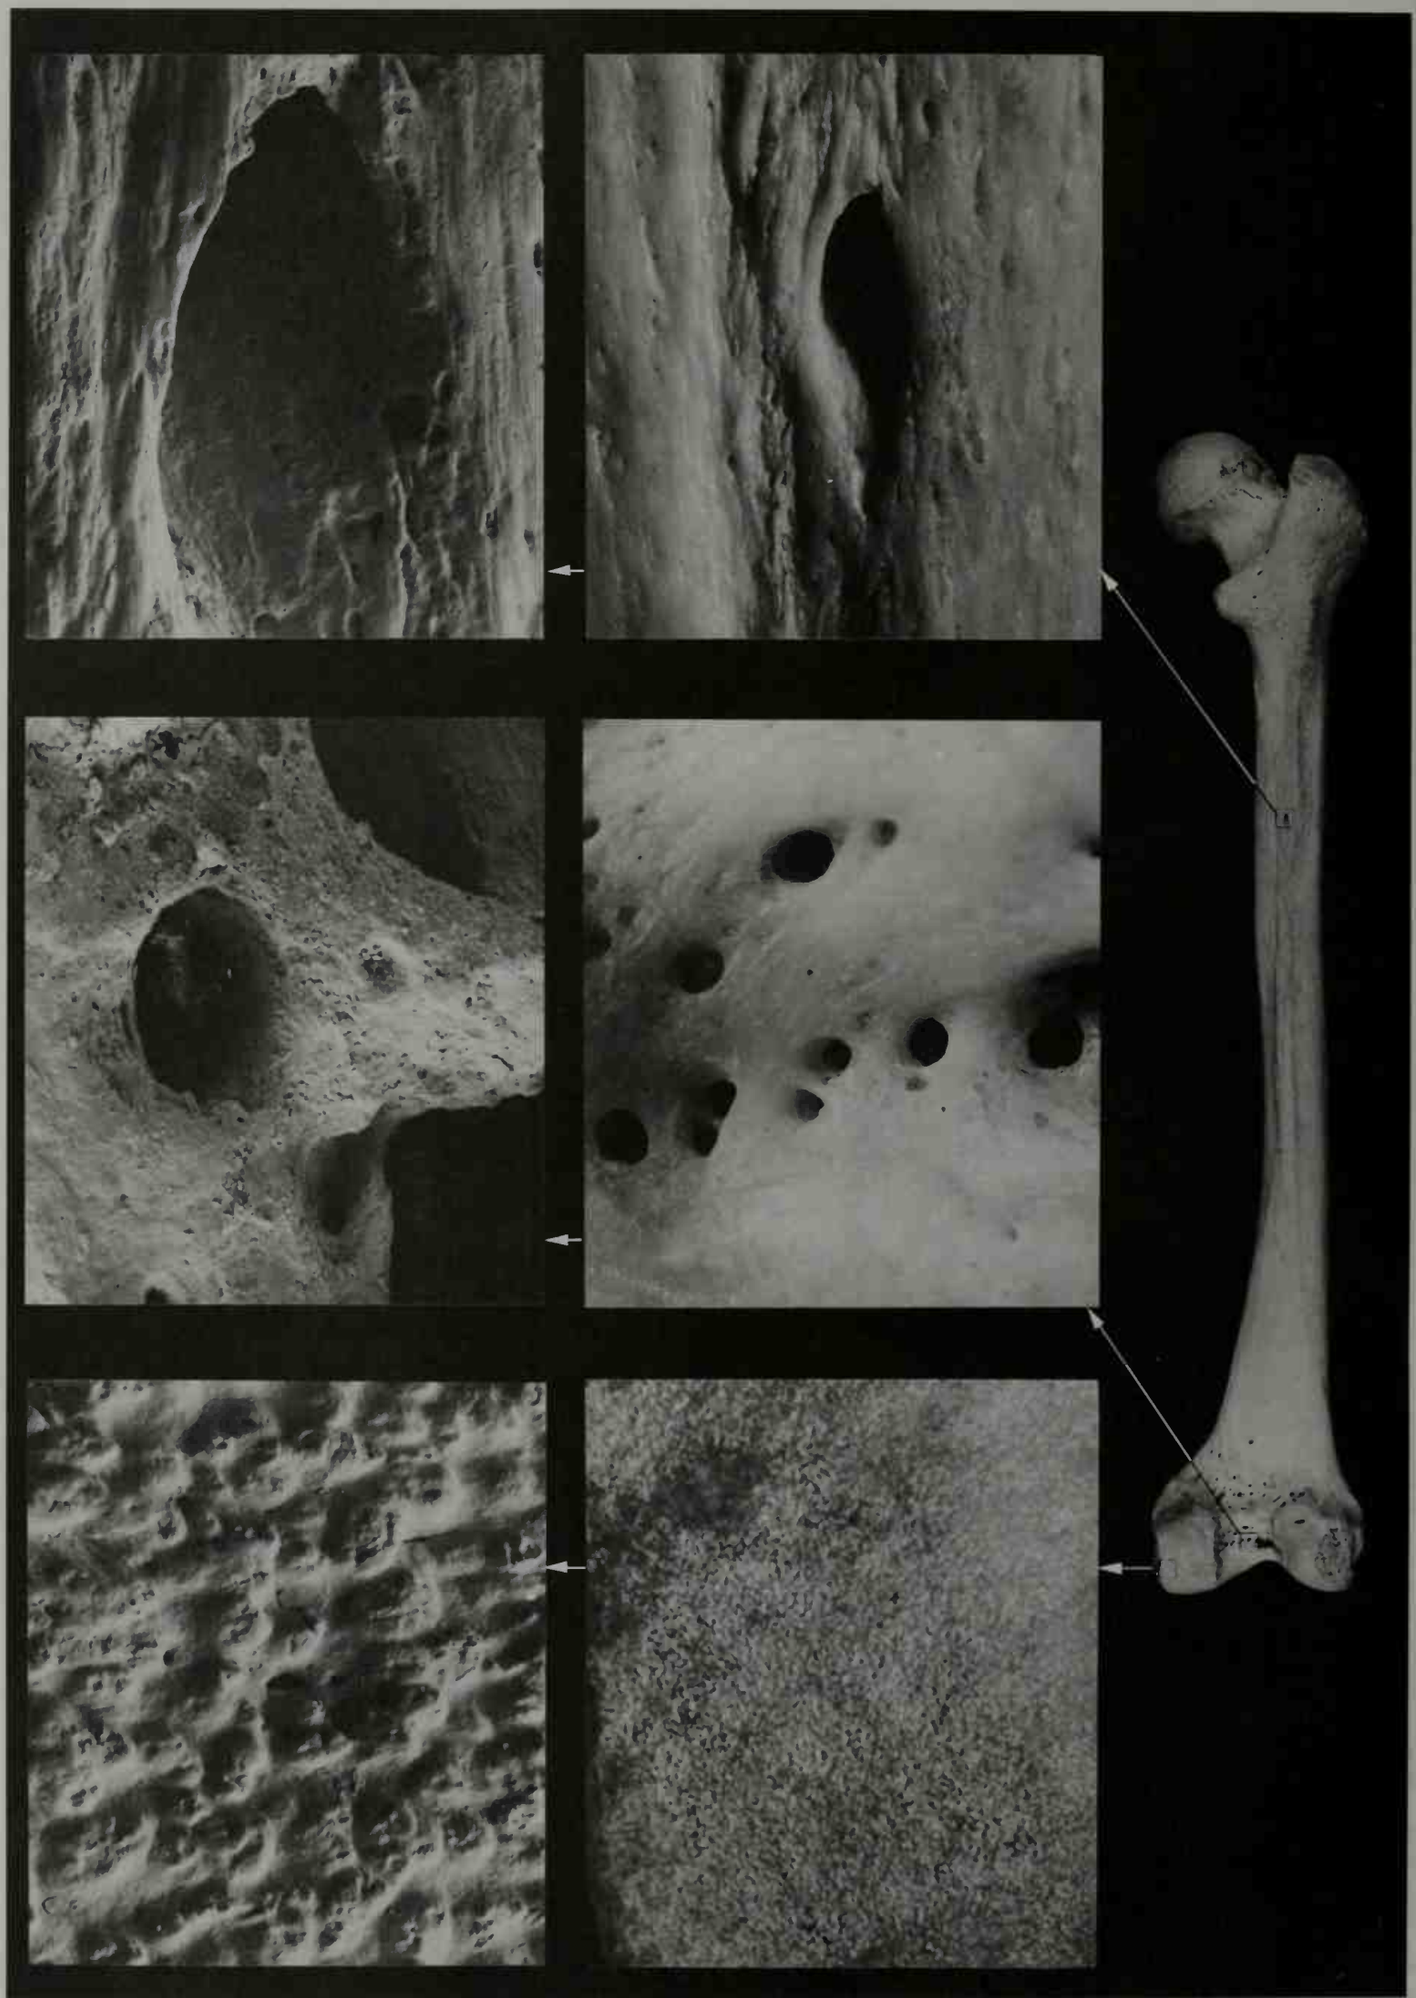
3.1B Compounded series of radiographs of the whole body of a young adult female. Note the general contours of the body (compare with **3.2**) and the relationship of the various parts of the skeleton to the disposition of the overlying soft tissues. Note also the relatively gracile proportions of the bones, the overall form of the pelvic skeleton, the obliquity of the femoral shafts, and the proportionate lengths of the limbs and their various segments. (Kindly prepared and provided by Messrs. Ilford Ltd.) Insets are high-resolution projection radiographs of, from above downwards, (*a*) part of parietal squama (*c.* ×2), (*b*) lumbar vertebral body—lateral view (*c.* ×2), and (*c*) contiguous femoro-tibial hypochondral articular surfaces adjoining the lateral tubercle of the intercondylar eminence (*c.* ×6). Note contrasting details of osseous architecture. (Projection radiographs kindly supplied by Dr. C. Buckland-Wright, Department of Anatomy, Guy's Hospital Medical School, London.)

3.1C Some macroscopic features of bone structure. 1. The ventral aspect of the proximal end of an immature humerus. Note the contrasting surface characteristics of the smooth articular surface covered in life by articular cartilage, the smooth periosteal surface of the metaphysis, the vascular foramina at the base of the greater tubercle, and the groove across which osseous fusion has not yet occurred, separating the compound epiphysis from the metaphysis. 2. The external aspect of part of the sagittal (horizontal) and coronal (vertical) cranial sutures. Note the variation in the form and degree of interlocking of the bones. 3. The ventral aspect of the proximal end of a mature humerus; complete osseous fusion has occurred between the compound epiphysis and the diaphysis. Note the variations in surface texture and the distribution and size of the vascular foramina. 4. The endocranial aspect of the sagittal margin of a parietal bone. Note the highly complex nature of the disarticulated sutural surface, the presence of vascular grooves and multiple vascular foramina on the endocranial surface. 5. A coronal section through the head, neck, greater trochanter and proximal shaft of an adult femur, showing the variation in thickness of the shell of compact cortical bone, and the geometrical patterning of the deeper intersecting bony trabeculae. 6. The posterior aspect of part of the shaft of a tibia. Note the relatively smooth areas which bear 'fleshy' attachments of muscles, the ridge where dense lamellae of collagen are attached, and an oblique vascular foramen which transmits the main nutrient vascular bundle to the shaft. 7. A sectioned bone of the cranial vault showing the internal and external tables of compact bone separated by the trabecular diploë, the diploic spaces of which, in life, are filled with haemopoietic red bone marrow.

The sectioned femur in No. 5 has been reproduced using a specialized photographic technique which produces a 'bas-relief' effect. Photographs by Mr. Kevin Fitzpatrick, Department of Anatomy, Guy's Hospital Medical School, London.

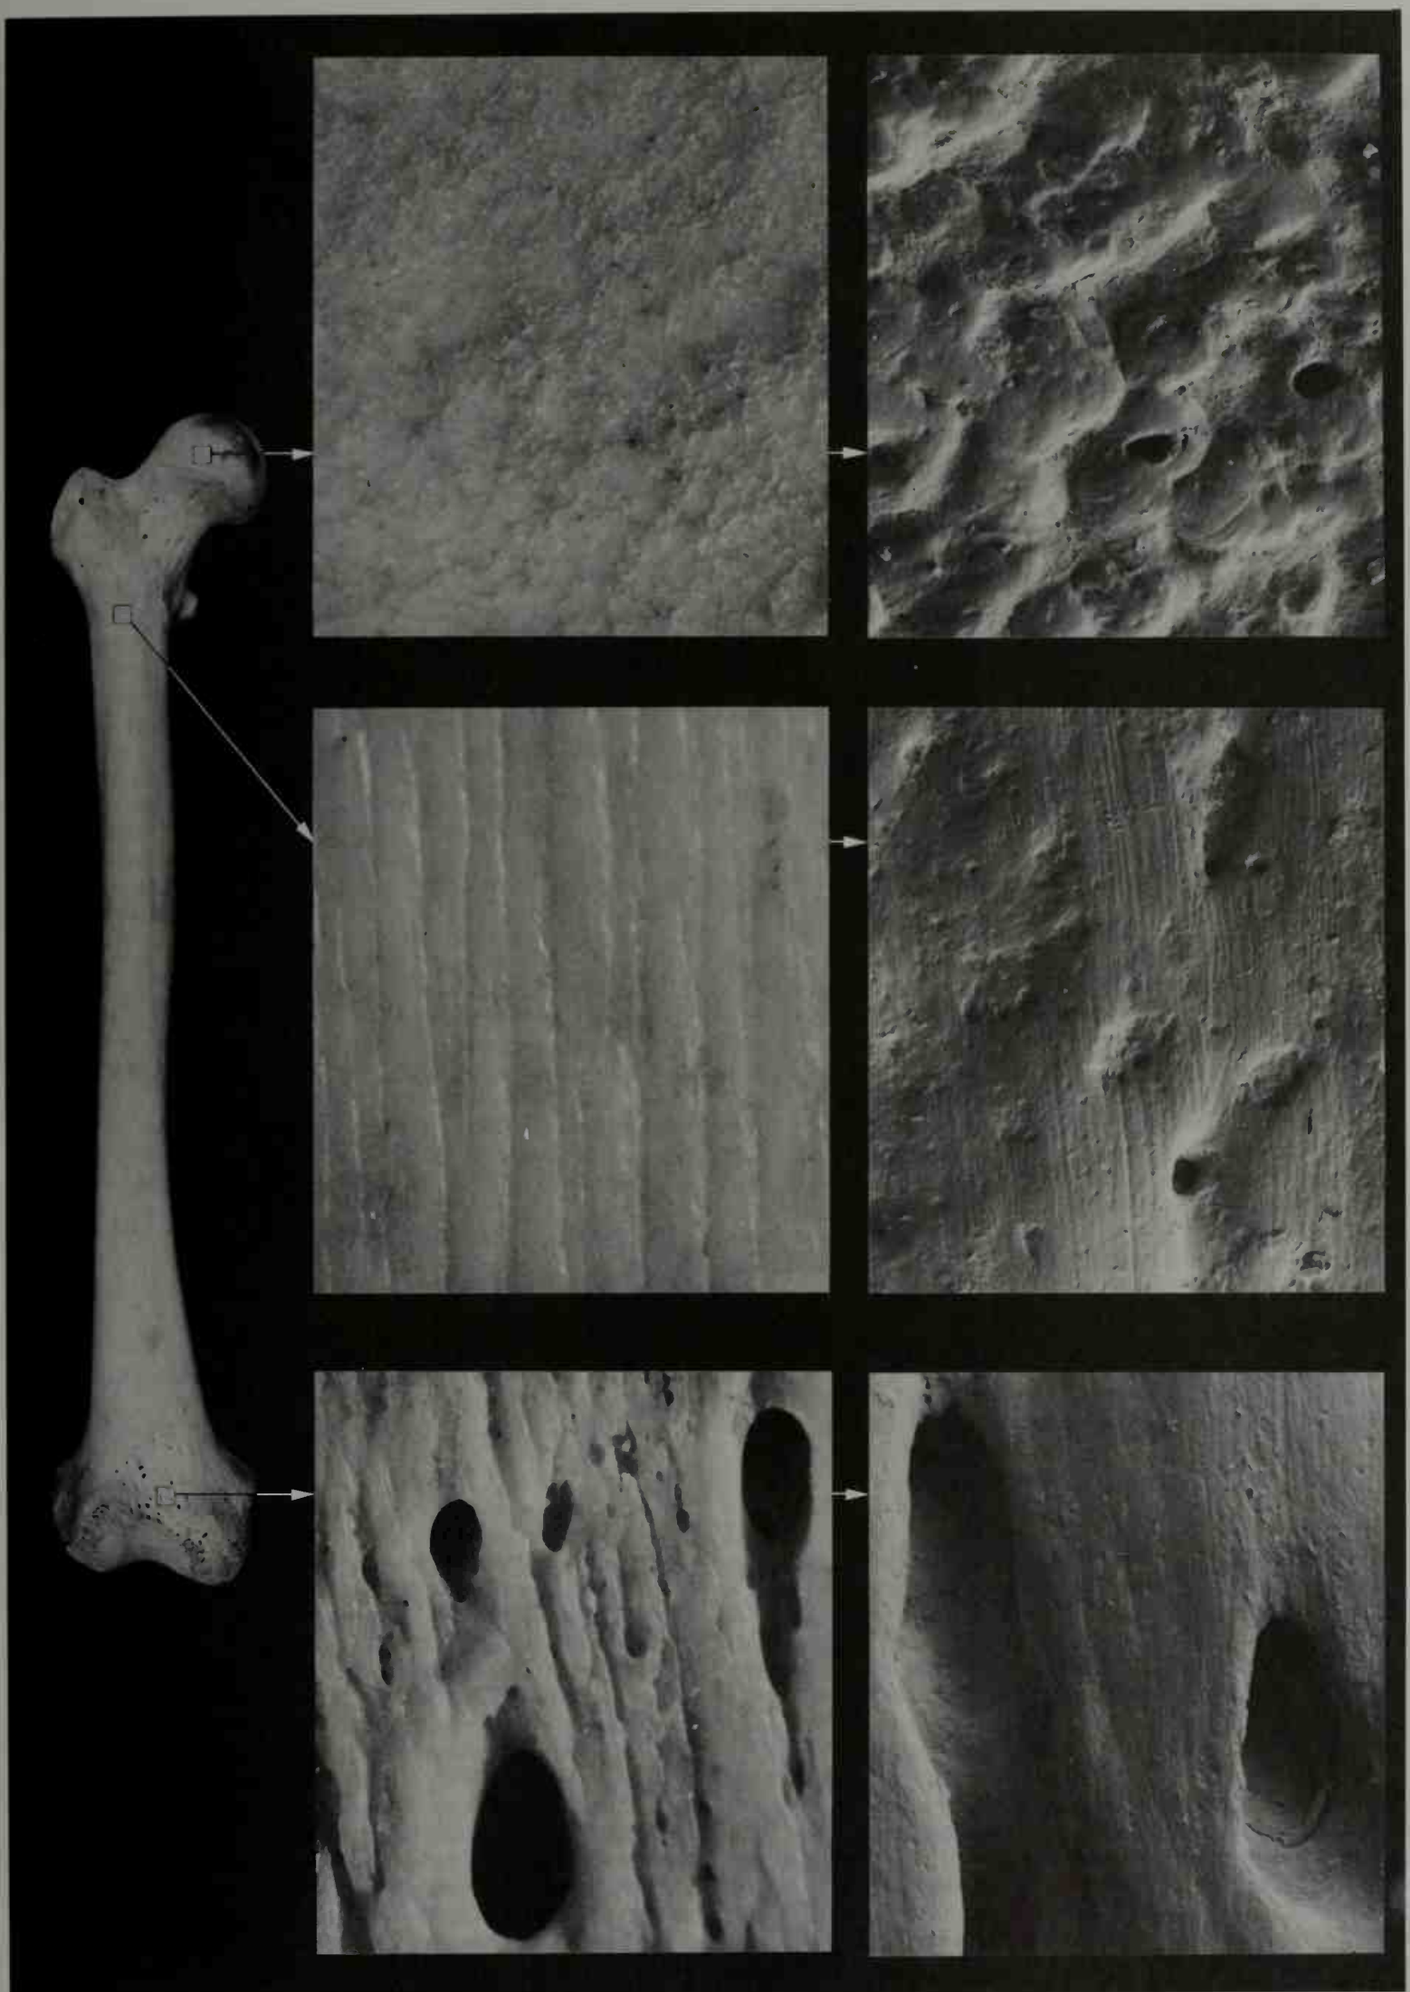
mechanical factors in the environment. The intimate blending of hard inorganic and resilient organic components in bone tissue affords almost equal resistence to compression and tension, unlike most structural materials used by man, which are usually better in one respect than the other. In tensile strength bone is comparable to cast iron, with only a third of the weight, the breaking stress being 15·5 and 18 metric tons per square inch respectively (Bell *et al.* 1941)—for additional and more recent data consult tables on p. 241. In its superior flexibility bone resembles steel more closely than iron, having about half the strength of the former. Compression tests show that bone has very large margins of safety to weight-bearing (Koch 1917) and to impact forces in jumping. It should be remembered in this connexion that contracting muscles are responsible for much the larger component of pressure, even at weight-bearing joints, especially in active movement (Bell *et al.* 1941; Williams and Svensson 1968). In the hip joint only a fraction of the pressure loading is due to body weight (*vide infra*).

A tubular structure, as is typical of the shafts of many limb bones, is the strongest and lightest—and hence the most economical—arrangement which can be designed. This particular adaptation of form to habitual stresses may perhaps also be evident in the approximately longitudinal direction of many osteons in elongated bones. In such long limb bones the thickness of the compact cortical shell is greatest at midshaft, where torsional and bending stresses are most severe, and where internal trabecular structure is absent or comparatively trivial in development. At their articular extremities these same bones must withstand chiefly compression forces, and these may be surprisingly large. In standing, the hip joint takes half of the body weight, and the pull of muscles multiplies this by a factor of about six; in walking or running, the full body weight (less the weight-bearing leg) is carried alternately at each hip joint. Conservatively, in an average adult male, this means a total load of 600 lb. (*c.* 270 kg.), and there is evidence that this can easily be doubled in powerful exertion. At such articular regions bone structure differs considerably from the arrangements in shafts, the whole of the interior being occupied by trabecular bone, which supports a comparatively thin shell of compact bone tissue. The same mode of structure occurs in smaller bones, such as those of the carpus and tarsus and in vertebral bodies, all of which are probably subjected more to compression forces than to any other form of stress. It seems likely that in joints where weight-bearing is comparatively trivial, marked pressure may nevertheless exist in working conditions, due to the action of muscles.



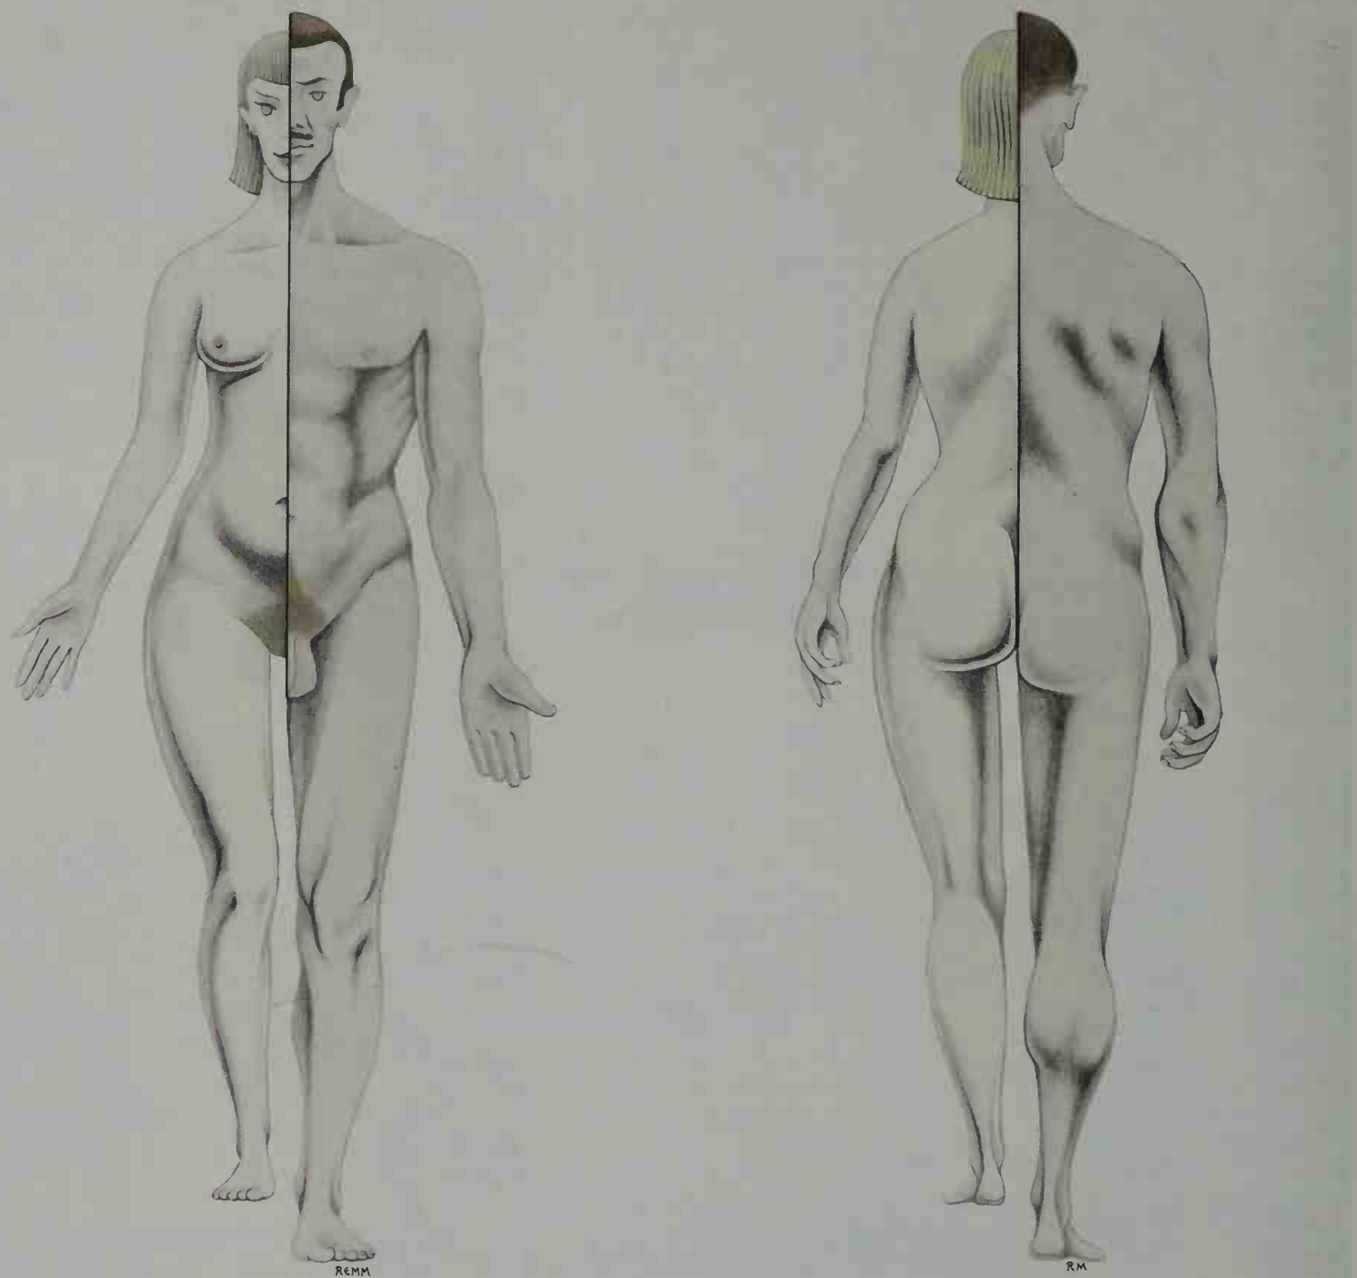
It has long been recognized that the trabeculae of cancellous bone, though individually small, may collectively provide powerful underpinning to relatively thin shells of compact bone. This form of construction is indeed widespread throughout the human skeleton, and it is perhaps only modified where bending, twisting and tensile forces demand more considerable aggregations of compact bone. Numerous instances of both arrangements will be encountered below in the descriptions of individual bones; in most of the larger elements of the skeleton both forms of construction, and intermediate arrangements, will be seen to occur in adaptation to the local mechanical problems. Mechanical forces directly influence the growth and forms of bones; and it can be safely assumed that in the protracted permutations possible during evolutionary time, a most apt biological solution to the mechanical demands impressed has been arrived at, in interaction with the limiting factors of nutritional resources, available muscle power, and the best compromise between size and weight (see also p. 238).

Sections through cancellous bone (**3**.1C, 3A, 10B) show trabecular patterns which resemble to some extent the crisscrossed arrangements of girderwork. Attempts to equate this pattern in individual bones, such as the femur and calcaneus, with analyses of the lines of force corresponding to habitual stresses, were made at an early date (Ward 1838; Meyer 1867). Such architectural explanations of internal bone structure have attracted some marked criticism, (e.g. Murray 1936). Nevertheless, numbers of studies of individual bones, and even comprehensive works covering the entire skeleton (Hall 1966), continue to augment the evidence of a most intimate correlation between stress and structure in bone, not only in the disposition of trabeculae but equally in the pattern of cortical bone. Wherever localized stresses are applied to bone, as in the attachment of tendons and ligaments, sections show that external features, such as ridges or facets, are not the only local change in osseous architecture. Thickening of compact cortical bone may also occur, and a subjacent condensation of trabeculae is usually evident and often pronounced. It is impossible to avoid the conclusion that patterns of stress and trabeculation are closely related, whatever the precise terms of the equation (see also p. 238). Many features of the *surface* architecture of bones remain unsuspected if they are merely examined superficially with the naked eye. Much additional information may be gleaned using a loupe, macrophotography, incident light microscopy, and recently, scanning electron microscopy (*see* the enormous variations in surface texture and incidence of foramina in selected regions of a normal human femur shown in **3**.1D).



The Shape and Proportions of Bones

Individual bones vary in shape, but some shared features prompted a categorization into long, short, flat and irregular bones. *Long* bones are typical of the limbs, their length in primate animals, such as man, reflecting the degree of speed and power in movement. They display elongate tubular shafts, containing a central medullary cavity, and expanded articular ends, which are epiphyses, having separate centres of ossification, often multiple (e.g. humerus and femur). Smaller examples of this shape are metacarpals, metatarsals and phalanges, although these bones are proportionately greater in diameter of shaft. The so-called *short* bones are exemplified in the carpus and tarsus, the elements of which are often approximately cuboid, cuneiform, trapezoid, or scaphoid in shape. Being subject to pressures rather than other forms of stress, they consist typically of a comparatively thin cortex of compact bone, supported by an interior completely occupied by cancellous bone. The *flat* bones include the curved laminar members of the cranial vault, in which an internal layer of trabecular bone, the diploë, variable in thickness, is enclosed between inner and outer laminae, or *tables*, of compact structure (**3**.1C). The scapulae, despite their irregular form, are described as flat. The class of *irregular bones* comprises any element not easily assigned to the foregoing groups. It is obvious that this classification, though time-honoured, has no great merit. Bones are better studied individually, and in relation to the functional demands made upon them.



In their overall shape and details of structure, bones are affected by a number of factors, which may be summarized as genetic, metabolic and mechanical. In all but its finer features and proportions, every bone is the product of a long functional history extended over countless successive generations. The basically genetic nature of the determination of the primary shape of bones has been demonstrated in organ culture, and by experimental transplantation of embryonic skeletal tissues (Murray and Huxley 1924; Fell and Canti 1934; Willis 1936). All the major characteristics of a particular bone appear to be self-differentiated. This is perhaps to be expected. Mechanical influences, such as moulding by the proximity and activity of associated muscles, often regarded as of first importance, can scarcely be operative at the early stage of development when the primary form of a bone is being established. As muscles become active during prenatal life, they may perhaps exert some influence upon the bone growth, though this is difficult to estimate. After birth, and up to adolescence, before all epiphyses are fused, increased use of muscles appears to augment growth of bones, both in length and girth. The reduction in osseous development, in limbs affected by paralysing diseases, such as poliomyelitis, implies that the play of active muscles is necessary to normal skeletal growth. Experimental studies (Appleton 1935; Washburn 1947; Wolffson 1950), usually consisting of removal of muscles, have confirmed, though in the same negative manner, the role of activity in bone growth. Again, comparison of the rate of increase in strength and stature shows some correlation in timing in adolescents (Jones 1949).

3.1D Surface details of a normal adult human femur photographed at the sites indicated, by macrophotography and scanning electron microscopy. The macrophotographs which are immediately adjacent to the whole bone photographs are at a magnification of ×5, except for that showing the diaphysial nutrient foramen which is ×4. All the scanning electron micrographs are at a magnification of ×80, with the exception of that

showing the diaphysial nutrient foramen, which is × 15. (Prepared and provided by Kevin Fitzpatrick, Derrick Lovell, and Michael Crowder, Department of Anatomy, Guy's Hospital Medical School, London.)

3.2 Comparison profiles of male and female to illustrate common differences in proportions. For details see text. Note, however, the heavier build of the male above the waist, the female below it, differences in limb proportions, carrying angle of forearm, muscularity, and apparent length of neck.

Metabolic influences on bone growth may operate at all stages of their development. The availability of calcium, phosphorus, vitamins A, C, and D, and the secretions of the hypophysis, the thyroid, parathyroid and adrenal glands, and of the gonads, all exercise essential roles in the growth of bone tissue (*vide infra*), and hence in the macroscopic features and dimensions of the skeleton. The effects of gross disturbance in many of these factors are well recognized pathological states; but in some of these it is impossible to define the limits between what is frankly pathological and merely variation from the norm. Body height provides an example; between the extremes of dwarfism and gigantism, demonstrably due to hormonal dysfunction, great variation from mean height can occur. Variations in stature and other dimensions associated with age, sex and race, are clearly to some degree genetically conditioned; but nutritional levels also have profound effects, especially in regard to race (Greulich 1951; Acheson 1960; Tanner 1962).

Bodily proportions, as well as absolute dimensions, exhibit a considerable range of variation in respect of age and sex (**3**.2) within a single racial group, and also in different races. While this is in part dependent upon the varying degrees of development of muscles and adiposity, such differences are chiefly due to skeletal variation. *Anthropometry* is the study of such variations (Martin 1928; Hrdlička 1939). The data of anthropometry may be non-metrical, such as the presence or absence of a feature (e.g. the sagittal crest of the Eskimo skull, the pre-auricular sulcus of the female innominate bone), or the persistence of a characteristic which usually disappears (e.g. the interfrontal suture), or the degree of development of some detail (e.g. frontal ridges, projection of chin). However, the great majority of anthropometric observations are measurements, carried out by internationally accepted techniques, upon the living body or upon skeletal material. These measurements may involve the whole body, e.g. stature, or sections of it, such as the limbs; or they may be carried out on individual bones. The cranium early attracted special attention in such studies, but methods of recording the principal dimensions are established for all skeletal elements. Proportions are expressed by indices; for example, the breadth of a skull may be reckoned as a percentage of its length, this being the cranial index of that individual. Such indices may have an ethnic

significance; Mongoloid people display a range of cranial indices at a higher level than some other races—they are 'broader' in the head, relatively and, in this instance, absolutely. A Mongolian child, however, might display a cranial breadth metrically less than that of a Negro adult, and yet be proportionately broader in this dimension. Ratios or indices between the length of the limbs and the 'sitting height', or between the arm and leg, the upperarm and forearm, the thigh and foreleg, are all used, and they show characteristic differences according to age, sex and race. Some details of such measurements and indices will be found in the appropriate sections on individual parts of the skeleton.

Any observations and measurements which aid in establishing the age, sex, size and race of an individual skeleton, or parts of it, are not only of interest in anthropology and archaeology (Brothwell 1968; Warwick 1968), but also of great value in forensic medicine (Glaister and Brash 1937; Boyd and Trevor 1953; Harrison 1953; Stewart 1970).

Estimation of skeletal age depends upon a number of criteria, which differ in usefulness at various stages of chronological age. Up to the age of about 25 years, including fetal life, the states of dentition and of ossification provide numerous data upon which an assessment can be made. The accuracy of this as an indication of actual, or chronological age is dependent upon the precision of the observations, the existence of adequate statistics for the sex and racial affinities of the individual under examination, and upon the nutritional history and endocrine activities of the individual. The latter data are not always forthcoming, and it is to be noted that available tables of appearance of ossific centres and fusion of epiphyses are usually based upon studies of well nourished children and adolescents. Moreover, these groups are usually derived from white communities in Europe or America. A few excellent studies of other racial groups exist (Todd, 1931; Modi 1957; Chang 1969). Racial variations in the order of the events of ossification would necessarily be genetic, and there is no clear evidence that such variation exists (Krogman 1962). Variations in timing of ossification are affected by wide divergence in standards of nutrition between, and even within, the racial groups so far studied. In all groups the data for females show an earlier appearance of centres of ossification and of fusion of epiphyses, a difference which is presumably genetic. Despite these complications, it is usually possible to assess the age of a complete skeleton within a year or so each way up to the age of 25, and with greater accuracy in the earlier years, especially if dental observations are also available. (For details *see* Teeth and sections on individual bones, and consult McKern 1970.)

From about 25 years onwards, skeletal age can be estimated to within ± 5 years by the state of the cranial sutures and of the bony surfaces of the symphysis pubis. From the mid-twenties onwards into old age, sutures exhibit a progressive closure (*see* p.344 and Todd and Lyon 1924–5). Unfortunately, closure begins from within, and unless crania can be opened for internal inspection, observations are likely to be misleading. Subsequent studies have thrown doubt upon the value of this particular technique (Singer 1953; Genovese and Messmacher 1959), and possible complications due to racial variation have been recorded (Abbie 1950). A series of progressive changes in the borders and surface configuration of the articular aspects of the pubic bones at their symphysis have been shown to occur. Appearances characteristic of ages from late teens to the fifties and beyond have been established (Todd 1920–30; McKern and Stewart 1957; McKern 1968). Most authorities now regard this as the best method available for estimation of skeletal age in the decades of maturity. Sequences of age changes have also been described for other skeletal elements (*see* scapula, sternum and costal cartilages), but these provide less accurate estimates. Lipping of the borders of vertebral bodies and around the margins of articular surfaces, exaggerated secondary markings on bones, and ossification into tendons and ligaments, are all manifestations of advancing years, but they provide no more than vague indications of actual age.

Estimation of sex in the human skeleton, when this is complete, can be effected with little error, and without resort to measurement, provided the individual under examination has passed the age of puberty. Sexual differences are particularly marked in the pelvis (p. 387) and skull (p. 346), though not to the same degree in different populations. The 'sexing' of a collection of whole skeletons from the same racial group may be almost free from error, whereas assessment of a single individual, of unknown extraction, may be much less certain. Inspection of other post-cranial bones than the pelvis, especially the larger limb bones, may provide clear evidence of sex, particularly if other individuals of the same race and of both sexes are available for comparison. Female bones are not only, on average, appreciably smaller than their male equivalents, they are also more slender. That is to say, they are of lesser diameter in the shaft relative to length. This is also reflected in their comparative *weights*. In a study of the femora of Hindus, for example, mean weights were approximately 385 gm. in males, and 279 in females (Singh and Singh 1974).

It has long been customary among anatomists, anthropologists, and forensic experts, to judge the sex of skeletal material by such non-metrical observations. Latterly, sexual divergence has been based upon actual measurements in many different bones; current texts should be consulted for details (Montagu 1960; Krogman 1962; Giles 1970). Of some recent discriminant analyses, one example may be quoted: Rother *et al.* (1977) examined 70 humeri by analysis of capital dimensions, and they concluded that the sex of unknown humeri was not easy to establish (whereas approximate age *could* be assessed). Perhaps the most useful aspect of such studies has been recognition of the need for appropriate standards of sexual dimorphism in different populations. The pelvis remains, however, by far the most reliable skeletal region in establishing sex, displaying differences not only before puberty, but even in infancy (Reynolds 1947) and fetal life (Boucher 1957).

Estimation of size, and particularly of height, from measurements of individual limb bones, has long been a matter of calculation (Rollet 1899), and with an increasing accuracy as successive studies have refined the formulae used (Trotter and Glaser 1958; Trotter 1970). The rationale of all such formulation is the observation—long familiar to artists (cf. Leonardo da Vinci)—that the major parts of the body, the trunk and limbs, exhibit characteristic ratios among themselves and in comparison with total height. These proportions are linked to age, sex and race. In infants the relatively huge head, long trunk, short arms and even shorter legs present a familiar picture of proportions which would appear grotesque even in an older child, and monstrous in an adult. As each infant grows in size it also changes in its proportions, gradually approaching adult shape, with a divergence towards one sex or the other around the time of puberty. The limbs become relatively longer in adult males, the shoulders relatively broader and pelvis narrower, and there are other differences (3.2). Between major races, at least, and to some extent between ethnic groups within each race, there are characteristic variations in bodily proportions. Negroes, for example, are comparatively long in leg and arm; moreover, the foreleg and forearm are long relative to the upperarm and thigh. In view of these variations it is clear that formulae designed to estimate height from long bones in one population cannot be applied indiscriminately to another. Alternative formulae for the sexes must be used, and immature bones must be recognized as such and subjected to suitable corrections.

The length of the femur has sometimes been used alone for estimates of stature, by application of a simple multiplier derived from the comparison of femoral length with the known height in a large number of individuals. However, from the earliest studies onwards, the humerus, radius, ulna, tibia and fibula have all been utilized; and more complex formulae, based upon the combined lengths of several long bones, have been shown to yield more accurate estimates. Whatever the methods used, it should be remembered that estimates are mean values with appropriate standard deviations. Assessment of the stature of unidentified skeletal remains, however carefully carried out, may show errors of several centimetres.

Since estimates of stature (and other assessments) must sometimes be made from *fragments* of bones, attempts to establish reliable formulae have been made (consult Steele 1970).

Estimation of race from skeletal observations has provided a

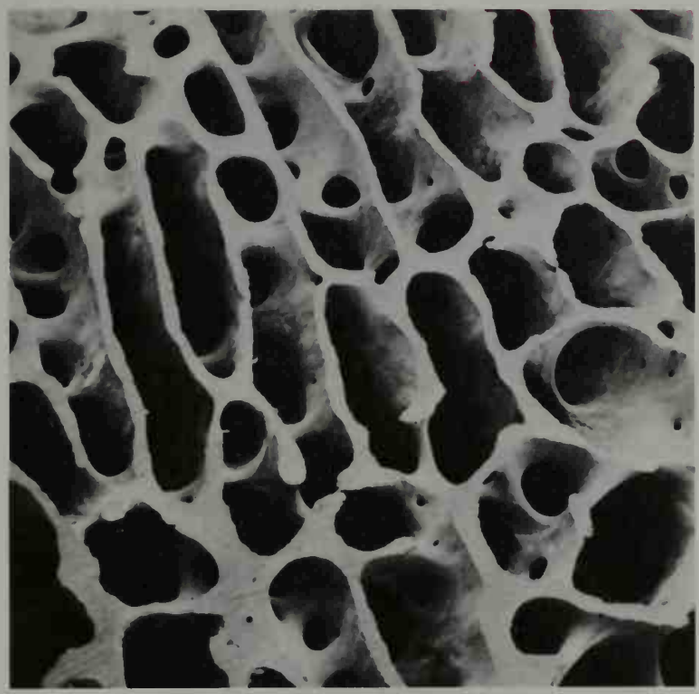
central theme in anthropology since its emergence as a discipline. The skull in particular has attracted great attention in this regard. A large array of *non-metrical* features (Wood Jones 1931) and of cranial, facial and mandibular indices have been widely used and continue to be (Martin and Saller 1958–61; Berry and Berry 1967; Berry 1975), and elaborate statistical analysis of *metrical* data has been introduced (Giles and Elliot 1960). Skulls from the three major racial groups, Caucasian, Mongoloid and Negro, can be identified as such with considerable success (perhaps in 85–90 per cent of instances), and without elaborate measurement. However, with further division into racial groupings the percentage of errors rises steeply. The worldwide intermingling of races entails that 'pure' races are difficult to indicate. This has been recognized particularly in America, where the existence of large collections of skeletons of both Whites and Negroes, both well documented as to their derivation, has stimulated extensive comparative studies. The results were surveyed in detailed criticism (Krogman 1962), with the conclusion that only the skull (but not the mandible) and the pelvis (Todd and Lindàla 1928) have any value in estimating race. (For some details of *cranial* features of racial significance *see* the section on the skull, p. 346.) However, metrical peculiarities in limb bones of Japanese have been claimed to exist by Takahashi (1975, 1976). In addition, the racial significance of a number of *postcranial* non-metrical skeletal characteristics has recently been re-examined, using rigorous statistical techniques, by Finnegan (1978), and the same worker has summarized the findings of other observers. The value of non-metrical features in evaluating populations from skeletal data is currently receiving renewed and intense interest. Consult Finnegan and Faust (1974) for a bibliography.

Functions of Bone and Skeleton

Bone tissue and the skeletal struts and levers formed of it, are evidently adapted with exquisite precision to resist all forms of stress, and with a suitable degree of resilience, in the varying play of musculature. The skeleton is sometimes said to give shape and support to the body; but the shape is itself largely an expression of the characteristic motor activities of an animal, and this simply returns us to the role of bones in movement. In some lower vertebrates, of course, a cartilaginous skeleton, calcified to a varying degree, provides the levers of the locomotor system, and it is a matter of controversy whether cartilage was ancestral to bone in this respect (Romer 1942, 1970; Bassett 1962; Krompecher 1967). However that may be, a bony skeleton is not merely an advantage in the locomotor sense. Bone differs from cartilage in being much more intensely vascularized (p. 257) and for this reason it might be expected that the calcium salts with which it is hardened could be as easily removed as deposited there. As will be considered elsewhere (p. 261), this is indeed the case. At least some part of the calcium in bone is freely labile, and can be mobilized into the general circulation with but little delay. The well established effects of depressed calcium levels in rickets and osteomalacia indicate that calcium in bone and in the body at large are in a constant state of balanced interchange. This is confirmed by much evidence from more recent and precise observations (McLean and Urist 1968). The skeleton thus plays an integral part with other tissues in the general metabolism of calcium, providing the major store of calcium salts (97 per cent of the total bodily content).

Some skeletal elements obviously afford protection from extraneous forces; but the exoskeleton which is so clearly protective in earlier vertebrates persists in the human body only in a highly reduced and modified form. Even in the case of the skull, much of the cranial cavity of which is enclosed by dermal bones, primitively protective in nature, this function is rather more complex than the mere provision of a barrier to *external* assault. Powerful muscles, both masticatory and postural, have invaded the cranial walls for attachment, a situation which demands isolation of the brain and its circulation from these far more frequent *internal* sources of disturbance. Again, ribs are commonly described as protective, and they certainly reduce the risks of impact, even with pointed objects, but such dangers are sporadic, whereas respiratory movements occur many times a minute throughout life.

As already described, all bones are, to some extent, internally trabecular in arrangement. This pattern is not only concerned with mechanical stresses, but also with the siting of the bone marrow. The innumerable minute spaces between the trabeculae, together with the much larger cavities in the shafts of the longer limb bones, are occupied in life by marrow, whether haemopoietic or adipose (p. 63). In some cranial bones air-filled cavities develop and these are then termed *pneumatic*. Pneumatization of bone may take the form of single large hollows, such as the maxillary *sinus*, or of multiple, small, intercommunicating *air cells*, as in the mastoid process of the temporal bone (*see* 3.95A–D). In the human skull, the saving in weight thus effected can scarcely be significant, as it is in the extensively pneumatized cranial vault of the elephant. Nevertheless, the cancellous architecture of most bones is generally regarded as conducive to lightness without loss of strength, though perhaps also associated with economy in the use of materials. Some sinuses, particularly the smaller air cells, in fact appear to develop from the *diploë*, or cancellous tissue, of certain cranial bones, and might therefore be an expression of the above principle. The larger sinuses are said to affect the timbre of the voice, but they may be no more than the result of unusual growth patterns of the bones in which they occur.



The Mechanical Properties of Bone

The resemblance of many bones to man-made levers, supporting columns, arches, struts and girders, inevitably prompts the application of mechanical or engineering concepts to functional analysis of them. Not only are bones obviously analogous to such structures in external configuration and internal architecture, but also in their uses. In fact, the apparently fragile but collectively strong lattices of struts and trusses of trabecular bone, and the occurrence of skeletal forms such as tubes, H-girders, ridges and other thickenings of cortical bone, pre-dates by aeons of time the mechanical inventiveness of mankind. Once human technology began to overtake natural biomechanics, then comparisons became inevitable. Galileo (1638) recognized the possible significance of trabeculation and he also asserted that hollow cylinders are, weight for weight, stronger than solid rods. Havers described his 'systems' and their axial orientation in 1692; Ward (1838) and perhaps others likened trabecular patterns, with compressive and tensile elements, to supporting brackets and similar structures. However, Meyer (1867), with his mathematician collaborator, Culman, first clearly enunciated what is now known as the *trajectorial theory*; and this, despite much subsequent argument, still survives. No more satisfactory hypothesis has replaced it. The theory basically states that the trabecular pattern coincides with routes of stress; and this has not yet been convincingly demonstrated, nor disproved. It is clear that trabeculae must be concerned in the support of the shells of compact bone which adjoin them, for these cortical strata are usually thin; but the relations between stress and strain and trabecular pattern are presumably more complex than the simplified mathematical analyses which have been frequently applied to sections of bones or models of them (Kummer 1972).

In contrast to the largely theoretical approach to the intimate adaptation of bone tissue to skeletal functions is the direct estimation of the strength of bone as a material by the methods of engineering practice, to assess the response of either bone samples or entire skeletal elements. Wertheim (1847), anticipating Meyer's observations, applied physical tests to bone tissue, and many subsequent workers, particularly in recent times, have expanded such techniques. Developing interest in the mechanics of locomotion has added a stimulus to investigation of bone, and there are to be found, scattered through a large number of papers and monographs, a somewhat bewildering variety of numerical values for the various physical parameters of the tissue. The subject is, of course, fraught with difficulties and fallacies. Obviously differences are likely between bone material from different species, and sex and age are also likely to be factors. The nature of the specimen tested is also a variable; whole bones and

3.3A Scanning electron micrographs of trabecular bone at different sites in the proximal part of the same human femur. All fields are shown at the same magnification (× 20). (1) is an area in the subcapital part of the neck, (2) and (3) are in the greater trochanter, and (4) in the rim of the articular surface of the head. Note wide variation in the thickness, orientation and spacing of the trabeculae. (Original photographs from Whitehouse and Dyson 1974, by kind permission of the authors, the *Journal of Anatomy*, and Cambridge University Press.)

blocks of cortical, trabecular, or a mixture of these behave differently. The immediate source of the specimen is thus important to define, if results are to be comparable. It is now established that bones from preserved cadavers yield misleading values, especially as regards plastic deformation (Reilly and Burstein 1974), but also in its elasticity, hardness, and compressive and tensile properties (Evans 1973). Dead bone, however, provided that it is kept wet, does not differ in its characteristics from living bone, tested *in vivo*, whereas, dried bone is harder but less deformable. Selecting a sample area from a given bone presents problems, because the difference in distribution of Haversian systems or trabeculae may affect parameters and vitiate comparisons. Testing of such specimens and intact bones, especially to the point of breakage, is rendered very difficult by problems of support or attachment of tension devices, which may incur undesigned collapse at points of support or attachment. This is particularly true of the testing of axial tension.

Because of these and other difficulties, the experimental data, which have been recorded in profusion, present a highly complex picture. It is clear, for example, that it is impossible to give even useful mathematical means for the physical characteristics of bone as a material, because the resistance to various forms of stress and elasticity vary in different regions of the same bone. In view of the structural complexity of a complete skeletal element, in which occur well-recognized variations in thickness, density and modelling of the cortical shell, coupled with marked variation in the internal trabecular pattern (**3**.3A), it is not surprising that

3.3B Photographs illustrating three methods used to investigate possible interrelations between structural organization and patterns of force transmission in bone. *Above*, split-line patterns produced in a decalcified skull (*Macaca mulatta*) by repeated puncture with an ink-tipped needle. *Centre*, pattern of cracks in colophonium resin coating of a femur subjected to a compressive stress of the head, vertically applied. *Below*, photo-elastic pattern produced in a flat plastic sheet modelled upon the proximal end of the femur. A compressive force has been applied to the femoral 'head', whilst a tensile force has been applied to its 'greater trochanter'. (The lowest photograph is from von Knief 1967, the others kindly contributed by Dr. C. Buckland-Wright, Department of Anatomy, Guy's Hospital Medical School, London.)

some authorities emphasize the improbability of ever establishing more than an approximate picture of the mechanical behaviour of an individual bone. The observations illustrated refer to the proximal end of the human femur (Whitehouse and Dyson 1974). A similar regional variability has been demonstrated in the distal end of the bone and in the proximal extremity of the tibia (Behrens *et al.* 1974). In the latter study, strength was not directly correlated with trabecular pattern or total specimen density, indicating a multi-factorial relationship. For quantitative data on the sternum *see* Whitehouse (1975), and, for the iliac squama, Whitehouse (1977).

A considerable variety of techniques, and combinations of them, have been employed to assess isolated physical properties of samples of bone tissue and whole bones, and also to assess the distribution of strains within the latter in response to various forms of stressing. The results of a very large number of tests, using engineering techniques, have been recorded and are summarized in the writings of Ascenzi and Bell (1972), Kummer (1972), and Evans (1973). Although these values vary amongst different workers, much greater disagreement characterizes the problems of how forces are transmitted in bones. The problem has been investigated in actual bones, commonly the femur, and also in plastic models. The use of such models is based on a false assumption, that bone is an isotropic, homogeneous material. In fact, bone tissue is a visco-elastic, biphasic substance, analogous to fibre-glass, the tropocollagenous content corresponding to the fibres and the crystalline hydroxyapatite to the 'glass'. Hence a plastic model can merely indicate the surface behaviour of stresses in the bone it is supposed to imitate. In both, the stress pattern can be studied by inspection of the cracks produced in a surface covering of colophonium resin (Kuntscher 1934) or special lacquers (Gurdjian and Lissner 1945), but there are grave doubts as to how far these superficial indications record more than a crude picture of the strains in bone. Hallermann (1934) introduced a photo-elastic technique, which reveals stress patterns in bones and plastic models using polarized light. Pauwels (1965) and Kummer (1966) have exploited this technique, but Brekelmans *et al.* (1972) have emphasized the limitations of such methods, not only in the use of models constructed of isotropic materials, but also in the over-simplification inherent in mathematical analyses of a two-dimensional nature.

Benninghoff (1925) used the *split-line phenomenon* in decalcified bones, claiming that the surface pattern of split-lines or cracks, induced by puncturing with a round-bodied needle or awl, followed the distribution of osteons orientated in the axes of compression or tension. He accepted the trajectorial theory of trabecular bone and considered that this was directly related to the behaviour of osteons in cortical bone. Tappen (1954) has made similar claims, but such views have been attacked; Tappen (1970) himself admits that the patterns may follow 'immature' osteons, and Isotupa (1972) considered that they represent the distribution of points of weakness due to vascular spaces. Most recently, Buckland-Wright (1977) has attributed the cracks to the existence of weaker zones of bone (which incidentally may be concerned in the genesis of fractures), and included cement-lines, interlamellar interfaces, osteocyte lacunae, and vascular canals. He considered the split-line technique an unreliable method for structural and force transmission analysis in bone.

Strain gauges have been used to record the results of stresses on whole bones, both as dead, isolated elements and during *in vivo* experiments in intact animals, and also on bone samples. Unfortunately they cannot be bonded on to bone in large numbers, and the data obtained are limited. Nevertheless, interesting *in vivo* results have been obtained by Lanyon (1973) on the vertebrae, tibiae, and calcanei of sheep, recording a deformation cycle during locomotion. Lanyon himself was critical of the method, which has, however, confirmed the elasticity of bone and shown that the elastic modulus is an inconstant quantity, varying with speed of movement.

Interference holography has been applied to the study of surface strains in the human mandible (Gupta and Knoell 1973), but the technique has proved difficult and has apparently not yet been adapted to experiments on the living.

Mathematical analysis has been widely developed in this field, but since the basic data employed are usually limited, or are based upon the over-simplification inherent in the use of models, the usefulness of this approach is restricted. (For examples of such work consult the papers of Koch 1917; Kummer 1966; Rybicki *et al.* 1972.)

A combination of techniques appears to offer the most fruitful approach to the problems of bone mechanics, and it is therefore appropriate to end this brief review of a most complex and difficult field of research by reference to a recent study by Buckland-Wright (1978) of the patterns of transmission of strains in the feline skull during biting. This study combined the techniques of radiology and projection microradiography with the use of strain gauges, colophonium resin experiments, and histology, the limitations of each technique being offset by the others. The projection microradiographs were assessed by a stereoscopic technique, permitting a three-dimensional interpretation of the relation between bone structure and impressed stresses. On the basis of these observations a modified version of the trajectorial theory was propounded. Further work by such combined methods must be awaited with interest.

As already stated above there has been a profusion of estimates of the physical parameters of bone tissue recorded. The following results are cited as interesting representatives of such estimates, including a comparison with other materials.

Table of the approximate tensile breaking strengths of bone and a few other materials *(From Gordon 1968)*

Growth of Individual Bones

As in any other mammal the bones of the human skeleton are preformed in hyaline cartilage or, in a minority of elements, in condensed mesenchyme. Thus, a soft tissue model at first appears, and this is gradually converted into hard osseous tissue by the development of osteogenesis, frequently in a central position, from which the process of transformation spreads, until the whole skeletal element is ossified. The appearance of such *centres of ossification* is spread over a long period of time. A large number are first detectable in embryonic life (**3**.4), some do not appear until much later in prenatal life, and others do not start until well into the growing period after birth. The process is complex, presenting phenomena which must be studied at different levels of organization. At the microscopic, ultrastructural and molecular levels are the basic problems of histogenesis, growth and transformation of skeletal tissues, including primitive mesenchyme and its differentiation into the various forms of connective tissue, cartilage and bone. All these matters will be considered in the next section which is concerned with the fine structure, histogenesis, growth, remodelling and regeneration of all the skeletal connective tissues (*vide infra* p. 245 *et seq.*).

At first, microscopic in size, ossific centres soon become macroscopic and their subsequent behaviour can be followed by the unaided eye, whether by plain inspection, dissection, or by radiological technique. It is this scale of events which will be considered here.

Many bones are ossified from a single centre; these include those of the carpus and tarsus, the lacrimal, nasal, and zygomatic bones, the inferior nasal concha, and the auditory ossicles. Even in this limited group the appearance of their centres extends from the eighth week of intrauterine development to the tenth year of childhood, thus providing in themselves a wide sequence of events in studying skeletal growth or in estimating age. However, most bones are ossified from several separate foci, one of which appears during late embryonic or early fetal life (seventh week to fourth month) near the middle of the future bone (**3**.4). This centre is concerned with progressive ossification towards the bone ends. In all such bones their ends are cartilaginous at birth (**3**.4), though displaying their typical shape and articular congruities. These terminal regions are ossified by separate centres,

3.4A An alizarin stained and cleared human fetus of about 14 weeks *in utero*. Note the degree of progression of ossification from primary centres, which is endochondral in the appendicular and axial skeletons, excepting the clavicles, and the intramembranous centres for the majority of the cranial bones which are visible here. The carpus and tarsus are wholly cartilaginous except the primary centre for the calcaneus, as are, of course, the epiphyses of all the long bones. The centra and neural arches of the vertebrae are separate. The sternum is still unossified. The membranous anterolateral and posterolateral fontanelles are particularly obvious. (Photographed by Kevin Fitzpatrick, Department of Anatomy, Guy's Hospital Medical School, from a specimen prepared by Roslyn Holthouse, formerly of the same Department.)

3.4B The skeleton of a neonatal infant, with all cartilages preserved. Note particularly proportions of neurocranium, orbital cavities, and face, interfrontal (metopic) suture, sternebral ossification, extensive costal cartilages, large cartilaginous epiphyses, and metaphysial flaring of long bones, especially the humeri, femora, and tibiae. (Photographed by Kevin Fitzpatrick from a preparation by Dr. Michael C. E. Hutchinson, of the Department of Anatomy, Guy's Hospital Medical School, London.)

sometimes multiple, which develop from about the time of birth onwards into the late teens; they are said to be *secondary* to the earlier *primary* centre from which the majority of a bone is ossified. This is the mode of ossification in the long bones of the limbs and their shorter elements, metacarpals, metatarsals and phalanges; it is also characteristic of ribs and clavicles.

Typically, therefore, a bone such as the tibia has become, at birth, ossified throughout its shaft, or *diaphysis*, by the activity of a primary centre which appeared in the seventh week of embryonic existence; whereas its two extremities, its *epiphyses*, are subsequently transformed into osseous tissue by secondary centres. As the latter enlarge, replacing the surrounding cartilage, they come to occupy almost the whole of the articular ends of the bone. A layer of specialized hyaline cartilage persists over the actual joint surface (p. 249) and a thicker zone remains between the diaphysis and epiphysis. As described in detail below (p. 243) it is by the persistence of this growing *epiphysial plate* or *disc* of cartilage (synonymous terms are *growth plate* or *growth cartilage*), that the bone is able to increase in length until its characteristic dimensions are attained, at which stage the mechanism is abolished by ossification of the disc. The bone can then be said to have reached maturity. The process of coalescence of epiphysis and diaphysis is called *fusion*, final fusion usually representing the

amalgamation into one osseous element of a number of osseous units, developed separately in the same cartilaginous or mesenchymal model, which has itself been growing throughout the process. Fusion also brings to an end the period of active gross dimensional growth in a bone.

Many bones show epiphysial arrangements at both extremities, others at one end only. The long limb bones illustrate the former mode of ossification, while metacarpals, metatarsals, phalanges, clavicles and ribs possess an epiphysis at one end only, although it might be suggested that costal cartilages may represent rib epiphyses which do not normally develop ossific centres. (For an interesting discussion of the *pseudo-epiphysis* of the distal end, or head, of the first metacarpal bone consult Haines 1974.) In some bones the epiphysial centres at one end or both ends are more complex. For example, in the proximal end of the humerus, which is wholly cartilaginous at birth, three separate centres appear during childhood. They soon coalesce to form a single epiphysial mass, which later fuses to the diaphysis. In this instance only one of the centres is involved in forming the articular surface, the others being concerned in the growth of the greater and lesser tubercles, projections to which muscles are attached. Similar composite epiphyses occur at the distal end of the humerus and in the femur, ribs and vertebrae. Because some centres ossify parts of bones exposed to pressure at joints, and others to regions subjected to tension by the pull of muscles, a classification into *pressure*, *traction* and *atavistic* has been proposed (Parsons 1903–5). Atavistic epiphyses are formed by centres of ossification which are considered to represent the skeletal elements which were separate in some earlier evolutionary stage. The evidence of comparative morphology suggests, strongly in some cases, that mammalian bones are composites of several separate reptilian or amphibian elements. The skull, clavicle, scapula and innominate bones afford examples. For instance, the small centre which regularly occurs in the coracoid process of the human scapula and the epiphysis at the medial end of the clavicle may be vestiges of separate skeletal elements present in earlier vertebrates, and repeated as transient features in the development of mammalian bones. Incidentally, the medial end of the clavicle could equally be regarded as a pressure epiphysis.

Many cranial bones develop from multiple centres of ossification, and the morphological evidence that there is an atavistic element in this is considerable. That there has been a marked reduction in the number of cranial bones in mammals, when compared with reptiles and other lower vertebrate groups, is certain. The sphenoid, temporal and occipital bones are examples of skeletal units which almost certainly are composites derived from a number of previously separate cranial elements. It is not difficult to equate at least some of their centres with these ancestral elements; and they present additional evidence of fusion in the existence of dermal (membranous) and cartilaginous derivatives, at first separate but united during growth to form a complex whole. Details of these derivations will be considered in the appropriate sections (*see* p. 315). It must be added that these events in cranial bone development are not precisely equivalent to the atavistic epiphyses in post-cranial bones, where such epiphyses are always *secondary* in nature. In the composite cranial bones, on the contrary, the human condition is the result of the coalescence of a number of elements, each with a *primary* centre of ossification.

The classification of epiphyses has perhaps little significance *per se*; it does, however, direct attention to matters of great interest concerning the evolution of the mammalian skeleton. Epiphysial centres of ossification do not occur in other vertebrates, with the exception of sporadic appearances in reptiles and birds (Haines 1937). When they do appear, they are pressure epiphyses, associated with articular surfaces. Traction epiphyses are peculiar to mammals, but may be regarded as genetically well established, for their appearance is not arrested by division of the structure attached to them (Appleton 1922; Barnett and Lewis 1958). There is, however, a general lack of such experimental evidence in connection with epiphysial development.

The rate of growth of ossific centres is more rapid than that of the cartilaginous mass in which they occur, though it must be emphasized that the latter is itself growing in concert with the general increase in size and change in proportions of the skeletal element to which it contributes. As a result the epiphysial region, at first wholly cartilaginous, is gradually converted into bone, with the exceptions noted above. The whole process starts at a time, and continues at a rate, which is characteristic for each bone. Individual, sexual and racial variations naturally occur, and must be taken into account, as far as established data permit, when assessing the skeletal age of an individual.

The rate of growth in bones varies both in those with epiphysial plates, and also those without epiphyses. Were this not so, and the rate uniform in all bones, their centres of ossification would appear in a strict descending order of size. That this is not so is illustrated by the primary centres for such widely different masses as the shaft of a terminal phalanx and a femur, separated by a week of embryonic life at the most. In the case of the primary centres for the carpal and tarsal bones there is some association between the size of each element and the order of ossification from the largest (the calcaneus in the fifth fetal month) to the smallest (the pisiform in the ninth to twelfth year of postnatal life). In individual bones, such as the humerus and the femur, the succession of ossific centres is approximately in the order of volume of bone which each produces. The largest epiphyses, the lower end of the femur and the upper end of the tibia, do ossify earliest (immediately before or after birth—points of forensic interest), but when comparisons between other bones are attempted, inconsistencies are numerous. Such dissimilar bone masses as a phalangeal epiphysis and the lesser tuberosity of the humerus begin to ossify about the same time, and both long before the massive greater trochanter of the femur, again emphasizing widely differing rates of bone development.

Experimental evidence in mammals indicates that at the epiphysial plate growth is initially equal in rate at both ends of bones possessing two epiphyses, but after birth one cartilage grows faster then the other (Brookes 1963). Since this end also usually fuses later with the diaphysis, the total contribution to the length of the bone is considerably greater at this extremity. Although the faster rate can only be presumed in man, the later fusion is a fact of radiological observation, and the curious recurrent direction of the nutrient arteries as they enter the femur, radius and ulna accords with the above facts (cf. p. 257).

The more active extremity of a long limb bone in respect of growth in length is often referred to as the *growing end* but this does not imply that growth is limited to this end. The variable rate of growth at epiphyses in general is evidenced by changes in the rate of increase of height characteristic of human development (Krogman 1941; Tanner 1962). The rate is characteristically rapid in infancy and again at puberty, but usually slower in between. The existence of a spurt at puberty, or slightly before, which decreases as epiphyses fuse during the later teens, has been much studied of late (Sinclair 1969).

Growth cartilages do not necessarily grow at the same rate at all points throughout their substance, and this accounts for changes in the relation between diaphysis and epiphysis—e.g. the alteration in angle between the shaft and neck of the humerus. On their diaphysial faces, epiphyses do not display a uniformly flat junction with the growth cartilage, nor indeed does the latter at its junction with the diaphysis. By differential rates of growth the two bony surfaces usually become reciprocally curved, commonly in such a way that the epiphysis fits like a shallow cup over the convex end of the shaft (but with cartilage intervening temporarily). This form of junction appears adapted to resist shearing forces at this relatively weak point in the growing bone. The reciprocity of the bone surfaces is usually carried further in the development of small nodules and ridges, which are highly characteristic of these surfaces when denuded of cartilage. Such adaptations emphasize the fact that all immature bones formed from more than one focus of ossification are complexes of several bones held together by epiphysial cartilages. When it is remembered that this is the case in the majority of the elements of the human skeleton, not only through the highly active years of childhood, but also during the even more vigorous period of adolescence, the strength of the bonding of bone to bone through cartilage is seen in true perspective.

The forces exerted at growth cartilages are largely compressive,

3.4C Radiograph of neonatal arm. Ossification from primary centres is well advanced in all bones except the carpals, which are still wholly cartilaginous. The gaps by which individual elements appear to be separated are, of course, filled by the radiolucent hyaline cartilage, in which epiphysial or carpal ossifications will subsequently occur. In the long bones note the flaring contours, with narrow midshaft and relatively expanded metaphyses. Note also the proportions of the limb segments characteristic of this age, and in particular the relatively large hand.

3.4D Photograph of a preparation of a neonatal left arm (from the specimen shown in 3.4B). Compare the radiolucent areas in the radiograph (3.4C) with the preserved cartilaginous epiphyses and carpal elements in this specimen. (For acknowledgments see 3.4B.)

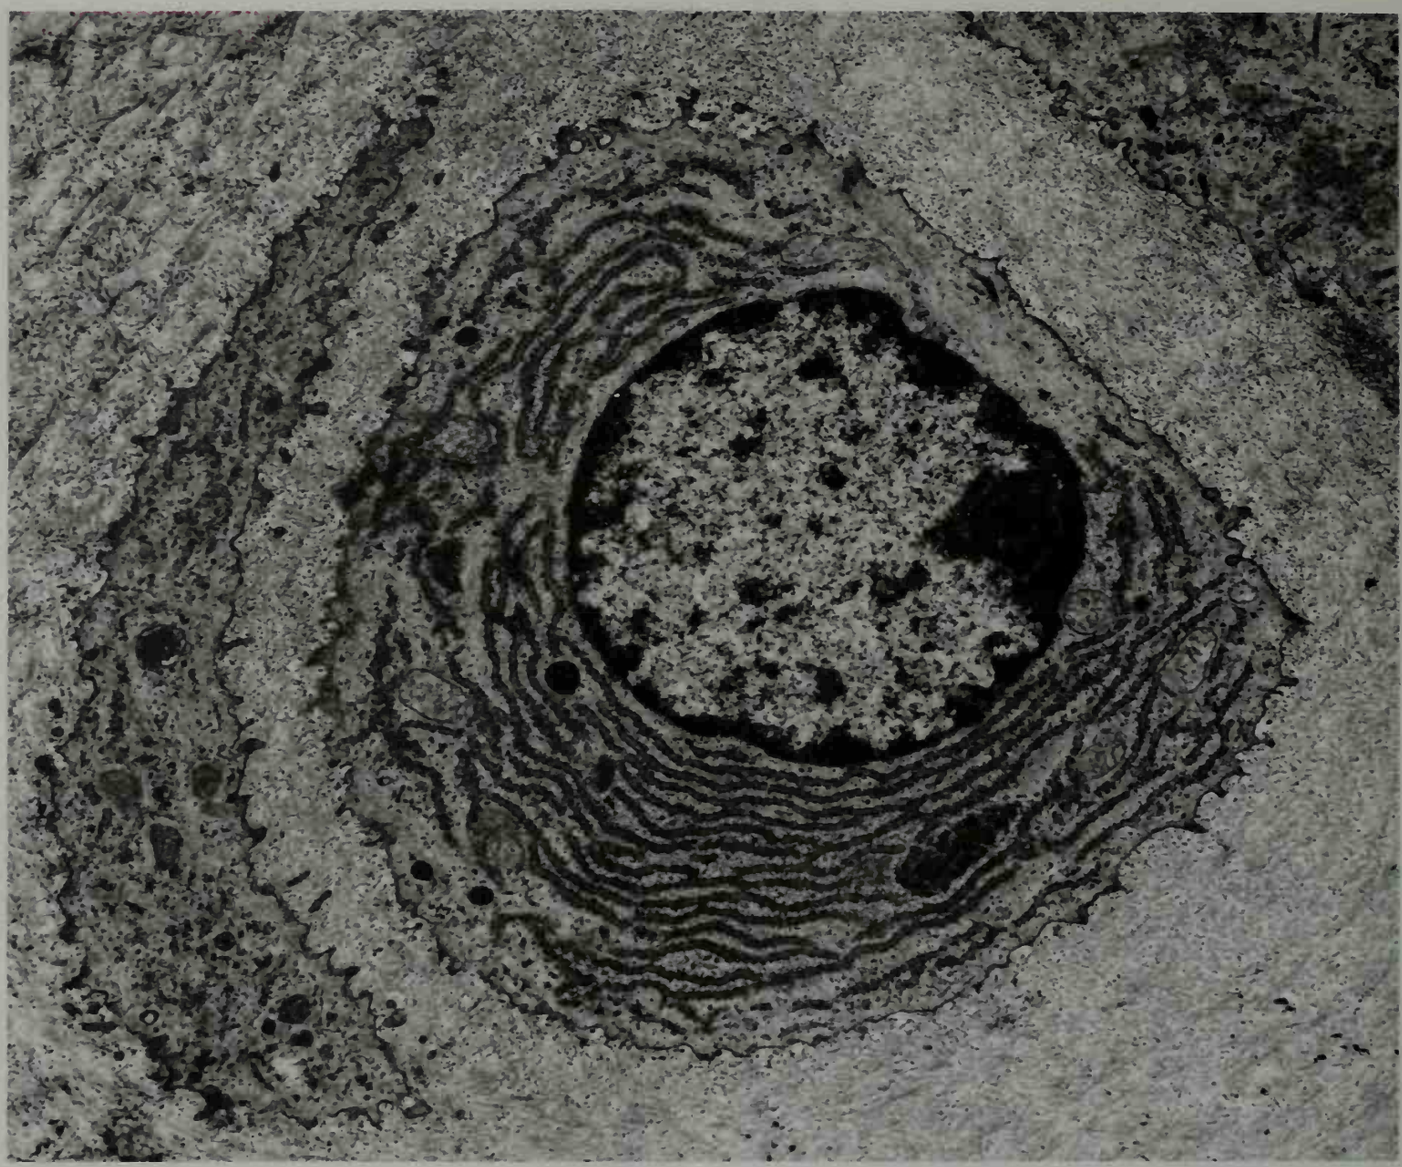
but with also a considerable element of shear. Where traction epiphyses are attached by cartilage, prior to fusion, the pull of attached structures, such as muscles, creates tension stresses, and this has been shown to be associated with the development of abundant collagen fibres oriented along the supposed lines of stress (Smith 1962). Damage to epiphysial growth due to violence does occur, but disturbance due to severe constitutional disease, such as the fevers common in childhood, is more frequent. The latter may produce visible change in the trabecular pattern of the bone formed at that period, discernible in radiographs as a dense transverse so-called *line of arrested growth* (Harris 1933). Several such lines may be apparent in the limb bones of children who have suffered a succession of severe illnesses.

The actual process of fusion of the epiphyses with the diaphysis is described later (p. 266). The actively growing part of the diaphysis adjacent to the epiphysial cartilage, the *metaphysis*, appears to overtake the cartilage, but there is also macroscopic evidence of a contribution by the epiphysis to this process in the formation of a denticulated edge between the two bone elements as they bridge across the cartilage-filled gap. These appearances have been extensively described and are of importance in establishing criteria for estimations of the time of fusion, whether by inspection or radiography (Stevenson 1924). Knowledge of the sites, times of appearance, rates of growth and fusion times of epiphyses is important in clinical medicine, forensic practice and anthropology. Dependable chronological data can only be derived from adequate numbers of observations made with standardized techniques. The wide variation in published figures is considerably due to failure in these respects. Radiographs need to be taken at more frequent intervals than is usually the case, and the angle of view must be carefully controlled. Routine positions may be inadequate; for example, the separate centre for the lesser tubercle of the humerus has often been denied by radiologists, probably because of the superimposition of its image upon that of another centre.

Nevertheless, considerable variation in the chronology of skeletal development does occur on the basis of individuality, sex, and possibly race. It is generally agreed that the *sequence* of events shows little or no variation and that this lies chiefly in the *timing* of the appearance and fusion of ossification centres. In both regards, the *female antedates the male* in all groups studied so far, and the difference, trivial and perhaps insignificant before birth, becomes progressively greater thereafter, rising to as much as two years or so in the later fusions of adolescence. Estimates have been most thoroughly established for white races, but even here few parts of the skeleton have been studied in sufficient detail, numbers, or over adequate time periods. Perhaps the best studies available at present are those for the hand (Todd 1937; Greulich and Pyle 1959; Mathiasen 1973), the knee (Pyle and Hoerr 1955), and the ankle and foot (Hoerr *et al.* 1962).

THE SKELETAL CONNECTIVE TISSUES

The skeletal tissues, cartilage and bone, are essentially specialized connective tissues and consist of the same three tissue elements—cells embedded in an intercellular matrix, permeated by a system of fibres. Physically, however, the sclerous tissues differ from the soft, pliant, generalized connective tissues, for their matrix is solidified. Cartilage and bone are, nevertheless, quite distinct in their structure, physical properties, vascularization, and in their patterns of growth and regeneration.



Structure of Cartilage

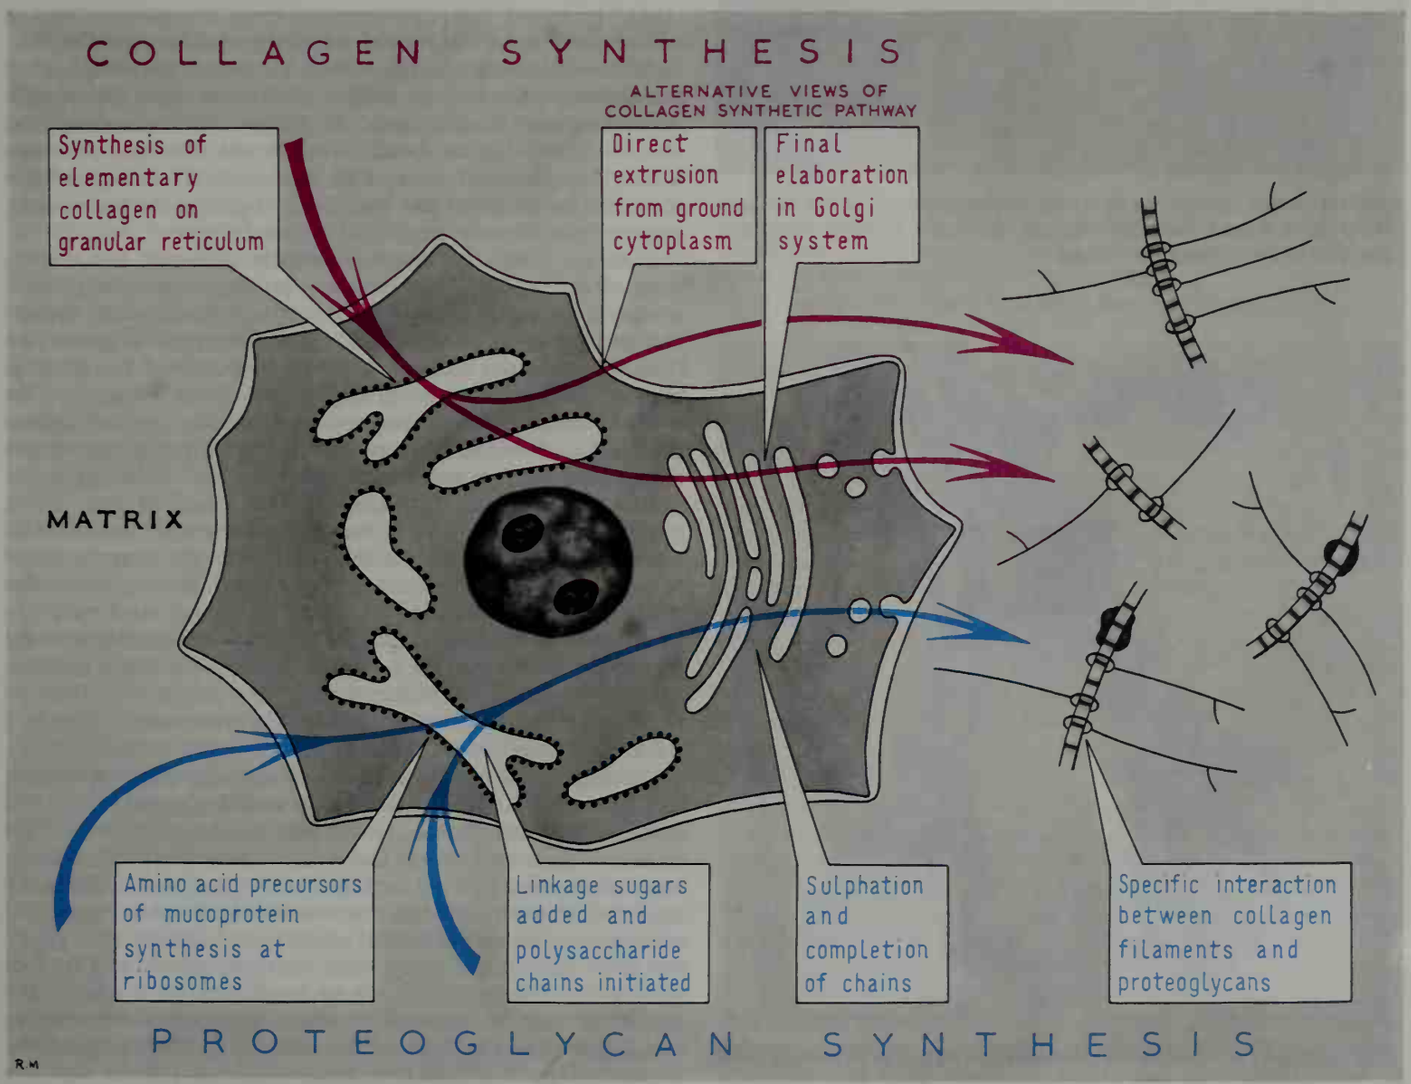
This is a phylogenetically ancient tissue and is widespread as a permanent or temporary skeletal tissue, throughout the vertebrates. As we have seen, in man during early fetal life, the greater part of the skeleton is cartilaginous, but eventually much of this is replaced by bone. In adult life, cartilage persists as the articulating surfaces of synovial joints, in the walls of the thorax, larynx, trachea, bronchi, nose and ears, and as isolated small masses in the skull base. However, in many cases it is not a simple partial replacement of a temporary cartilaginous skeleton by bone, for the cartilaginous plates between the ossifying epiphyses are diaphyses of long bones and in other situations are essentially *growth plates* which continue to proliferate, allowing length increases of the bones concerned. They are only replaced by bone when growth ceases. (For a review of embryonic cartilage *see* Glenister 1976; visceral cartilage was also reviewed by Reid 1976; the structure and biochemistry of cartilage is analysed in depth by Serafini-Fracassini and Smith 1974; for an alternative view of cartilaginous growth plate biology *see* Lutfi 1974.)

The distinctive properties of cartilage as a tissue are, therefore, its low metabolic rate and vascularity, its capacity for continued and often rapid growth, both interstitial and appositional (*vide infra*), combined with rigidity, a high tensile strength and resistance to compressive and shearing forces, whilst retaining some resilience and elasticity. The surfaces of cartilage masses are usually clothed with a fibrous *perichondrium* or abut against bone, but where they form the articulating surfaces of a synovial joint they are modified as wear-resistant, smooth, polished surfaces which are bathed by lubricant synovial fluid and have an extremely low coefficient of friction.

The *matrix* in which the cartilage cells (*chondrocytes*) are embedded varies in its appearance when freshly cut, in its detailed composition, and also in the nature of its contained fibres. Accordingly, the tissue is often classified, for convenience, as either *hyaline cartilage* (from *hyalos* meaning glass), *white fibrocartilage* (containing much collagen), and *yellow elastic fibrocartilage* (containing a rich elastin network). A densely *cellular cartilage*, with only fine septa of matrix separating the cells, is a normal stage in the development of cartilage during early embryonic life and is also found as a permanent tissue in the external ears of many mammals. The reader should appreciate, however, that whilst white fibrocartilage and yellow elastic fibrocartilage are specific, distinct, relatively unvarying tissues, the term hyaline cartilage embraces virtually all remaining types of cartilage which show *great variation* in composition and properties according to species, age, and location.

The cartilage cells occupy small spaces or *lacunae* in the matrix which conform to the cell shape. Young cells (*chondroblasts*) are relatively small, often flattened, with an irregular contour and many small surface projections (filopodia) which are received into complementary recesses in the matrix (3.5A). (Early post-mitotic chondroblasts often show specialized intercellular contacts which are necessarily transient, disappearing as matrix synthesis proceeds.) Mature cells (*chondrocytes*) increase in size with age and, although more rounded, still present a few surface projections (p. 264), and bear an occasional isolated cilium. Cartilage cell nuclei are round or oval with a variable number of nucleoli; multinucleate cells are not uncommon. The cytoplasm contains a paranuclear Golgi apparatus and diplosome, scattered mitochondria, a concentration of granular endoplasmic reticulum and often a few fat globules, glycogen deposits and pigment

3.5A Transmission electron micrograph of an ultra-thin section of a perfusion-fixed specimen of a rabbit's femoral condylar cartilage. The centrally placed chondroblast contains an active euchromatic nucleus with a prominent nucleolus. Its cytoplasm contains a rich concentration of roughly parallel concentric flattened cisternae of rough endoplasmic reticulum, scattered mitochondria, lysosomes and aggregations of glycogen. Its plasma membrane bears numerous short filopodia which project into complementary recesses in the surrounding matrix. The latter shows a delicate fibrillary feltwork with a finely dispersed granular interfibrillary substance. No pericellular 'lacuna' is present; the matrix separates the central chondroblast from the sectioned cytoplasmic periphery of two adjacent chondroblasts. The left profile, crescentic in outline, is characteristic of chondroblasts with an almost squamous form, that are sited near the articular surface. (Preparation by Mrs. Susan Smith of the Department of Anatomy, Guy's Hospital Medical School, London.) Magnification × 14,500.



granules. In the chondroblasts of young and actively growing cartilage (**3**.5A) the Golgi apparatus and granular reticulum are particularly prominent but are much less so in mature, relatively quiescent cartilage (Silberberg *et al.* 1964).

The matrix of cartilage consists essentially of water, varieties of proteoglycan, some lipid, collagen, non-collagenous protein, and electrolytes: on superficial examination it presents as an amorphous ground substance surrounding a feltwork of collagen fibres which vary in their type, density and disposition in different regions. The *ground substance* is a firm gel which stains positively with the periodic acid-Schiff reaction, metachromatically with toluidine blue, and is basophilic in ordinary histological preparations. The *proteoglycans* consist of a series of copolymers of *core protein* (mucoprotein) conjugated to long unbranched side chains of the *glycosaminoglycans* chondroitin 4-sulphate, chondroitin 6-sulphate, and keratan sulphate, the proportions of which vary with age—keratan sulphate increasing with maturity (Kaplan and Meyer 1959; Chvapil, 1967. Little is known of the detailed molecular architecture of the core protein, but analysis of the polysaccharides is now well advanced. Each consists almost exclusively of repeating disaccharide units, one unit of which is invariably a substituted hexosamine, and the other an esterified hexuronic acid or a substituted hexose. Thus chondroitin 4-sulphate and chondroitin 6-sulphate consist of repeating N-acetylgalactosamine and glucuronyl sulphate disaccharides, differing only in the position of the sulphate ester linkage: keratan sulphate consisting of N-acetylgalactosamine and D-galactose together with a sulphate ester linkage which is variable in position. The acidic nature of these sulphated polysaccharides accounts for the basophilia, metachromasia, water and ion-binding power, selective permeability, and most of the visco-elastic properties of the matrix. The *collagen* present in cartilage differs in its composition from that found in other vertebrate tissues. The tropocollagen molecule of the latter consists of two $\alpha 1$ and one $\alpha 2$ polypeptide chains, whereas the tropocollagen molecule of cartilage consists of three identical $\alpha 1$ chains. Subsequent analysis has shown that two varieties of $\alpha 1$ polypeptide chains with differing amino acid sequences are present in different tissues, and these have been designated $\alpha 1$(I) and $\alpha 1$(II)—*see* Miller (1971a & b). Using this classification the most widespread type of vertebrate collagen is $[\alpha 1(I)]_2\ \alpha 2$; in contrast the collagen characteristic of cartilage is $[\alpha 1(II)]_3$.

It has long been held that the compression-resisting properties and visco-elasticity of cartilage are expressions of its glycosaminoglycan content; similarly its high tensile strength has been considered mainly a property of its contained collagen. These propositions, whilst undoubtedly partly true, are an over-simplification. Many investigations on a wide variety of connective tissues, including collagen, have demonstrated intimate and spatially precise relationships between the repeating regional substructure of the collagen filaments and the distribution of the proteoglycans (for an excellent review *see* Serafini-Fracassini and Smith 1974). Thus it has been proposed that the core protein part of the copolymer is applied tangentially to, or encircles, the collagen filaments at specific points (the *a* and *b*1 loci) with some form of linkage between them. The sulphated and acetylated polysaccharide tails are thought to project laterally, radiating in all directions from the collagen filament, their terminals forming a variety of cross-links with either the polysaccharide or protein moiety of the proteoglycans of neighbouring filaments. The whole thus forms a complex *three-dimensional meshwork*, the polysaccharide elements of which are polyanionic bearing a fixed negative charge. The interstices of the meshwork are occupied by relatively large volumes of bound water, cations, and non-collagenous non-core protein, the structure of the latter being little understood. The reaction of cartilage to different forms of mechanical stress is accordingly a reflection of interacting contributions from *all* these structural elements: similarly, the properties of the 'walls' and 'contents' of the macromolecular labyrinth that constitutes cartilage affects the diffusion rates of both nutritive and degraded materials through the tissue.

For many years it was assumed, without direct evidence, that the chondroblasts and chondrocytes were somehow involved in the elaboration of *both* collagen and ground substance. In recent years histochemical, autoradiographic, and cell fractionation studies have confirmed and amplified this view (Davies and Young 1954; Bélanger 1956; Dziewiatkowski 1962; and *see* **3**.5B). Labelled collagen precursors were shown to accumulate sequentially over the ribosome bearing granular endoplasmic reticulum, the Golgi apparatus, and finally over the vesicular cell periphery and extracellular material (Revel and Hay 1963)—a common sequence in cells synthesizing exportable protein. However, evidence has also been presented consistent with the simpler view that, following initial synthesis at the ribosome, the elementary collagen is extruded directly from the ground cytoplasm of the chondroblast to the exterior, without involving endoplasmic reticulum cisterns of Golgi membranes (Cooper and Prockop 1968). The *details* of collagen synthesis in cartilage, however, appear similar to those obtaining in other tissues (p. 49).

Non-collagenous protein (mucoprotein) is also synthesized at the granular reticulum, and earlier work suggested that it was transferred to the Golgi apparatus, where sulphated polysaccharide synthesis was presumed to occur. More recently, however, the detailed structure of the chondroitin sulphate-protein linkage has been elucidated (Lindahl and Rodén 1966) and more detailed studies (Horowitz and Dorfman 1968) have now shown that core mucoprotein synthesis occurs at the ribosome; the linking sugar molecules are then added and chain initiation occurs in the rough endoplasmic reticulum, whilst chain completion occurs in the Golgi apparatus, and the final product is exported to the cell exterior by reversed pinocytosis. (For a

3.5B A summary of some of the important biosynthetic pathways of the chondroblast.

comprehensive review of cartilage biosynthesis *see* Serafini-Fracassini and Smith 1974.)

Such studies not only help to elucidate cellular synthetic pathways; but the speed of appearance of labelled precursors over various cartilage cell organelles (sometimes only a few minutes after injection, in the case of young growing cartilage), emphasizes the ready permeability of the cartilage matrix.

NUTRITION OF CARTILAGE

Cartilage is often described as a totally avascular tissue. While this is by no means true, the majority of cartilage cells are, compared with other tissues, an unusually long distance away from the nearest exchange vessels. In general, these lie in the perichondrial membrane on the surface of the blocks of cartilage. Between the perichondrial capillary network and the chondrocytes, nutrient substances and metabolites pass by diffusion down concentration gradients across the intervening cartilage matrix.

3.6B Capillary plexuses in the terminal arborization of a cartilage canal in the femoral condylar epiphysis of a 7-month human fetus. Specimen injected with Indian ink. (Kindly provided by Dr. Murray Brookes of the Department of Anatomy, Guy's Hospital Medical School, London.)

Cartilage Canals (Haines 1933–4; Hurrell 1934–5; Levene 1964; Blackwood 1965; Lufti 1970; Brookes 1971).

Nutrition is, however, augmented at least in cartilaginous epiphyses of large mammals (and analogous cartilaginous masses of many birds and reptiles) by an arborization of *cartilage canals* (Brookes 1971). Each canal contains a leash of small vessels which stem from centripetal offshoots from a perichondrial artery and vein. Perfusion techniques (Brookes 1958) and histological examination (Wilsman and Van Sickle 1972) suggest that the leash is composed of a central small artery or arteriole surrounded by numerous venules and perivascular capillaries (**3**.6A, B). The central vessel terminates in the blind end of the canal forming several capillaries from which venules pass back alongside the arterial twig to the parent perichondrial vein. Capillaries are also formed along the entire length of the canal, and these, together with the terminal capillaries, potentiate metabolic exchange with the cartilage mass (Wilsman and Van Sickle 1972). The blood vessels of cartilage canals are packed in loose connective tissues, rich in fibroblasts and macrophages, and continuous with the perichondrium.

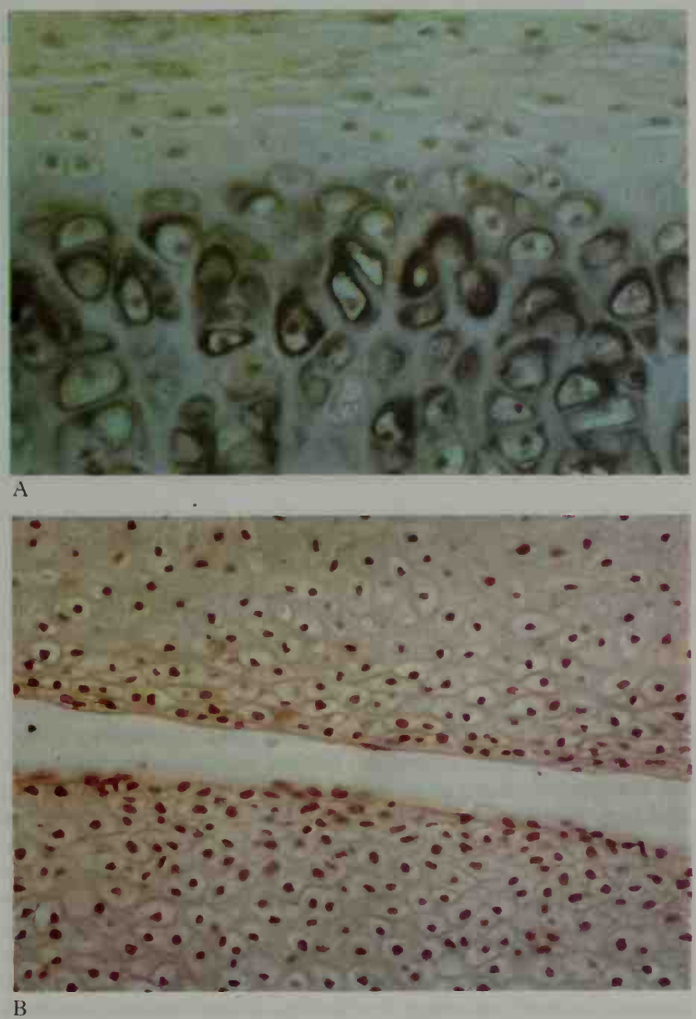
How cartilage canals develop and grow is problematical (as are the detailed growth patterns of a cartilaginous epiphysis as a whole). If the latter, in general, grows mainly by surface accretion, then the canals may be generated by the *passive inclusion* of perichondrial vessels of the advancing surface of the cartilage mass. Harris (1933) adduced evidence that cartilaginous epiphyses grow interstitially from a zone of chondrocyte mitosis below the surface, and this would preclude the passive inclusion hypothesis. Hence several investigators have suggested that the formation of the canals is an *invasive* phenomenon, involving chondrolysis. The vascular content of the canals was held to be lytic by Eckert-Möbius (1924) and Hurrell (1934). Waterman (1961) proposed that chondrocytes lysed themselves 'free' in advance of an ingrowing vessel, which thereby, in certain regions, finds its canal already prepared for it. Brookes (1971) emphasized the chondrolytic activity of the loose connective tissue cells supporting the canal vessels, in addition to matrix lysis by chondrocytes in the canal wall. These 'freed' cells then contribute to the mesenchymal content of the canal. The macrophages identified by Wilsman and Van Sickle (1972) in the perivascular mesenchyme are, presumably, also chondrolytic.

Cartilage canals are not haphazardly arranged, but show a pattern which is specific for each cartilage mass. In general, however, the cartilage canals of a fetal epiphysis can be divided into two groups. The canals of the more conspicuous group pass from non-articular surfaces towards the centre of the cartilage mass. The less prominent group pass from vessels in the ossification groove (of Ranvier—p. 259), and the capillary tufts in the blind ends of the latter are most complex and glomerular in appearance, similar to the vascular tufts that characterize the post-natal subchondral circulation (Trueta and Morgan 1960). According to Brookes (1971) the pattern of arteries in individual adult bony epiphyses is closely similar to the vascular canal pattern in the corresponding fetal epiphyses. He concluded that the vessels in the major group of cartilage canals are the forerunners of the main epiphysial vessels to be found later in the mature bone; also that the vessels in the minor group of cartilage canals which originate in Ranvier's groove are the precursors of the subchondral vascular network found on the epiphysial side of the growth cartilage in post-natal life.

Cartilage canals are believed to augment the nutrition of large cartilage blocks, which otherwise would depend solely on diffusion gradients from and to the perichondrial capillaries. This process is apparently much faster than was formerly considered, both in the case of young cartilage (*vide supra*), and additionally that labelled small ions were concentrated by the chondrocytes of mature articular cartilage with unexpected rapidity (Hall 1965); the latter tissue does not possess cartilage canals and its free surface is, of course, devoid of perichondrium. Furthermore, the half-life of the protein-polysaccharide complex in rabbit articular cartilage is 4 days (Mankin and Lipiello 1969). While large blocks of cartilage such as fetal limb bone epiphyses possess cartilage canals, it is perhaps surprising that they are also found in the cartilaginous carpal elements and even dimunitive sesamoids of

the hand in early fetal life. They are present, for example, in the epiphyses of human fetal phalanges at 11 cm crown-rump length (Gray *et al.* 1957).

Hence, while not denying the canals a nutritional function, nearly all workers have opined that cartilage canals are in some way involved in the process of formation of secondary centres of ossification (and primary centres in some small bones without epiphyses). However, there are some puzzling anomalies. Distal phalangeal and proximal metacarpal cartilaginous extremities do develop elaborate arborizations of cartilage canals but, however, they lack separate centres of ossification. Nor is there any secure relationship between the onset of chondrification, the timing of the first appearance of the canals, and the onset of ossification. All these events occur at specific times peculiar to each skeletal element (Brookes 1971). The contents of the canals, blood vessels and loose connective tissue, appear to furnish the osteogenic cells and capillaries characteristic of ossification when, and if, a separate ossific centre appears. The control of the timing of these events remains a complete enigma.



In the condylar cartilage of the mandible canals continue to form until the second year, when they disappear. Laryngeal and nasal cartilage canals first form in the seventh month *in utero* and persist until old age. They form in costal cartilages in the first year and reach the centre of the shaft about the tenth year. In long-lived canals, marrow elements may begin to form after the twentieth year; this may persist until about the sixties when atrophy of the marrow supervenes and the canals remain filled with a mucinous material.

VARIETIES OF CARTILAGE

These include hyaline, white and yellow fibrocartilage and cellular cartilage.

Hyaline cartilage (**3**.7) has a pearly, bluish, translucent, homogeneous appearance and consists of a gristly mass of firm consistency and considerable elasticity. Costal, nasal, some laryngeal, tracheo-bronchial, all temporary cartilages and most articular cartilages are of the hyaline variety, but it must be emphasized that they present differences in the size, shape and arrangement of both cells and fibres, and composition of matrix, in different locations and at different ages. With the light microscope the cells in hyaline cartilage appear rounded or bluntly angular, but this appearance is belied by ultrastructural studies (*vide supra*). They are frequently arranged in groups of two or more cells which are the offspring of a common parent cell. These small clusters are known as *cell nests* or *isogenous cell groups* and where the cells are closely apposed they have a straight outline, but are rounded in the rest of their circumference. The matrix is typically basophilic and shows a metachromatic reaction, both of which are more pronounced where recently formed matrix forms the boundary of a cell-containing lacuna. This distinctive zone is sometimes called the *territorial matrix* or *lacunar capsule*, in contrast with the remaining pale-staining *interterritorial matrix*.

When viewed with transmitted light the matrix is either transparent and apparently structureless or it presents a dimly granular appearance like ground glass. However, when examined in polarized light or with electron microscopy it is shown to be permeated by a system of fine fibrils and fibres. These are 10–20 nm in diameter and show the 64 nm periodic banding which is characteristic of collagen elsewhere. In the lacunar capsules the fibres have been described as especially fine. However, a detailed comparison of transmission electron micrographs with scanning electron micrographs (Clarke 1974) has thrown some doubt on the latter. It has been widely held that, following the preparative techniques necessary for electron microscopy, each chondroblast is surrounded by four zones. Immediately surrounding the irregular cell surface is a clear apparently 'empty' zone, followed externally by an amorphous or fine fibrillar zone with a radial organization (these two zones correspond to the 'lacuna' of customary cytology). The fine radial fibrils are surrounded by a delicate, territorial, circumferential network of small diameter collagen fibres and associated ground substance, the whole being encompassed by the coarse interterritorial network. Scanning

B Young hyaline cartilage bordering a fetal joint cavity.

electron microscopy by Clarke failed to confirm this disposition of territorial collagen. However, in a similar, more recent study of articular cartilaginous blocks the perilacunar collagen fibres were found to be of a finer diameter and more closely packed than elsewhere (Minns and Steven 1977).

Articular hyaline cartilage (**3**.8). This covers the articulating ends of bones in synovial joints where it provides an extremely smooth, wear-resistant surface bathed by synovial fluid. This allows almost friction-free movement (coefficient of friction 0·01–0·02, decreasing as joint loading increases). Its elasticity, together with that of the periarticular structures, dissipates the effect of concussions and provides the whole articular mechanism with some degree of flexibility particularly near the end of its range of movement in any direction. The structure of articular cartilage is admirably adapted to resist the relatively enormous compressive forces generated during weight transmission, but especially during rapid changes of momentum and muscle action (p. 233).

It shows no tendency to ossification and its thickness varies from 1 to 7 mm from the smaller to the larger joints. Its deep surface is moulded to the shape of the underlying bone, but its free surface smooths and often accentuates and modifies the general surface geometry of the bone. On convex surfaces it is thickest at the centre, the reverse being the case on concave surfaces, whilst its thickness decreases progressively from maturity to old age. Its free surface is not covered by perichondrium, but the synovial membrane can be traced over a small part of its circumference, where its cell types grade insensibly into those of the surface layers of the cartilage.

Articular cartilage shows a gradual zonal variation in structure

3.8 Articular cartilage. A section perpendicular to the joint surface of the head of a simian metacarpal bone, stained with Masson's trichrome method. Note the changing character of the cartilage (blue) with increasing depth from the surface, the zone of calcified cartilage (faint red) and the underlying epiphysial bone (red). Consult text for further details.

with increasing depth from the surface (Barnett *et al.* 1961; Davis *et al.* 1962; Palfrey and Davies 1966; Ghadially and Roy 1969). Except, possibly, for a thin surface lamina, the matrix is everywhere pervaded by collagen fibres. Those near the surface and surrounding the lacunae are fine, plexiform in arrangement and either faintly or not obviously banded, whilst elsewhere they are coarser and show the 64 nm banding typical of collagen (or some sub-unit of this periodicity). The arrangement of the fibres has been variously described as plexiform, coiled helices, or a series of arcades extending radially from the deepest zone towards the surface, where they pursue a short horizontal (tangential) course before returning vertically. (Most recent workers subscribe to the latter view.) It has long been known (Hultkrantz 1898; Amprino 1948) that if the surface of articular cartilage is pierced by a round-bodied pin, after withdrawal of the pin a longitudinal 'split-line' remains, and that on any particular joint surface, the patterned arrangement of the split-lines is constant and distinctive (cf. the cleavage lines of the skin). A more recent analysis (Bullough and Goodfellow 1968), using polarized light and electron microscopy, has shown that the splits follow the *predominant* direction of the collagen bundles in the *tangential* zone of the cartilage at any point (*vide infra*). It has also been proposed that they portray the 'tension trajectories' set up throughout the surrounding cartilage by compression at certain points during common activities. A series of subsequent investigations have largely confirmed the structural proposals of Bullough and Goodfellow—for example, detailed split-line analysis with transmission electron microscopy (Meachin *et al.* 1974), polarization microscopy (Ortmann 1975), and scanning microscopy (Minns and Steven 1977). Proposals concerning split-line disposition when superficial tangential fibre bundles are not parallel have been considered by Ortmann (1975), and theoretical models for the dynamics of articular cartilage have been put forward by Kempson *et al.* (1968) and Mow *et al.* (1974). It is perhaps pertinent at this point to recall that some of the earlier workers considered that split-line (and hence predominant collagen) orientation reflected the *direction* of the most *habitual movements*, the relationship of this to tension trajectories being unknown. Yet others (e.g. McCall 1969) deny any preferred collagen orientation in articular cartilage. Finally, Serafini-Fracassini and Smith (1974) propose that the most important function of articular cartilage collagen is not the direct resistance of tensile stresses, but to provide *fixation anchors* for the visco-elastic *domains* of the proteoglycan molecules when the latter are subjected to deforming and displacing stresses. Clearly, no theoretical model will prove adequate until it embraces the dyamics of *all* the *interacting* constituents of cartilage. (For an extensive review of the mechanical and biological properties of adult articular cartilage, *see* Freeman 1973.) (See also **4**.11.)

In the *superficial* or *tangential stratum* (*zone 1*) of articular cartilage the cells which are small, oval or elongated, flattened and disposed parallel to the surface, are surrounded by fine fibres arranged tangentially. These cells show a few short surface projections mainly from their lateral borders and deep surface, they possess scattered mitochondria and small cisternae of rough endoplasmic reticulum, and their Golgi apparatus is not prominent. Their cytoplasm is free of filaments, in contrast to the cells of deeper zones. The constitution of the *articulating surface* of articular cartilage—the thin superficial layer of zone 1—(often known as the *lamina splendens*), has long been uncertain. (Because of its wide usage the term lamina splendens needs clarification. It was introduced by MacConaill for the brilliantly illuminated surface zone, which contrasted with the dark main mass of cartilage, when *oblique* sections were studied using negative phase-contrast—*see* MacConaill 1951. The dimensions given are therefore not comparable with those obtained by other techniques, and the general utility of the term is questionable.) Recently, it has been claimed to be a cell-free layer about 3 μm in thickness containing tightly packed, non-banded, randomly arranged, fine filaments some 4 to 12 nm in diameter (Weiss *et al.* 1968). These filaments appeared to branch frequently and their associated proteoglycan ground substance was scanty. Deep to the lamina, typical banded collagen fibres are encountered; they are tangentially arranged, with directional regularity, and increase in diameter with depth. The authors point out that the flattened oval cells found in this deeper layer of zone 1 (*vide supra*) closely resemble quiescent mature fibrocytes. They propose that the articulating surfaces of all synovial joints should perhaps be regarded as formed almost exclusively by fine modified collagen filaments, with their characteristic cells of origin more deeply placed. Other authors (*see* Mow *et al.* 1974) designated the surface layer of zone 1 as the *superficial tangential zone*, considering it to consist of sheets of tightly *woven* fibrils that lie parallel to the free surface: they regard the fibrils as collagenous in nature, from 5 to 20 nm in diameter and forming a layer which varies from 1 to 200 μm in thickness in different locations. It has also been claimed that the surface zone although poor in glycosaminoglycans, is rich in hyaluronate.

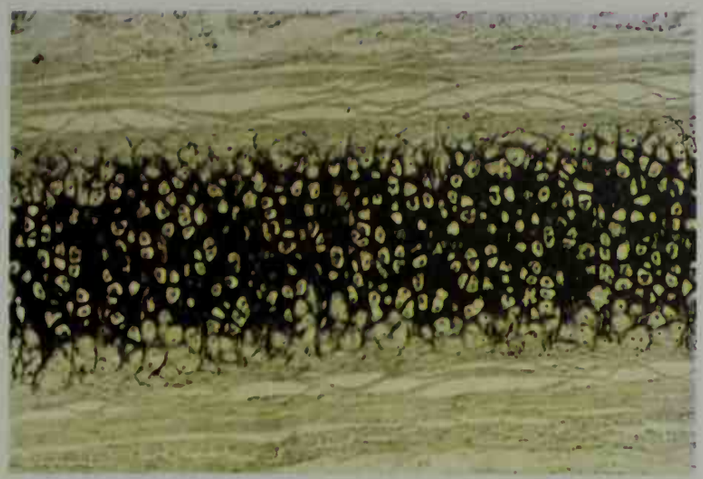
The deeper cells of the *transitional* or *intermediate stratum* (*zone 2*) are larger, more rounded, and either single or in isogenous groups. They are, in the main, typical active chondrocytes in their ultrastructural appearances (*vide supra*) and around them the collagen fibres pursue oblique courses.

More deeply still in the *radiate stratum* (*zone 3*) the cells are large, rounded and often arranged in columns perpendicular to the surface, with intervening radially disposed collagen fibres.

The deepest part of the cartilage (*zone 4*) forms a *calcified stratum* which abuts on the *hypochondral osseous lamina* of the underlying epiphysis. These adjoining surfaces show a reciprocal fine ridging, grooving and interdigitation which, together with the confluence of their fibrous architectures, resists the shearing stresses generated during postural changes and muscle action.

The concentration of glycosaminoglycans varies with increasing depth from the surface: the chondroitin sulphate increases some fivefold in concentration in the intermediate zones, reducing to threefold in zone 4. In contrast keratan sulphate increases linearly with depth, and is found mainly in the interterritorial matrix, whereas the chondroitin sulphates are largely circumlacunar.

It should be noted that the sequence of structural changes, with increasing depth, from normal hyaline cartilage, through a columnar arrangement of cells, a zone of calcified cartilage and eventually epiphysial bone, is typical of cartilaginous growth plates elsewhere (p. 263). It reflects the radial growth of the epiphysis by extension of the process of endochondral ossification into the overlying calcified cartilage. The process becomes quiescent in maturity, but the sequence of zones persists throughout life. Such a terminal growth mechanism is also characteristic of bones which possess no epiphysis at one or both ends.



Division of articular cartilage cells is by mitosis, but mitotic figures are infrequently seen except in the young skeleton. There is no evidence that the superficial cells of young and normal joint

surfaces are progressively worn away by joint movement, and equally there is no evidence for a continual replacement of surface cells from the deeper layers. However, degenerating cells may be found in any of the four zones and probably this accounts for the progressive reduction in cellularity of the cartilage with advancing age, particularly in the superficial layers (Stockwell 1967). Such cell degenerations probably contribute to the variable lipid content of the matrix.

Articular cartilage is believed to derive its nutriment by diffusion from three sources: the vessels of the synovial membrane, the synovial fluid and the hypochondral blood vessels of the underlying marrow cavity. Many capillaries derived from the latter penetrate into and even through the calcified layer of cartilage (Holmdahl and Ingelmark 1950; Barnett *et al.* 1961), and it has been estimated that they contact 1–7 per cent of the osseous surface of the cartilage. Opinions are divided concerning the *relative* contribution from these three sources, and as yet conclusive evidence is lacking. There have, however, in recent years been a considerable number of accurate determinations of the permeability both of articular cartilage (for detailed results and bibliography consult Marondas *et al.* 1975). Briefly, small molecules pass with ease through articular cartilage, with diffusion coefficients about half those in aqueous solution. Larger molecules pass less readily, their diffusion coefficients being inversely related to molecular size. For example, glucose, inulin and haemoglobin with molecular weights of 180, 5000 and 68000 respectively have molal distribution coefficients in the ratio 85:11:1. The permeability of cartilage to large molecules is extremely sensitive to variations in the glycosaminoglycan content; for example, a threefold increase in the latter is accompanied by a hundredfold increase in the partition coefficient.

In costal cartilage the cells and nuclei are large, and the matrix, which is usually homogeneous and transparent, has a tendency to fibrous striation, especially in old age. In the thickest parts of these cartilages a few large vascular channels and sometimes marrow elements may be detected (p. 248). The xiphoid process of the sternum and the cartilages of the nose, larynx and trachea (except the epiglottis and corniculate cartilages of the larynx which are composed of elastic fibrocartilage) resemble the costal cartilages in microscopic structure. The arytenoid cartilage of the larynx shows a transition from hyaline cartilage at its base to the elastic variety at the apex. Hyaline cartilages, especially in adult and advanced life, are prone to calcify and this occurs frequently in the costal and laryngeal cartilages. Quantitative studies have also demonstrated a reduction in cellularity throughout the thickness of costal cartilages with advancing age (Stockwell 1967).

White fibrocartilage consists of dense white fibrous tissue arranged in bundles, with attendant fibroblasts, and with small scattered groups of chondrocytes between the bundles; the cells are roughly ovoid in shape, and are surrounded by concentrically striated areas of cartilage matrix. When present in bulk, as in the intervertebral discs, it provides a tissue of great tensile strength combined with an appreciable degree of elasticity. When present in lesser amount, as in the articular discs (p. 423), the glenoidal and acetabular labra (pp. 458 and 477), the cartilaginous lining of bony grooves which lodge tendons, and certain articular cartilages (*vide infra*), it constitutes a tissue of considerable toughness and sufficient elasticity to enable it to resist the long-term effects of pressure and friction. The articular surfaces of the bones which ossify in mesenchyme are covered with white fibrocartilage (the squamous temporal, mandible and clavicle). The ultrastructure of such articular cartilages has been studied by Silva and Hart (1967). The *deep layers*, adjacent to the hypochondral bone resemble the calcified, degenerative, and hypertrophic regions of the radial zone of *hyaline* articular cartilage. The *superficial zone* consists of parallel bundles of closely packed, large diameter collagen fibres, interspersed with typical dense connective tissue fibroblasts, and scanty ground substance. Adjacent layers alternate in the direction of their fibre bundles, as in the cornea. An intermediate *transitional zone* with irregular bundles of coarse collagen, and fibroblasts with prominent Golgi vesicles separates the two. The latter are probably involved in the elaboration and export of proteoglycans. Others consider that the transitional cells area germinal zone for the deeper cartilage.

3.9 Elastic cartilage. A section of a rabbit's pinna stained with Verhoeff's method for elastin (black).

For estimates of the permeability of the white fibrocartilage of intervertebral discs consult Marondas *et al.* (1975).

Yellow elastic fibrocartilage (3.9) is found in the external ears, the corniculate cartilages of the larynx, the epiglottis, and the apices of the arytenoids. It contains typical chondrocytes but its matrix is pervaded by a network of yellow elastic fibres except where it borders the lacunae; here it approaches typical hyaline matrix in its appearance. The fibres resemble those of yellow elastic tissue in other situations, in being unaffected by acetic acid, in their affinity for orcein, and in the absence of any periodicity under the electron microscope (Sheldon and Robinson 1958). For a recent review of the fine structure, histogenesis and growth of the chondroblasts and matrix of yellow elastic fibrocartilage (of the rabbit's pinna) consult Cox and Peacock (1977). As mentioned elsewhere, the histogenesis of the elastic fibres of cartilage (and probably other tissues) is a two-stage process. An initial glycoprotein microfibrillar framework of oxytalan is first laid down, and subsequently this is impregnated by elastin (p. 51).

It is of interest that all the sites in which elastic fibrocartilage is found have *vibrational* qualities as important functional characteristics (laryngeal sound-wave production in phonation, and their collection and transmission in the auditory apparatus).

Histogenesis, Growth and Regeneration of Cartilage

In normal development, cartilage is formed initially by the transformation of embryonic mesenchyme (Glenister 1976; Serafini-Fracassini and Smith 1974; Cox and Peacock 1977). The mesenchyme condenses, i.e. the cells proliferate and become more tightly packed, the shape of the condensation foreshadowing that of the subsequent mass of cartilage. The condensing mesenchyme cells lose their irregular surface projections and become rounded, with prominent round or oval nuclei, but with indistinct cell boundaries. Soon each cell becomes surrounded by a fine basophilic halo composed of a delicate three-dimensional feltwork of fine collagen filaments and associated proteoglycans, both secreted by the cells themselves. The cells have now differentiated into chondroblasts and each is situated within a primitive cartilage lacuna. Continued secretion of fibrils and matrix causes the cells to move further apart until typical hyaline cartilage is recognizable. In other situations collagen synthesis predominates, many of the cells differentiating into fibroblasts, whilst chondroblastic activity is seen only in isolated groups or rows of cells which soon become surrounded by dense bundles of collagen fibres to form white fibrocartilage. Similarly, in other situations the matrix of the early cellular cartilage becomes permeated first by anastomosing oxytalan, and later, elastin fibres. In each of the foregoing cases the mass of developing cartilage is surrounded by a zone of condensed mesenchyme which differentiates into a two-layered perichondrium. The outer

cells form fibroblasts which secrete a feltwork of collagen fibres surrounded externally by vascular mesenchyme; the inner cells remain relatively undifferentiated, but are potentially chondrogenic.

Growth of a mass of cartilage is both *interstitial* and *appositional*.

Interstitial growth follows the continued mitotic division of the early chondroblasts throughout the thickness of the tissue mass. When such a cell divides, its descendants temporarily occupy the same lacuna but are soon separated by a fine matrix partition, which subsequently thickens with increasing separation of the cells. Further subdivision of these cells leads to an isogenous group. Interstitial growth is prominent only in young cartilage where it is assumed there is sufficient plasticity of the matrix to allow continued expansion from within. However, the mechanism of such expansions and internal reorganizations of the matrix and the factors determining the overall shape of a cartilaginous mass are little understood.

Appositional growth, as the name implies, follows proliferation of cells of the inner chondrogenic layer of perichondrium. Some of the resultant cells, applied to the outer surface of the cartilage, differentiate into chondroblasts and secrete a layer of matrix around themselves and thus become enclosed in a superficial lacuna. A continuation of this process leads to further surface increments and once enclosed in lacunae, the cells added by appositional growth now participate in interstitial growth. Appositional growth is often stated to be especially prevalent in the more mature cartilages, but interstitial growth of cartilage remains of fundamental importance for long periods, in the growth plate of cartilage between the epiphyses and diaphyses of long bones (pp. 243, 264).

In mammals the ability to regenerate a mass of cartilage which has been lost is quite low. Usually such a defect is slowly filled with vascularized connective (granulation) tissue which may become less vascular and persist for long periods as fibrous tissue. Occasionally, some cells in the centre of such a mass may transform to chondroblasts and secrete thin capsules of matrix around themselves.

Normal cartilage growth is dependent upon an adequate nutritional and hormonal background, and disturbances of these will be considered with the process of endochondral ossification (p. 263). With advancing years the matrix of many of the permanent cartilages of the body becomes *calcified*, and such a process is also an essential prelude to endochondral ossification.

An interesting feature of the biology of cartilage concerns the low antigenicity of its matrix, its relatively low vascularity and the isolation of its chondrocytes in lacunae. All these are features which permit successful homotransplantation of the tissue without evoking a marked cellular or humoral immune response.

Bone as a Tissue

Bone is essentially a highly vascular, living, constantly changing, mineralized connective tissue. It is remarkable for its hardness, resilience, characteristic growth mechanisms and its regenerative capacity. Whilst all bone consists of cells embedded in an amorphous and fibrous organic matrix permeated by inorganic bone salts, its fine structure varies widely with the age, site and natural history of the tissue. Thus, bone may develop either by the direct transformation of condensed mesenchyme or be preceded by a cartilaginous model which is later replaced by bone. Its collagen framework varies from an almost random network of coarse bundles to a highly organized system of parallel-fibred sheets or helical bundles. The inorganic matrix may exist as irregular dense masses with scattered bone cells or it may be arranged as a series of thin sheets (lamellae) in a variety of more or less precise patterns, with intervening rows of bone cells. Both lamellar and non-lamellar bone often develops as minute roughly cylindrical masses or *osteons*, each with a central vascular canal. Again, the various longitudinal and radial zones of a long bone have distinctive developmental histories and structures, and have been given regional names.

For all these reasons, a large and initially often rather confusing terminology has been developed to describe bony tissue. For clarification, the commonly used terms have been grouped as a table and they will be treated more fully in the following pages.

Classification of Bone Tissues

1. **Macroscopic appearance of cut surface** (p. 232).
   (*a*) *Compact bone*—the ivory-like surface layers of mature bone.
   (*b*) *Trabecular bone*—the interior of mature bones (also termed *cancellous* or *spongy* bone). Early embryonic bone is also spongy—the *primary spongiosa* (*Os spongiosum primum*).
2. **Development origin**
   (*a*) *Intramembranous* (*mesenchymal* or *dermal* bone)—from direct transformation of condensed mesenchyme.
   (*b*) *Intracartilaginous* (*cartilage* or *endochondral* bone)—replacing a preformed cartilage model.
3. **Regions of long bones**
   (*a*) *Diaphysis*—central region of shaft.
   (*b*) *Metaphysis*—more recently developed ends of shaft.
   (*c*) *Epiphysis*—the bone ends with a separate centre of ossification.
4. **Organization of collagen fibres**
   (*a*) *Woven-fibred* bone (*coarse-bundled* bone), with an irregular collagen network: includes embryonic bone; isolated patches in adult; formed during fracture repair.
   (*b*) *Parallel-fibred* bone—this includes all forms of lamellar bone and non-lamellar primary osteons.
5. **General microstructure**
   (*a*) *Non-lamellar* bone—includes early woven-fibred bone and primary osteons.
   (*b*) *Lamellar* bone—almost all mature bone.
6. **Disposition of lamellae**
   (*a*) *Circumferential* lamellae (*primary* lamellae)—parallel to both periosteal and endosteal bone surfaces.
   (*b*) *Osteonic* lamellae (*secondary* lamellae)—concentric lamellae around the vascular canals of mature bone.
   (*c*) *Interstitial* lamellae—in the crevices between osteons.
7. **Types of osteon**
   (*a*) *Primary osteons* (*atypical Haversian systems*)—the first formed, non-lamellar osteons.
   (*b*) *Secondary osteons* (*typical Haversian systems*)—concentric lamellae around the vascular canals of mature bone.
8. **General terms**
   (*a*) *Surface bone*—usually circumferential lamellae but may include woven-fibred areas.
   (*b*) *Interstitial bone*—found between osteons; often the lamellar remnants of secondary osteons but may include woven-fibred or primary osteon fragments (*vide infra*).

The Structure of Mature Bone

As we have seen, a mature bone is composed of two kinds of tissue, one of which is dense in texture like ivory, and termed *compact bone*; the other, consisting of a meshwork of *trabeculae* within which are easily visible intercommunicating spaces (or *cancelli*), is called *trabecular* (*spongy* or *cancellous*) bone. The compact bone is always on the exterior surrounding the spongy bone and their relative quantities and architecture vary characteristically for each bone, in a manner which reflects its overall shape, position and functional roles (p. 233). In long bones the origin and significance of their diaphysial, metaphysial, epiphysial regions and associated growth cartilages have already been considered in general (p. 241) and will be further considered with intracartilaginous ossification (p. 263). The thick cylinder of compact bone forming the shaft, presents a few trabeculae and spicules of bone on its inner surface; it encloses a large central *medullary* or *marrow cavity* which communicates freely with the intertrabecular spaces of the expanded bone ends. These various spaces are lined by a highly vascular condensation of areolar tissue, the *endosteum*, and are filled with bone marrow, either haemopoietic or adipose, its character varying with the age and

region of the bone concerned. The marrow cavity begins to appear in the shaft during fetal life, and slowly extends in both directions through the subsequent years, until it almost reaches the epiphysial lines which mark the zone of fusion between epiphysis and diaphysis occurring when growth in length has ceased (p. 245).

Close examination of the compact bone shows it to be extremely porous, so that the difference between it and spongy bone depends largely upon the relative amount of solid matter and the size and number of spaces in each; in compact bone, spaces are small and the solid matter abundant, whilst the reverse is the case in spongy bone. During life, bone is permeated by many blood vessels and, except for its cartilage-covered articular surfaces, it is everywhere clothed by a membranous *periosteum*. When strong tendons or ligaments are attached to a bone, the periosteum blends with them. It consists of two layers closely united together, the outer formed chiefly of white fibrous tissue containing a few fat cells; the inner of fine elastic fibres forming dense membranous networks, which again can often be separated into several sub-layers. In young bones the periosteum is thick and very vascular, and is separated from the bone by a layer of soft *osteogenetic tissue*, containing a number of granular cells, the *osteoblasts*, through the agency of which surface ossification proceeds. Later in life the periosteum is thinner and less vascular, and the deeper layer consists of flattened, relatively quiescent cells which are, however, still potentially osteogenic. The periosteal blood vessels communicate with those of the underlying bone (p. 257), and a bone surface denuded of periosteum shows an increased susceptibility to exfoliation or necrosis.

Microstructure (**3**.10, 11, 12, 13, 14). In the adult, compact bone consists mainly of a number of irregularly cylindrical units, termed *typical Haversian systems* or *secondary osteons*, each consisting of a central *Haversian canal* which contains a neurovascular bundle and is surrounded by concentric lamellae of bony tissue. Between these lamellae are a number of small spaces termed *lacunae* which are connected with each other and with the central Haversian canal by many fine radiating channels called *canaliculi*. The lacunae and their canaliculi contain, respectively, the cell bodies and fine cytoplasmic extensions of the bone cells or *osteocytes*. The angular intervals between the secondary osteons are occupied by *interstitial bone* (most commonly in the form of interstitial lamellae with their lacunae and canaliculi running in various directions, but *vide infra*). Again, other lamellae are found encircling the inner and outer surfaces of the bone; and they are termed *circumferential* or *primary lamellae*.

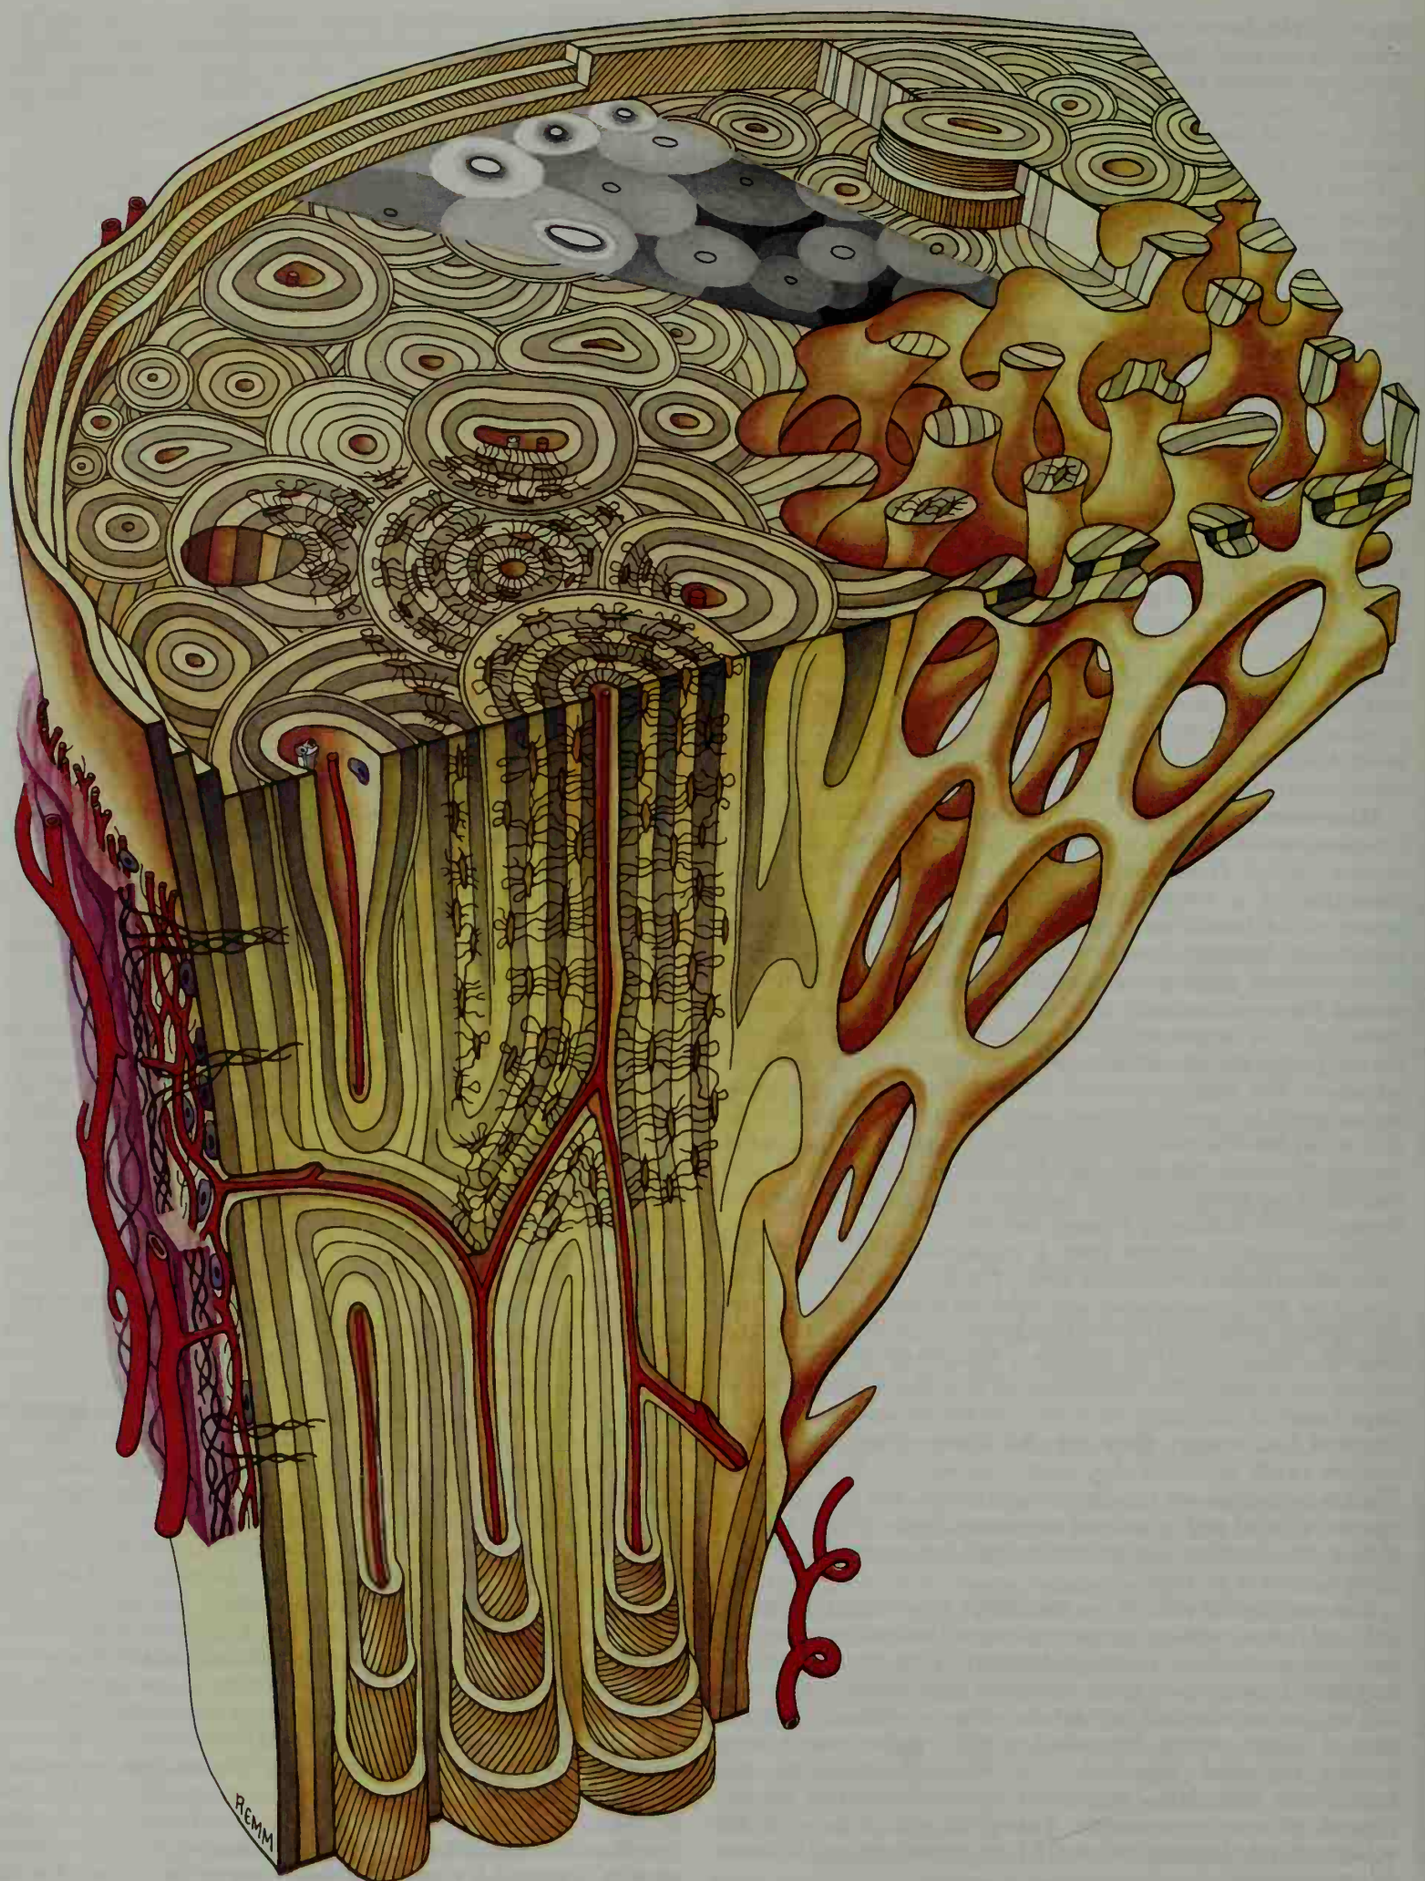
The secondary osteons have a predominantly longitudinal orientation (Cohen and Harris 1958), but they frequently spiral, branch or intercommunicate and some terminate blindly. They may appear round, oval or ellipsoidal in transverse section and they vary considerably in diameter, containing on average six concentric lamellae, but these may be as many as fifteen in the largest osteons. Similarly, the contained Haversian canals vary in diameter but average about 50 μm, whilst those close to the marrow cavity are somewhat larger (Cohen and Harris 1958). Within each canal are one or two capillaries, and usually some non-myelinated and occasional myelinated nerve fibres (5–9 μm in diameter) together with their associated Schwann cells (Cooper 1969; Cooper *et al.* 1966).

The endothelial cells of the capillaries are fenestrated (cf. p. 628) and their cytoplasm contains occasional caveoli and electron-dense filaments about 10 nm in diameter. They are surrounded by a basal lamina which splits to enclose typical pericytes.

The perivascular cell population varies in different regions, even of a single osteon, depending on whether the bone is being actively deposited, absorbed or is relatively quiescent, and accordingly osteoblasts, osteoclasts or undifferentiated mesenchymal cells may predominate. Lining the wall of the canal are collagen fibres showing the usual 64 nm periodicity and of about 60 nm diameter.

The Haversian canals have long been claimed to communicate with the medullary cavity, with the spaces in spongy bone, and with the surfaces of bone by oblique or transverse channels termed *Volkmann's canals*, which lodge blood vessels and nerves, and are said not to be surrounded by concentric lamellae of bone. It has been shown, however (Cohen and Harris 1958), that the majority of the canals so described are in fact simple interosteonic anastomotic canals, or radial canals passing through the circumferential lamellae, and that the frequency and calibre of periosteal vascular connexions in the diaphysis may have been over-emphasized (*vide infra*).

The trabeculae of the spongy bone consist of fragmentary systems of superimposed lamellae with numerous intervening cement lines (*vide infra*), and in places they may contain small islands of calcified cartilage. The trabeculae receive their nutriment from the blood vessels in the marrow around them and except for occasional large trabeculae which contain small Haversian systems, they are not penetrated by blood vessels.



Because of its regular microstructure, normal adult bone is termed *lamellar bone* and each lamella is a thin plate of bony tissue varying from 5 to 7 μm in thickness. The bony tissue consists of a ground substance or *matrix* in which are embedded fibres and which is impregnated with bone salts. In mature bone about one-fifth of the weight of the matrix is water; organic material forms 30–40 per cent and mineral salts 60–70 per cent of the dry weight of bone. The main organic components are collagen (90–95 per cent), mucopolysaccharide in combination with a non-collagenous protein (1 per cent) and a resistant protein (5 per cent), e.g. *see* Eastoe and Eastoe (1954). Organic matrix which is as yet uncalcified, is known as *osteoid matrix*. In normal bone its amount is very small, owing to the rapidity with which calcification follows. The amount of osteoid matrix is, however, greatly increased in certain disease states, such as rickets.

All Haversian and most interstitial systems of lamellae in adult bone are demarcated from neighbouring systems by a *cement line* which is strongly basophilic; it has little or no collagen and a high content of inorganic matrix. A cement line is formed when a cavity which has been formed by bone *resorption* is subsequently filled by the successive *deposition* of bony lamellae on its inner surfaces. The cement line indicates the limit of the erosive process and the commencement of the process of deposition and is, therefore, often called a *reversal line*.

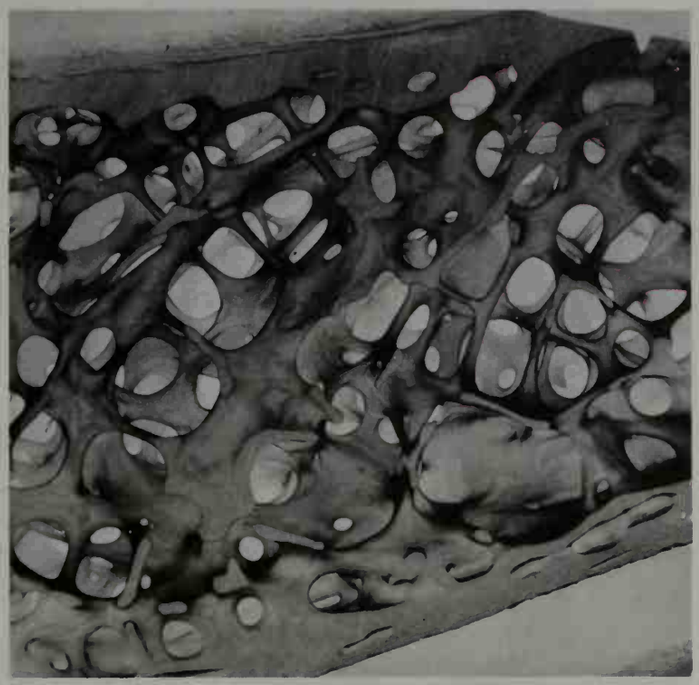
The normal variation in the composition of bone from various sites and at different ages is not yet fully elucidated. It is, however, of considerable importance when attempting to assess (usually radiologically) the degree of rarefaction of bone (osteoporosis), which may occur in disease or as a result of disuse. Whether this arises from an actual reduction in the amount of bony tissue, rather than an overall reduction in its degree of mineralization, is difficult to determine experimentally because of the problems attendant on the separation of bone from other tissues. Further difficulties concern the quantitative determination of the related sizes of the vascular, lacunar and marrow spaces. Some have tried to minimize these difficulties by making estimates on cortical bone, it having been suggested that trabecular bone is more labile than cortical bone. It is maintained, however, that *normally* there is little difference in the composition of cancellous and compact bone. Overall, the water content decreases and the mineralization increases with age up to the sixth or seventh decade, whilst the organic content remains unchanged. Thereafter the degree of mineralization declines (Mueller *et al.* 1966).

Microradiographic and interferometric investigations on compact bone, however, show an uneven distribution of mineral salt. The inner and outer circumferential lamellae and the interstitial lamellae are in general evenly and highly mineralized. The secondary osteons exhibit varying degrees of mineralization, and in a single osteon there are differences in concentration in different areas. Young osteons have a low concentration which increases with age and initially is highest close to the central canal and decreases towards the periphery. This gradient in mineral content becomes less pronounced as the osteon grows older, and in very old highly mineralized osteons there is an even distribution of mineral salt. Bone resorption may be found both in areas of high and low concentration (*vide infra*). In developing fetal bone, mineralization up to 70–80 per cent is rapid (occurring in about 3 weeks), but thereafter, up to 100 per cent, it is a much slower process. Such sequences may also hold for the later developing osteons.

The lamellation of bone (**3**.10, 11, 12, 13, 14). There have

3.10A A schematic diagram of some of the main features of the microstructure of mature bone seen in both transverse section (top) and longitudinal section. Areas of compact and cancellous bone are included. The central area in transverse section simulates a microradiograph, the densities reflecting variations in mineralization. Note the general construction of the osteons, the distribution of the osteocyte lacunae, the Haversian canals and their contents, resorption spaces, and the different views of the structural basis of bone lamellation. See text for more detail.

been various explanations of the lamellar appearance of mature bone, but it seems largely due to the relative orientation of the anisotropic structures found in each layer and also the interposition of a thin interlamellar zone between successive layers. The anisotropic components are collagen fibre bundles and hydroxyapatite crystals, and these all lie parallel within a single lamella. In successive lamellae, however, the orientation of the fibre bundles (together with their associated crystallites) may change through an angle of 0–90°. Stratification is most apparent when this angle is large. Fibre bundles frequently leave one lamella and pass into the next through discontinuities in the interlamellar cementing zone. In the latter, the organic matrix is composed almost completely of irregularly disposed collagen, heavily flanked by very large concentrations of crystallites.



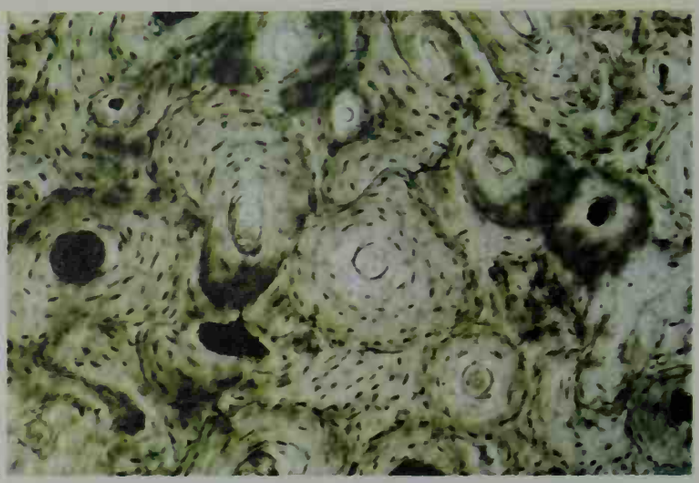
Earlier authorities (Gebhardt 1905) suggested that the collagen fibres are mainly longitudinal and circumferential in adjacent lamellae or that they have a spiral course, the pitch of the spiral differing in successive lamellae. The latter view has received recent support from a series of interesting investigations into the structure and compressive properties of isolated single osteons (Ascenzi and Bonucci 1968).

Other investigations, however, suggest that the fibre arrangement varies (Smith 1960). In some secondary osteons the fibres are predominantly longitudinal and circumferential in successive lamellae but in approximately equal concentration. In others, lamellae with dense, closely packed longitudinal fibres alternate with lamellae containing fewer dispersed circumferential fibres. In a third type of osteon, there is a predominance of the dense longitudinal fibre bundles with here and there very thinly dispersed circumferential fibres forming incomplete arcs, and in these cases the lamellation is indistinct. These different fibre patterns have been described as coexisting in different parts of the same osteon and may be associated with differences in mineral salt distribution. Since the mineral content is closely associated with the collagen fibres, it is believed to be in high concentration in those lamellae with a high fibre content and this may be reflected by variations in the X-ray absorption of different lamellae. Furthermore, it has been suggested that with ageing there is an increase in the number of longitudinal fibres and a simultaneous decrease in circumferential fibres with a loss of distinct lamellation (Smith 1960).

As mentioned above, the investigators analysing the mechanical properties of isolated osteons subscribe to a helical conformation of the lamellar fibrous architecture, with again, three main types of osteon (Ascenzi and Bonucci 1968). In the first type all lamellae have a predominantly transverse, spiral course of their collagen fibres; in the second type, alternate lamellae are longitudinal and transversal in their main helical fibre direction; type three osteons possess lamellae all showing a largely longitudinal orientation of fibres. The compressive strength and modulus of elasticity was greatest for osteons with transverse bundles and lowest in those with mainly longitudinal ones.

The circumferential lamellae are pierced by tapering bundles of collagen fibres which spring from the periosteum and run obliquely through them, apparently pinning them together, and are termed the *perforating* fibres of Sharpey.

The bone 'salts'. (For details consult Robinson 1952; Bourne 1956; McClean and Urist 1969.) The organic matrix of bone is impregnated by inorganic material, sometimes termed *bone salts*, and these confer on bone its hardness and rigidity. Their most important ionic constituents are calcium (Ca^{2+}), magnesium (Mg^{2+}), phosphate (PO_4^{3-}), carbonate (CO_3^{2-}), hydroxyl (OH^-), chloride (Cl^-), fluoride (F^-), and citrate ($C_6H_5O_7^{3-}$). The mineral substances of bone may be obtained by calcination, which destroys the organic matter, following which bone retains its original form but is white and brittle, loses about one-third of its original weight and crumbles under the slightest force. On the other hand, the mineral constituents of bone are mostly soluble in mineral acids and may be removed by prolonged immersion in dilute solutions. The bone then retains its shape but is highly flexible, so that a long thin bone (such as the fibula) can easily be tied into a knot. In a transverse section of such a softened bone the arrangement of the Haversian canals, lamellae, lacunae and canaliculi can still be recognized.



3.10B Low power scanning electron micrograph of a segment of a human rib. Note the cortical shell of compact bone and the delicate lattice of trabeculae, separated by labyrinthine marrow spaces. (Reproduced by kind permission of Drs. W. J. Whitehouse, E. D. Dyson, and C. K. Jackson, of the Medical Research Council Radiology Unit, Harwell. Such specimens are used currently for quantitative studies of bone architecture.) Magnification × 7.

The mineral salts consist of crystalline and amorphous components, and X-ray diffraction and ultrastructural studies have shown that the principal crystalline component is composed of needle-shaped crystals of hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$) which are about 20–40 nm in length and 3–6 nm in breadth. In general the needles are arranged with their long axes parallel to those of the collagen fibres and they lie partly within the fibres, but their precise relationship to the periodic substructure of the collagen is still uncertain. Citrate ions are probably arranged on the surface of the crystallites, and carbonate ions may also be located on the surface or they may replace phosphate ions within the crystal. Substitution of various chemical groups for those normally present in the crystallites is of frequent occurrence. Thus, fluoride commonly substitutes for hydroxyl, and a series of *bone-seeking cations*, e.g. the cations of radium (Ra^{2+}), strontium (Sr^{2+}) and lead (Pb^{2+}), all readily substitute for calcium (Ca^{2+}). The accumulation of an isotope of strontium (^{90}Sr) may cause widespread radiation damage to the cells of its contained bone marrow.

The bone lacunae appear under the light microscope as small oblong or ovoid spaces situated along the margins, or in the middle, of the compact lamellae. At high magnification they are seen to possess rough walls and to be irregularly stellate spaces and the pointed extremities are continuous with the surrounding canaliculi. With few exceptions each lacuna is occupied in life by a branched bone cell or osteocyte, the processes of which extend into the canaliculi.

The bone canaliculi are minute channels, crossing the lamellae and connecting the lacunae of a Haversian system with one another and with the central Haversian canal. The peripheral canaliculi do not as a rule communicate with those of neighbouring systems, but form loops and return to their own lacunae. The average life of an osteocyte has been estimated at 25 years. Old osteocytes may retract their processes and their associated canaliculi may be empty. When osteocytes die, their lacunae and canaliculi may become plugged with cell débris and minerals and this may interfere with diffusion through the bone. Dead osteocytes are more numerous in interstitial bone than in

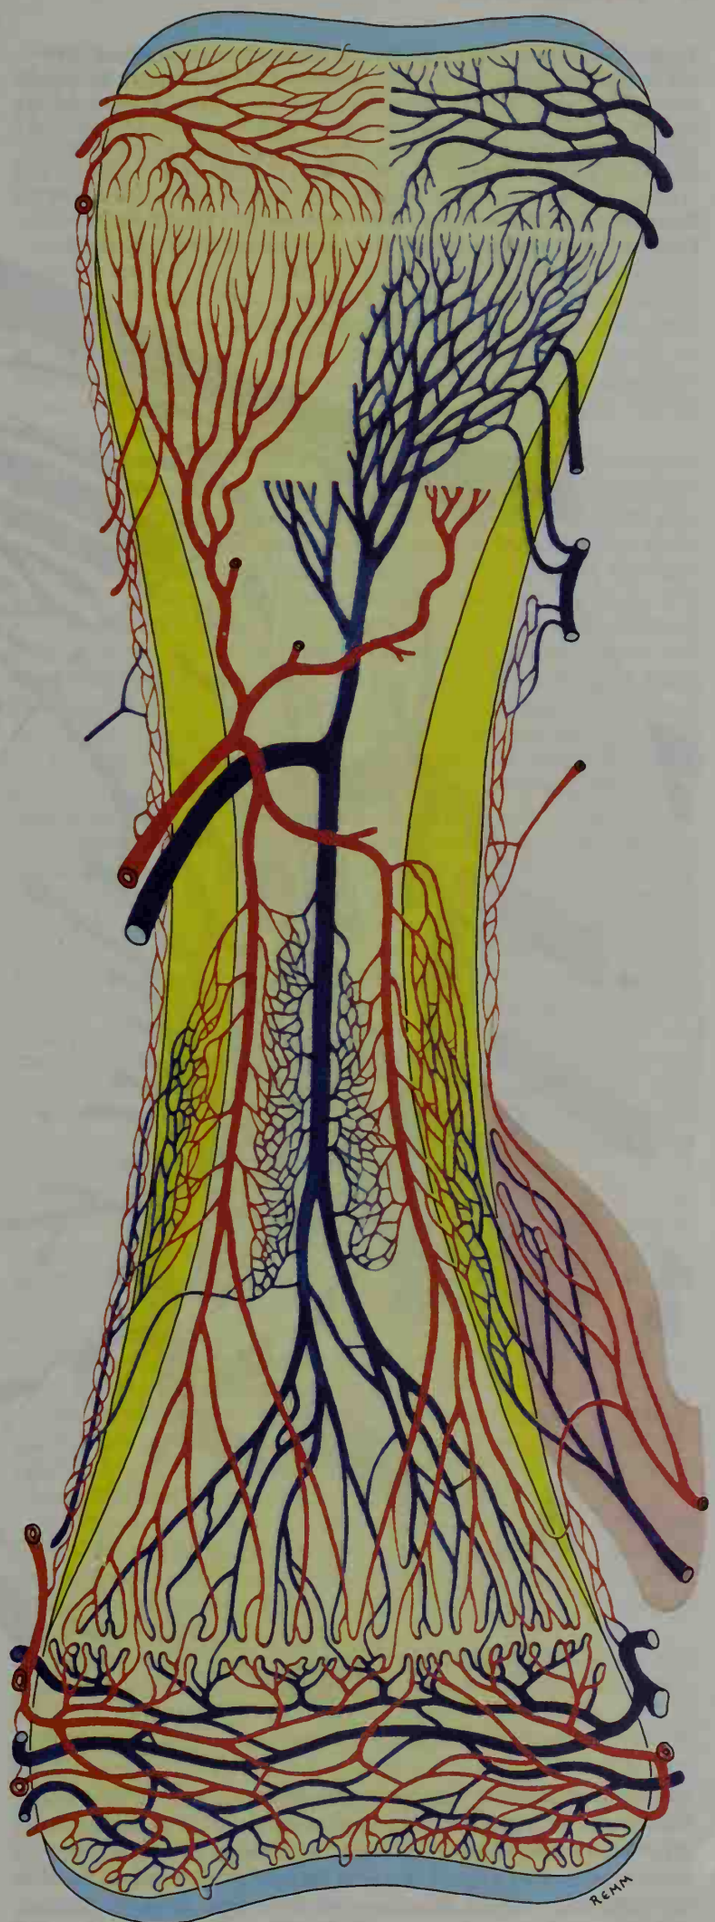
secondary osteons and they become particularly noticeable in the second and third decades.

The osteocytes vary in number, spatial arrangement and appearance. They are most numerous in young bone and they conform to the general shape of the lacunae in which they lie. Their processes, which have a more or less uniform diameter of 80–100 nm, pass into the canaliculi; they may be of considerable length and may also branch. Sometimes two processes lie

alongside one another in a single canaliculus. The processes are not continuous but terminate in end-to-end or side-to-side juxtaposition without any obvious junctional specializations. It is not known whether some simply terminate in blind-ending canaliculi. The cytoplasm of the cell processes contains no distinctive organelles other than a few smooth-walled vesicles and electron-dense granules.

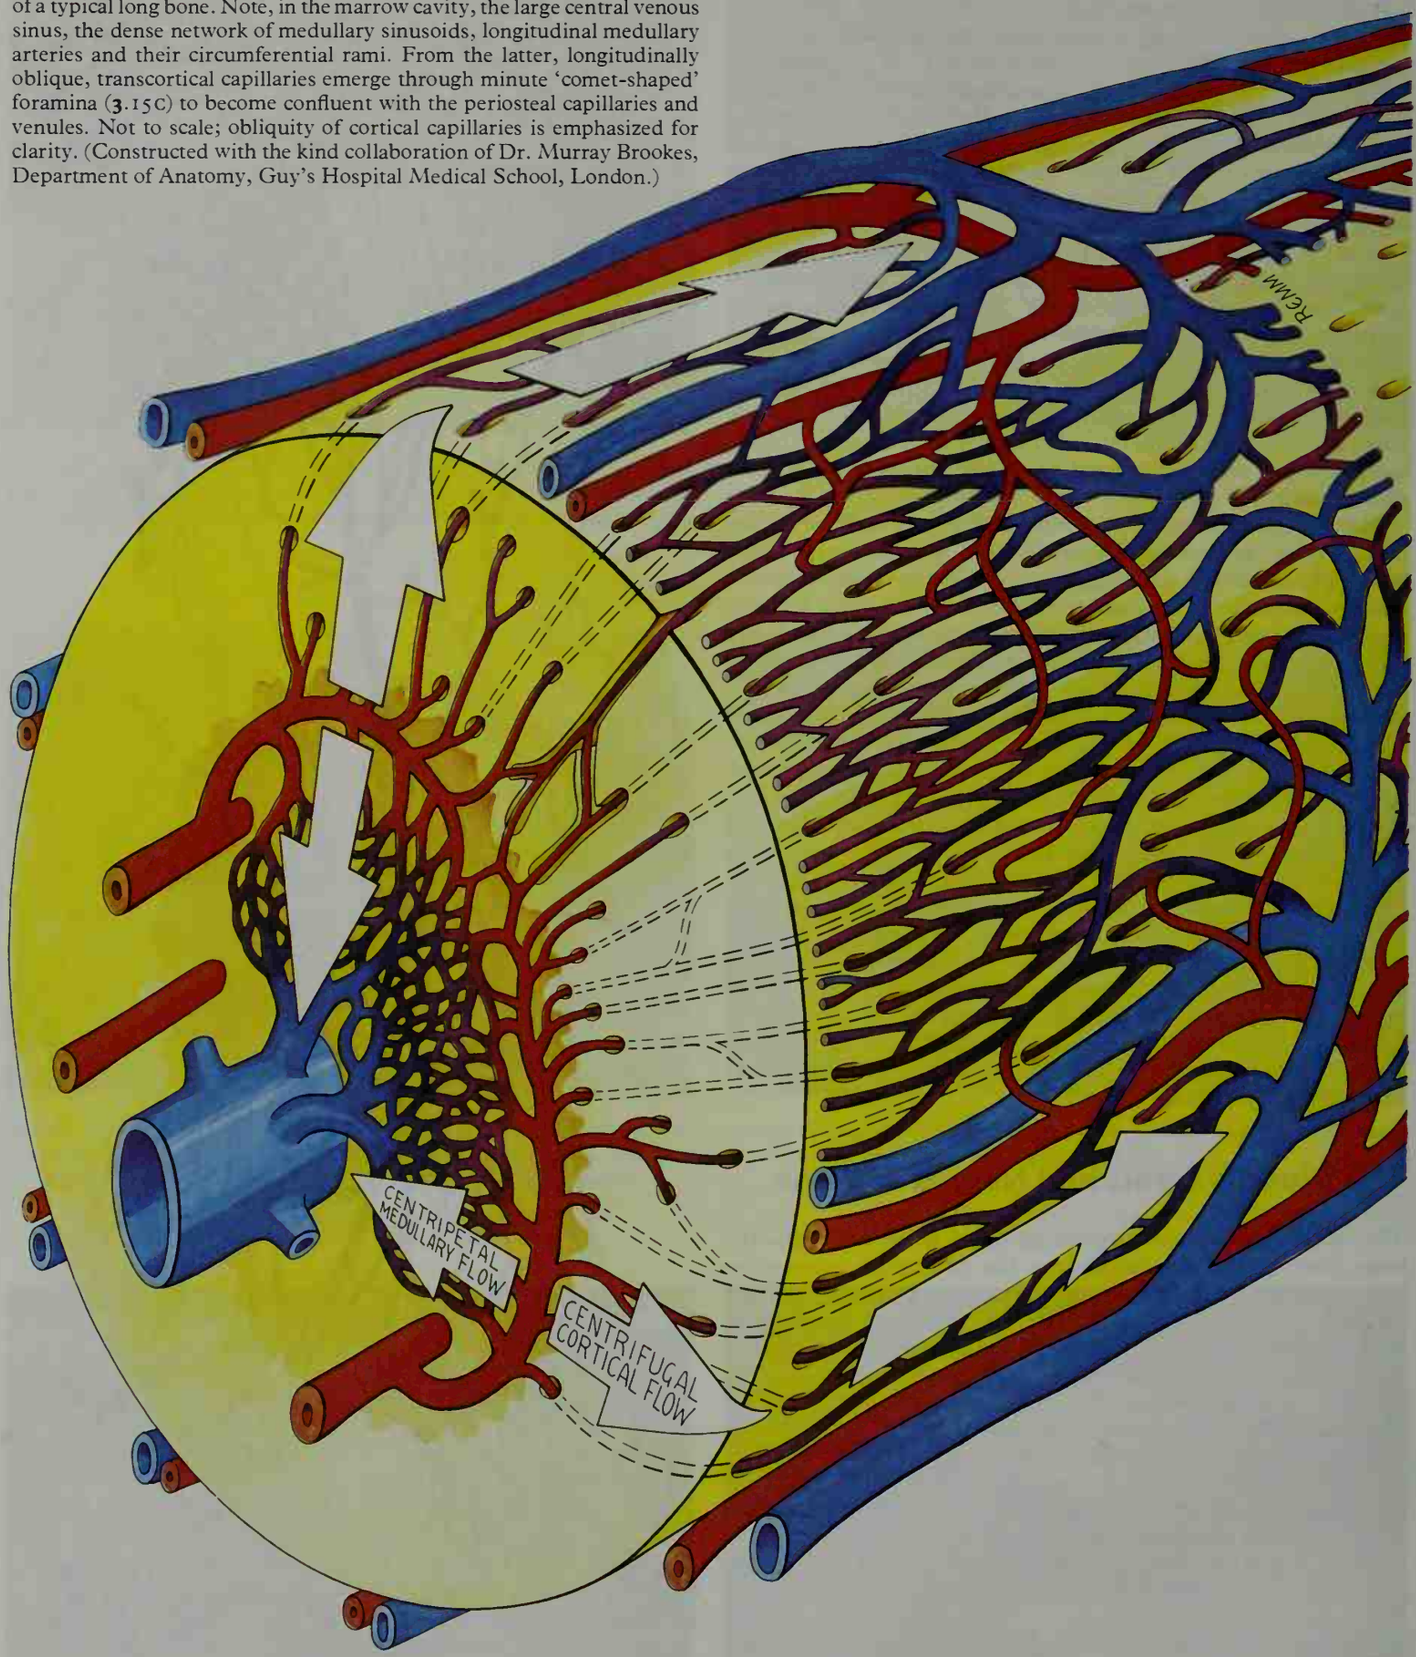
The cell bodies of mature relatively quiescent osteocytes contain an oval nucleus surrounded by a fairly small volume of faintly basophilic cytoplasm. There is a correspondingly small concentration of rough endoplasmic reticulum, some free ribosomes, centrioles and a small juxtanuclear Golgi apparatus. Like the osteoblasts from which they are derived, newly incorporated active osteocytes have a more basophilic cytoplasm corresponding to a greater concentration of rough endoplasmic reticulum, and the Golgi apparatus is more prominent. On the walls of the lacunae surrounding the osteocyte cell body, there is a small amount of non-mineralized or lightly mineralized collagen, but this is not seen in the canaliculi where the walls are heavily mineralized.



Neither the cell bodies of the osteocytes nor their processes occupy fully the lacunae and canaliculi in which they lie, and a space, presumably fluid-filled, surrounds them. There is thus a continuous extracellular space from the Haversian canal through its canaliculi and lacunae along which the cells of the osteon are nourished and through which the ions for the mineralization of the bone are transported. It has been estimated that the crystal surface exposed to extracellular fluid in the walls of this system in a 70 kilogram man is between 1,500 and 5,000 square metres, thus providing an enormous surface area across which exchanges of mineral ions can occur (Robinson 1964). In addition there is a further surface of some 8 square metres associated with the periosteal and endosteal membranes.

The osteocyte and its processes, deeply entrapped within the bone substance, probably maintain the architecture of the lacunae and canaliculi (i.e. the diffusion pathways), and they are possibly directly concerned in cellular transport of materials along these channels. There is increasing evidence that they are actively involved in modifying the neighbouring bone matrix, thereby facilitating the return of various ions, particularly calcium, from the bone salts (osteolysis) back into the bloodstream (Heller-Steinberg 1951; Bélanger 1963).

The Blood Vessels and Nerves of Bone



The osseous circulation supplies the bony tissue and cells, the bone marrow, the perichondrium, the epiphysial cartilage in young bones, and in part, the articular cartilages. Modern researches (Brookes 1964, 1967, 1971; Kelly 1968; Rhinelander 1968) have emphasized the essentially *centrifugal* flow of blood through the cortical bone of the shaft of long bones, revising the earlier concept of a substantial *centripetal* flow of arterial blood into the bone cortex from overlying periosteal vessels. In summary, the vascular supply of a long bone consists of several discrete points of arterial inflow, which feed complicated and regionally variable sinusoidal networks within the bone; in turn these drain into venous channels leaving the bone through all its surfaces which are not covered by articular cartilage. The principal features of these vascular patterns are summarized in **3**.15A and B.

One or two principal *diaphysial nutrient arteries* pierce the shaft of a long bone obliquely through, usually one, occasionally two, *nutrient foramina* leading into *nutrient canals*. These have long been recognized (Havers 1961; Bernard 1835). Their site of entry and angulation are fairly constant and, characteristically, the vessels point *away* from the dominant growing end of the bone (p. 259). This constitutes the widely accepted *growing-end hypothesis* concerning the mechanism leading to nutrient foramen and canal disposition (Clark 1965). Simple growth considerations, however, do not account for the exceptions to this pattern which some authors have described in various species and sites (Hughes 1952). However, in a study of human long bones, Mysorekar (1967) found anomalously directed canals only in the fibula, and

3.15A A scheme of the main features of the blood supply of a long bone based upon descriptions by Dr. Murray Brookes (Guy's Hospital Medical School). Note the contrasting supplies of the diaphysis, metaphysis and epiphysis, and their connexions with periosteal, endosteal, muscular and periarticular vessels. Consult the text for a more extended description.

3.15B Diagram of the circulatory arrangements in part of the diaphysis of a typical long bone. Note, in the marrow cavity, the large central venous sinus, the dense network of medullary sinusoids, longitudinal medullary arteries and their circumferential rami. From the latter, longitudinally oblique, transcortical capillaries emerge through minute 'comet-shaped' foramina (**3**.15C) to become confluent with the periosteal capillaries and venules. Not to scale; obliquity of cortical capillaries is emphasized for clarity. (Constructed with the kind collaboration of Dr. Murray Brookes, Department of Anatomy, Guy's Hospital Medical School, London.)

attributed this to the unique ossification pattern in that bone. Subsequently in a study of 848 metacarpals and 811 metatarsals, apart from a few bones with absent or double foramina, over 90 per cent possessed a single nutrient foramen in the middle third of the shaft, and without exception, all foramina, single or double, were directed away from the epiphysis, thus supporting the growing-end hypothesis. For details of the latter investigation, a bibliography, and an introduction to alternative hypotheses such as the '*periosteal slip*' theory of Schwalbe (1876), the 'vascular theory' of Hughes (1952), and the '*asymmetrical muscular development theory*' of Lacroix (1951), consult Patake and Mysorekar (1977). Finally, for an interesting comparative study of the contrasting growth patterns of foramen and canal in the rat femur and tibia consult Henderson (1978). In its cortical canal, a nutrient artery does not branch, but once within the medullary cavity it divides into ascending and descending branches. These pass towards the bone ends and divide repeatedly into smaller branches which pursue a helical course in the juxta-endosteal zone of the marrow. Near the bone ends they are joined by the terminals of numerous *metaphysial* and *epiphysial arteries*. The

3.15C A scanning electron micrograph of the periosteal surface of the diaphysis of an adolescent tibia. Note the oblique 'comet-shaped' groove and foramen which in life transmitted a minute neurovascular bundle; numerous foramina of this general type are scattered over the surface of the diaphysis, but their pattern, direction, and degree of obliquity, vary with the overall subperiosteal deposition of bone that characterizes the various growth zones of the diaphysis. Magnification × 80. (Preparation by Mr. Michael Crowder, Department of Anatomy, Guy's Hospital Medical School.)

former pass directly into the bone from neighbouring systemic vessels, whereas the latter are derived from periarticular vascular arcades which are formed on the non-articular bone surfaces (p. 257). Numerous vascular foramina penetrate the bone surfaces, often at fairly specific points (*see* **3**.1D), near the bone ends and some are occupied by these arteries, but the majority contain thin-walled veins. Once within the bone these various arteries are distinctive in that they consist of a single endothelial layer surrounded by a thin layer of supportive connective tissue (Yoffey 1962). The epiphysial and metaphysial nutrient arteries are quantitatively much more important than the diaphysial supply, which they can effectively replace, when the latter has been obliterated experimentally.

The medullary arteries of the shaft (**3**.15A and B) give off (*a*) centrally directed branches which contribute to a hexagonal mesh of marrow sinusoids draining into an extremely wide, thin-walled central venous sinus; (*b*) a series of cortical branches which pass through endosteal canals to feed the fenestrated capillaries of the Haversian systems. The central venous sinus drains into veins which retrace the path of the nutrient arteries, or sometimes pierce the shaft elsewhere as independent emissary veins.

The cortical capillaries obviously conform to the pattern of the Haversian canals, often described as predominantly longitudinal with oblique interosteonic connexions. However, an oblique, radial pattern has been demonstrated in which the vessels largely radiate from the site of the primary ossification centre (Brookes 1964; 1967; 1971). At the bone surface, the cortical capillaries form capillary and venular connexions with the overlying periosteal plexuses (**3**.15A, B and C). The latter are formed by arteries from neighbouring muscles which form vascular arcades with longitudinal interconnexions on the fibrous periosteum. This external plexus supplies a capillary plexus which permeates the deeper osteogenetic layer of the periosteum. At points of direct muscular attachment to bone, the periosteal and muscular vascular plexuses become confluent and the cortical capillaries of the underlying bone drain into the interfascicular venules of the muscle.

The preceding account of an almost exclusively centrifugal supply to the cortex of the shaft of long bones is receiving increasing support, but some authorities (de Marneffe 1951; Morgan 1959) maintained that there exists an appreciable centripetal flow of arterial blood to the outer zones of the cortex from the overlying periosteal vessels.

The large nutrient arteries of the epiphysis form a free series of intraosseous anastomoses, and branches pass towards the articular surface in the trabecular spaces of the bone. Near the articular cartilage their branches form a series of anastomotic arcades (e.g. 3 or 4 in the femoral head) before giving off a series of end-arterial loops which often pierce the thin shell of hypochondral compact bone (**3**.1D) to enter, and sometimes perforate, the calcified zone of the articular cartilage before returning to the venous sinusoids of the epiphysis.

In immature long bones similar sources of supply exist but the epiphysis forms a discrete vascular zone; distinct epiphysial and metaphysial arteries can be distinguished, entering on either side of the growth plate of cartilage, and anastomoses between these vessels are either infrequent or absent. The growth cartilage probably receives its nutritional supply from both these sources and also from a collar of anastomotic vessels in the adjoining periosteum, although the relative contribution from each is not certain (Brookes 1964, 1967, 1971; Trueta and Morgan 1960; Rang 1969). Occasionally a cartilage canal becomes incorporated in the growth plate (p. 266). The metaphysial bone is nourished by the conjoined terminal branches of the metaphysial arteries and those of the primary nutrient artery of the shaft. Their terminals form sinusoidal loops in the zone of advancing ossification and the dilated bend of each loop is separated by a small gap from the nearest transverse partition of calcified cartilage (p. 264). This gap is often packed with red blood corpuscles which has been described as evidence of a 'microrupture' of the vessel at this point (Trueta and Morgan 1960). Other authors, however, have emphasized the intimate contact of the sinusoidal endothelium and the calcified cartilage, and in addition to providing a nutritive source for the growth cartilage, the vascular loops have been ascribed a chrondrolytic role (Cameron 1961; Brookes and Landon 1963). The periosteum of young bone is more vascular than that of the adult; its vessels communicate more freely with those of the shaft and also give rise to many metaphysial vessels.

Large irregular bones like the scapula and innominate bone receive a superficial blood supply from the periosteum and are frequently provided with large nutrient arteries which penetrate directly into the cancellous bone. The two systems anastomose freely.

Short bones receive numerous fine blood vessels from the periosteum. They enter at the non-articular surfaces and supply both compact and cancellous bone and bone marrow. In the vertebrae, arteries enter around the circumference but particularly close to the base of the transverse process. The marrow is drained by two voluminous basivertebral veins which converge at a large foramen on the posterior surface of the body.

The flat bones of the skull are supplied by numerous vessels from the covering periosteal or mucoperiosteal layers. The veins are large and run in tortuous canals in the diploë (cancellous bone). They have very thin walls so that when the bone is divided they remain open.

Lymphatic vessels are to be found accompanying the periosteal vascular plexuses but their presence within the bone substance has never been convincingly demonstrated.

Nerves are most numerous in the articular extremities of the long bones, in the vertebrae and in the larger flat bones. They are distributed freely within the layers of the periosteum, and fine myelinated and non-myelinated nerve fibres accompany the nutrient vessels into the interior of the bone and even into the perivascular spaces of the Haversian canals (p. 253).

The Histogenesis of Bone

As we have seen, some bones such as those in the roof and sides of the skull are preceded by a fibro-cellular membrane, whereas the majority of bones are preceded by shaped rods or masses of

cartilage. Hence, two kinds of ossification are described; intramembranous and intracartilaginous, but there is no essential difference between these two methods of bone formation.

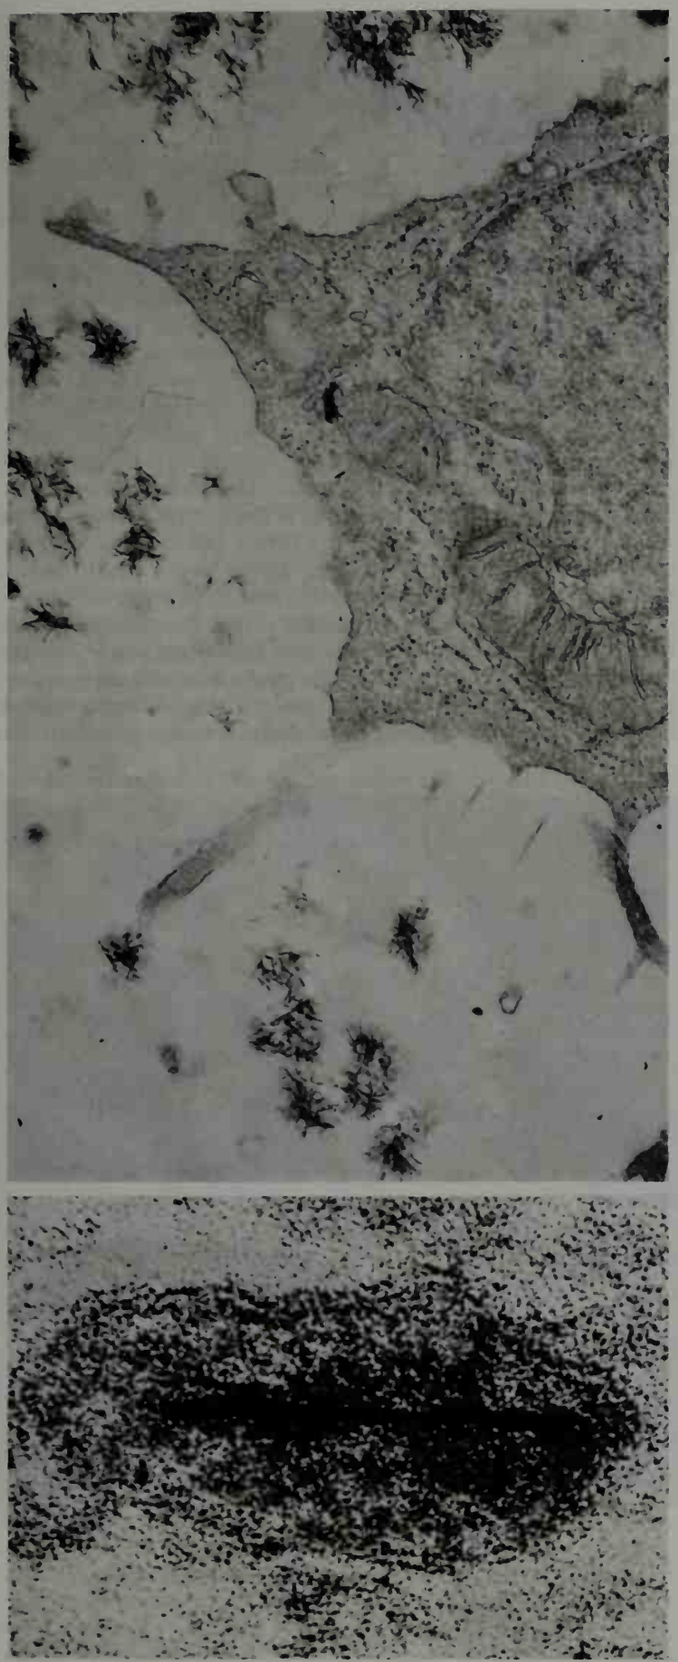
Intramembranous (Mesenchymal) Ossification

This process, which is essentially the direct mineralization of a highly vascular connective tissue, commences at certain constant points known as *centres of ossification*. At such a centre, the mesenchyme cells (*osteoprogenitor cells*) proliferate and condense around a profuse capillary network. Between the cells and around the vessels, is a fine meshwork of collagen fibres and an associated amorphous ground substance. The most central cells enlarge, and simultaneously fine strips of an eosinophilic matrix (the earliest bone) appears between the blood vessels. These strips rapidly extend and fuse to form a delicate labyrinth, the spaces of which enclose the blood vessels and transforming mesenchyme cells. The latter enlarge, becoming polygonal, roughly cuboidal, or low columnar, and arranged as an incomplete layer in close contact with the surfaces of the primitive, eosinophilic bony matrix. (It is now firmly established that the earliest hydroxyapatite crystallites appear inside minute extracellular *matrix vesicles* which are products of the differentiating osteoprogenitor cells, or osteoblasts —*see* p. 257 and **3**.16A, B).

The cells retain contact with each other via short side branches. Their cytoplasm becomes intensely basophilic and the nucleus often becomes eccentric with a pale area of cytoplasm on its inner side. The cells are now termed *osteoblasts* and ultrastructurally are seen to possess an open-faced nucleus with obvious nucleoli, a prominent paranuclear Golgi apparatus with centrioles, a profuse concentration of granular endoplasmic reticulum and some free ribosomes. Lipid droplets, scattered mitochondria and lysosomes are found throughout the cytoplasm which, using appropriate techniques, can be shown to contain periodic acid-Schiff positive granules and vesicles and to give a strong positive reaction for alkaline phosphatase. These cells are similar in some respects to the chondroblasts of developing cartilage (p. 245), and similar synthetic pathways are involved during their rapid production of collagen and its associated proteoglycans. These are extruded into the extracellular space, where they form the so-called osteoid matrix which rapidly becomes calcified with the appearance of minute deposits of calcium phosphate (*vide infra*). These are later transformed into typical needle-shaped hydroxyapatite crystallites intimately related first to the cores of matrix vesicles, and subsequently to the collagen fibres of the matrix. These collagen fibres form increasingly coarse, interweaving networks in the walls of this early sponge-work or labyrinth of *woven-fibred bone*—the so-called *primary spongiosa*. As further layers of calcifying matrix are added to the delicate early trabeculae, some of the osteoblasts become surrounded by matrix and are now included in primitive lacunae within the developing bone. The surface projections of the entrapped cells, however, retain contact with those of neighbouring cells, and as these projections elongate, the matrix condenses around them to form canaliculi. Further generations of osteoblasts form on the trabecular surfaces by transformation of adjacent vascular mesenchyme cells.

As the sequence of matrix secretion, calcification and entrapping of osteoblasts proceeds, the trabeculae gradually thicken and the intervening vascular spaces become progressively narrowed. Where the bone persists as cancellous bone, however, the process slows and the spaces later become occupied by haemopoietic tissue. In regions where compact bone is formed, the process of trabecular thickening and vascular space narrowing continues. As this occurs, the collagen fibres of the matrix which are secreted on to the narrowing walls of the spaces become rather more highly organized as parallel, longitudinal or spiralized bundles and the entrapped cells come to occupy roughly concentric sequential rows. These irregular, anastomosing, sometimes roughly cylindrical, masses of compacted, parallel-fibred bone containing a central vascular canal are termed *primary osteons* or *atypical Haversian systems*. These, and the intervening areas of woven-fibred bone are subsequently largely eroded and replaced by generations of lamellar *secondary osteons* (see also pp. 252, 253, 266).

As these changes are proceeding in the ossification centre, the surrounding mesenchyme condenses as a fibro-vascular periosteum around its edges and surfaces. Extension of the ossification process occurs through the agency of stem cells derived from the deeper layers of the periosteum. The cells are potentially osteoprogenitor and maintain themselves by mitotic division. Some of the derived cells progressively secrete new matrix and collagen fibres which radiate from the ossification centre, and enmesh further periosteal blood vessels and again become encrusted with ossifying bone matrix, eventually enclosing the young osteocytes within lacunae. Further growth of a bone involves a continuation of these processes together with much remodelling with varying rates of bone deposition in some areas and balanced resorption of bone in others. Obviously, these overall patterns vary with the topography and fine architecture of the particular bone in question and have been studied using a variety of techniques over many years. Examples of this will be considered elsewhere (p. 266) whilst the more intimate processes of calcification and bone resorption common to all forms of bony tissue, follow briefly.



Calcification and the Osteoblast

Whilst the essential crystallite unit in bone is in the nature of a complex hydroxyapatite with a number of other associated ions (p. 255), the necessary ions involved in the initial stages of calcification are only calcium (Ca^{2+}) and phosphate (PO_4^{3-}), and the problem, although unexplained in detail, was treated for many years as one simply involving precipitation dynamics. It was assumed that the product of the ion concentrations $[Ca^{2+}] \times [PO_4^{3-}]$ in the general body fluids was insufficient for precipitation to occur, whereas in osteoid matrix special conditions obtained and precipitation followed. General support for this view followed the observation of calcification deficiencies in subjects with a low intake of these ions and conversely, the phenomenon of calcification in sites other than the skeleton (e.g. blood vessel walls) with dietary excesses in experimental animals, or in clinical conditions involving massive doses of vitamin D or in hyperparathyroidism. The special conditions thought to occur in the osteoid matrix were sought in the alkaline phosphatase positivity of the osteoblasts (thereby raising the local concentration of phosphate) or in some mechanism whereby the local *p*H was raised to alkaline levels (with a consequent reduction in the solubility of the calcium salt). However, it is now apparent that simple consideration of the solubility product of the ions involved is inadequate, that their relevant *activity coefficients* must be considered, and that these are difficult to extrapolate from *in vitro* studies to the microenvironment of the osteoblast; as yet, it has proved impossible to measure them directly. For reviews of these various theories consult Urist (1966); Neuman and Neuman (1958).

There soon followed a change of viewpoint with the stating of the theory of *epitactic nucleation* (Neuman and Neuman 1953, 1958). The latter is based upon the concept of *seeding* or *epitaxy* in which a nucleus is somehow formed, with a crystalline structure which closely mimics that of hydroxyapatite and is effective in causing the initial aggregation of calcium and phosphate ions. Thereafter the hydroxyapatite crystal grows spontaneously by addition from the sufficiently saturated surrounding fluids.

With the wide acceptance of the general aspects of the theory of seeding, many investigators attempted to determine the nature and distribution of the nucleation sites involved. These were variously claimed to be points in the periodic substructure of collagen, the ground substance links between the collagen fibrils, or structural aspects of the proteoglycans (consult Bernard and Pease 1969 for a review).

The latter authors, however (foreshadowed by Bonucci 1967), proposed an interesting role for the osteoblast and claimed that the initial nucleation site was provided by cellular 'buds' or extrusions which appeared to have a polysaccharide core and which, possibly in association with protein, formed an 'image' of the crystal salt. Further aggregation of hydroxyapatite crystals around this initial locus was considered to lead to the formation of spherulitic bone nodules which eventually coalesced to form seams of bone, the association with neighbouring collagen fibres being a secondary phenomenon. On this view the 'cellular seeds'

3.16A Transmission electron micrograph of part of an osteoblast, its surface bearing long filopodia, which project into the surrounding intercellular matrix. Within the latter are clusters of 'matrix vesicles' which provide the initial nucleation sites for the formation of hydroxyapatite crystallites in the early mineralization of bone. The specimen is from the subperiosteal ossifying front of a chick's tibia in tissue culture.

B A high power transmission electron micrograph of a single 'matrix vesicle' from the specimen shown in 3.16A. The vesicle is membrane-bound, has a granular content and centrally, along its long axis, is a dense needle-shaped crystallite of hydroxyapatite. (Specimens kindly prepared and provided by Dr. J. J. Reynolds, Strangeways Laboratory, Cambridge.)

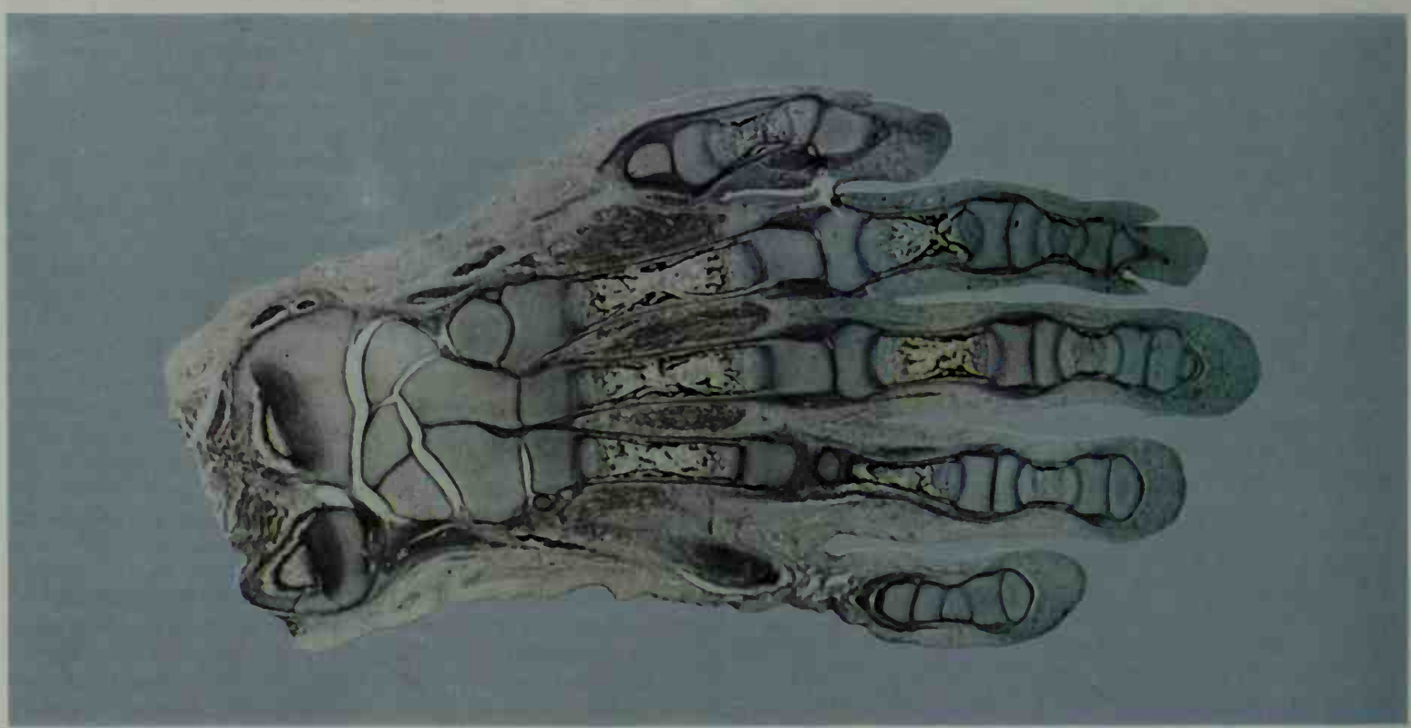
which initiate calcification were specific cell products of the osteoblasts only, and were absent in generalized connective tissues.

Although the theory of epitactic nucleation failed to obtain confirmatory and continuing support, the essential and intimate role of cellular products extruded into the surrounding matrix, as the site of initial mineralization in all vertebrate hard tissues, has aroused intense interest and numerous investigations. The cell products are minute membrane-bound spheres, with a characteristic granular, electron-dense core, and about 0·1 μm in diameter; they have been named *matrix vesicles* (3.16). The vesicles have now been convincingly demonstrated as the loci within which the earliest needle-like hydroxyapatite crystallites appear. They have been identified in calcifying cartilage (Anderson 1967, 1969; Bonucci 1967, 1970), woven bone (Bernard and Pease 1969), dentine (Sisca and Provenza 1972; Katchburian 1973), and subperiosteal bone (Anderson and Reynolds 1973; Reynolds 1976). Thus it appears that matrix vesicles with similar properties can be produced by chondroblasts, odontoblasts and osteoblasts. The mechanism of initiation of calcification, however, remains a matter of some speculation. Being membrane-bound, the vesicles provide a partition between internal and external environments. They have been shown to carry a localized extracellular concentration of alkaline phosphatase, ATPase, inorganic pyrophosphatase and, in some sites, a relatively high concentration of a variety of lipids. It appears a sound working hypothesis that the matrix vesicles provide the necessary enzymes and environment to sufficiently concentrate calcium and phosphate so that crystallization is initiated, and thereafter proceeds spontaneously beyond the confines of the vesicle. Other hypotheses include the proposal that the membrane of the vesicle incorporates an inwardly-directed calcium pump, or alternatively, that there occurs calcium binding by the vesicle lipids.

It may also be noted here that there has been considerable controversy concerning the shape and size of the initial hydroxyapatite crystals. Some authorities hold that they are plate-like in form, whilst others claim a rod-like or needle-like conformation. Most agree that the smallest dimension of the crystals is about 5 nm, but disagreement persists concerning the largest (*c*-axial) length, estimates varying from 20 to 35 nm to values of some three times larger than this. These differing estimates reflect the variety of techniques used: thus polarized light microscopy, transmission electron microscopy, and X-ray diffraction all show that the long crystal axis lies *parallel* to adjacent collagen fibrils. However, X-ray diffraction and dark-field electron microscopy give a comparably short value for the *c*-axial length, whereas transmission electron microscopy of ion-beam thinned sections gives a much larger value (*see* Boyde 1976; Jackson *et al.* 1976).

Calcium Balance, Bone Resorption and the Osteoclast

A central theme of physiology concerns the dependency of many cellular activities upon the relative constancy of their micro-environment (in terms of osmolality, ionic species and concentrations, *p*H, etc.), and many delicately balanced feedback control systems operate to ensure such *homeostasis* (*see* e.g. Reynolds 1974). To this, the circulating level of calcium ions is no exception, and it is preserved despite wide variations in diet, rates of bone growth and remodelling. Involved in the mechanism, but varying quantitatively at different times, are both the labile and stable areas of bone salts (*vide infra*), the interrelated varieties of bone cells—osteoblasts, osteocytes and osteoclasts—and two endocrine secretions, parathyroid hormone and thyrocalcitonin.



Calcium in the blood and tissue fluids is in constant interchange with calcium salts in bone, and it has been shown that approximately one-quarter of the ionic blood calcium is so interchanged each minute. The blood calcium is in equilibrium with the tissue fluid calcium, especially the perivascular fluids which perfuse the Haversian canals and the systems of bone lacunae and canaliculi, by which means vast areas of bone salt are exposed for such physico-chemical exchanges (p. 255). The calcium content of the most recently developed bony tissue is more labile than that of older regions and the process of replacement of mature osteons by new ones, which continues

gradually throughout life, provides a reservoir of readily available calcium ions. It has been proposed that bone salt release is in some way dependent upon active modification of the matrix by neighbouring osteocyte processes (Bélanger 1963), but it is uncertain to what quantitative extent such *active cellular osteolysis* contributes to the rapid continuous turnover of calcium and how much is simply a direct physico-chemical exchange.

A depression of the circulating ionic calcium level results in an increased secretion of parathyroid hormone, which in turn causes a rise in calcium level by a number of distinct mechanisms; firstly, by a direct action on bone, secondly, by increasing renal tubular reabsorption of calcium and thirdly, a minor effect by increasing absorption of calcium from the gut. The action of parathyroid hormone on bone is complex and imperfectly understood. It may have an effect by modifying the surface shells of ions which are associated with the hydroxyapatite crystals, or alternatively, by changing the structure of the collagen-associated mucopolysaccharides of the organic matrix. Finally, it has been proposed that it increases osteocyte activity and bone resorption by osteoclast action (*vide infra*). Conversely, a raised circulating calcium level results in an increased secretion of calcitonin (thyrocalcitonin) by the parafollicular cells of the thyroid gland (p. 1451 and **8**.203) which in turn causes a fall in circulating calcium levels by an ill-understood direct action upon bone. It has been suggested that calcium release from bone is inhibited by stabilization of the collagen of its organic matrix, and possibly by an increased cellular deposition of bone by osteoblasts.

simply degenerating cells released from bone during the erosive process, and otherwise unconnected with the erosion. It has also been proposed that they arise by fusion of osteoblasts which have undergone modulation and assumed a bone-erosive function (Tonna and Cronkite 1962). However, recent studies using parabiotic systems suggest that the osteoblast and osteoclast are derived from *different* sources. The evidence indicates a local connective tissue progenitor cell for the osteoblast, whilst the osteoclast originates from a circulating blood cell—either a monocyte or some other variety of phagocyte (Owen 1976).

Osteoclasts contain a variable number of oval, closely packed nuclei, often 15–20, which closely resemble those of osteoblasts. Their cytoplasm contains many mitochondria, a low concentration of granular endoplasmic reticulum, a small paranuclear Golgi apparatus, and is filled with characteristic vacuoles. Some of the latter show a positive reaction for acid phosphatase, as do the more typical lysosomes which are plentiful in the deeper parts of the cell. Where the cell surface abuts against bone, light microscopists have often identified a finely striated appearance which superficially resembled the brush border seen in many other cells (p. 18). In tissue culture this border is seen to be in a state of constant vigorous movement and to be the site of active pinocytosis. Ultrastructurally, however, the striated appearance is seen to be due to both the character of the cell surface and that of the adjacent bone undergoing resorption. The cell surface does not possess an array of microvilli (as in other brush borders) but is highly infolded with deep extracellular clefts extending between

3.17A A survey photograph of a section of a fetal hand showing cartilaginous models of the carpal bones and various stages of development of primary ossification centres in the metacarpals and phalanges. Note that none of the carpal elements show any evidence of ossification.

When active bone growth is occurring, much remodelling takes place, involving deposition of bone on some surfaces and its removal from others. In mature bone also, continued remodelling of the osteon systems is preceded by bone removal. Surfaces undergoing massive bone resorption (in contrast to the less dramatic ionic interchanges referred to above) are associated with large, often multinucleate cells, with a foamy, lightly basophilic cytoplasm, termed *osteoclasts*. They are often found in close contact with the walls of localized erosions of the bone surface, and such pits are called the *resorption lacunae of Howship*. Their origin and significance has long been debated and many authors have held them to arise by endomitosis of osteoblasts or to be

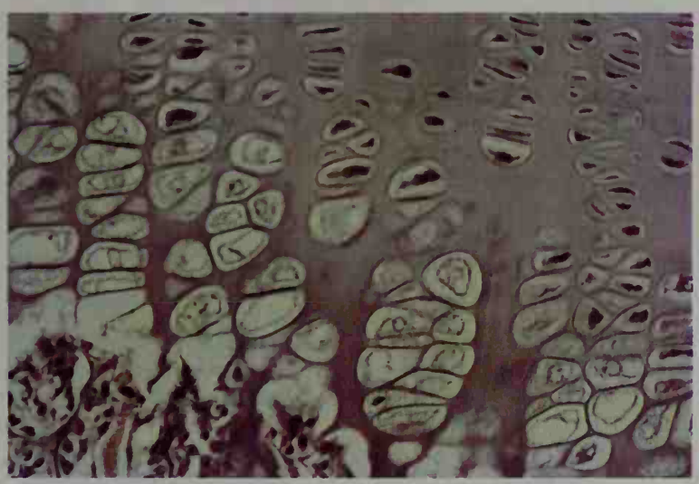
irregular cell processes or lobopodia. The neighbouring bone surface is often partly demineralized and shows a frayed series of collagen strands extending towards the cell (and probably contributing to the striated appearance of the junctional zone). Minute crystals of bone mineral and collagen fragments have been observed deep within the clefts and also in cytoplasmic vesicles assumed to form from the depths of the clefts (Dudley and Spiro 1961; Hancox and Boothroyd 1963).

Whilst such appearances are suggestive of bone removal, the mechanisms of osteoclastic action are still unclear. The presence of lysosomes and a high level of proteolytic enzyme activity in the cytoplasm may be relevant in this context, whilst others have

3.17B Cartilaginous models of carpal bones and the connective tissue junctional zones between them.

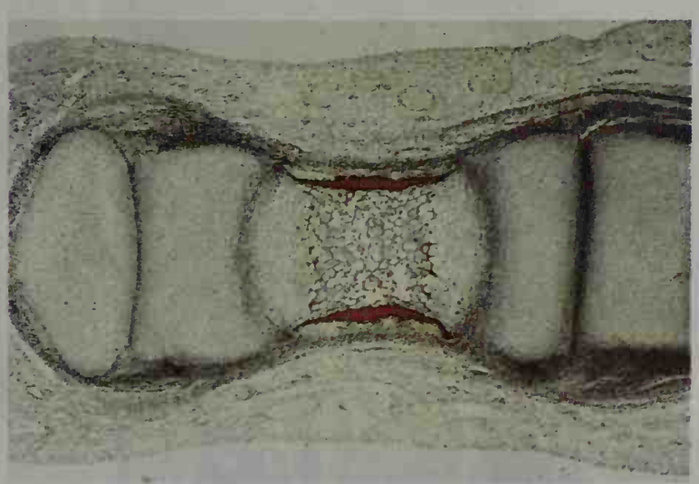
suggested that they secrete chelating agents which form soluble, weakly ionized complexes with bone salt constituents. When the erosive process is complete, the osteoclasts disappear either by degeneration or by reversion to their parent cell type, but objective evidence concerning their fate is lacking.

Intracartilaginous (Endochondral) Ossification



As we have seen, most human bones are preformed in cartilage and each long bone is represented in early fetal life by a rod of hyaline cartilage (**3**.17A) which replaced a rod of condensed mesenchyme, its shape foreshadowing that of the early bone. (The smaller, e.g. carpal, bones are preceded by appropriately shaped cartilaginous 'models'—*see* **3**.17A and B.) Within and upon this cartilaginous model, orderly sequences of changes occur with the appearance of *centres of ossification*. The general significance of primary and secondary (epiphysial) ossification centres and their associated growth plates of cartilage have been discussed elsewhere (p. 241) and the microscopic changes follow here.

The cartilaginous model is surrounded by a highly vascular condensed mesenchyme or perichondrium, similar in every way to that which precedes and surrounds intramembranous ossification centres (p. 260), and again, its deeper layers contain osteoprogenitor cells.



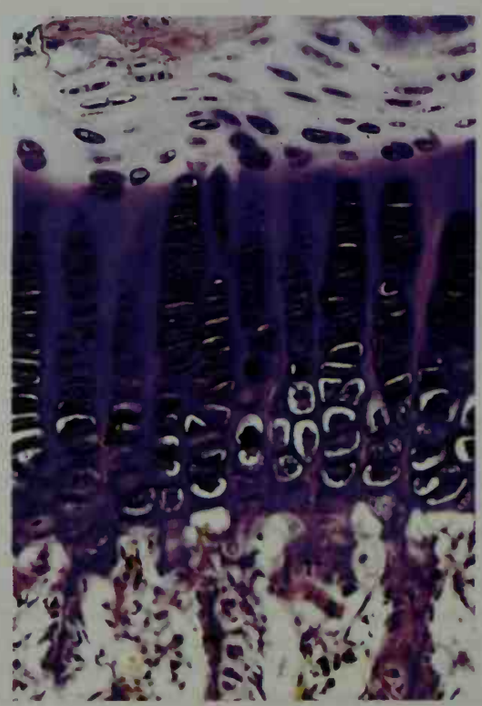
The first indication of the appearance of a primary ossification centre involves the cartilage cells deeply placed in the centre of the primitive shaft (**3**.18, 19). These become greatly enlarged, their cytoplasm becomes vacuolated and develops accumulations of glycogen, whilst the intervening matrix becomes reduced to thin and often perforated partitions. As the process of lacunar enlargement continues, the enlarging cells, possibly due to auto-intoxication by chondrolysing matrix products, undergo progressive degenerative changes and ultimately die, leaving their enlarged and sometimes confluent lacunae as the *primary areolae*. With the death of the chondrocytes the thin walls of the primary areolae become calcified. Simultaneously, the subperichondrial cells transform to osteoblasts and lay down a peripheral layer of fenestrated young bone. This '*periosteal collar*' of bone is formed by the same sequence of cell changes described under intramembranous ossification (p. 260) and is at first a thin-walled tube enclosing the central region of the shaft. However, it progressively increases in girth and the process continues towards the extremities of the shaft (*vide infra*), whilst a series of further important changes are occurring deep within the cartilaginous model. (It should be noted that the calcifying cartilaginous areolar walls and the extracellular ground-substance of the periosteal collar are both sites containing *matrix vesicles*—*see* p. 261.)

Near the shaft centre where the periosteal collar overlies the calcified walls of the primary areolae, the collar is invaded by sprouts from the deeper layers of the periosteum. These sprouts consist of vascular channels and their accompanying cells which continually divide and transform into osteoblasts and osteoclasts. The latter excavate passages through the newly formed bone to pass into the underlying calcified cartilage where they continue to erode some of the walls of the primary areolae, with a fusion of the original cavities to form an irregular system of larger, intercommunicating *secondary areolae* or *medullary spaces*. These spaces become filled with *embryonic bone marrow* (vascular mesenchyme, osteoblasts and osteoclasts), and their delicate residual walls of calcified cartilage become covered by a layer of osteoblasts. The latter lay down osteoid which soon transforms to patches of bony tissue which coalesce to form a complete lining for the spaces, and for a period, the process continues with the addition of further layers of bone, the entrapping of young osteocytes within lacunae and a narrowing of the vascular spaces. With continued deposition of subperiosteal bone, however, the formation of bone on the centrally placed areolar walls ceases, and a process of erosion begins with removal of these early spicules of bone and enlargement and confluence of the marrow spaces until a primitive marrow cavity forms. While these changes are proceeding in the centre of the shaft, the adjoining cartilaginous regions undergo a similar series of changes (**3**.18, 19). Since the changes are most advanced centrally and the ends of the bone are still cartilaginous, the various intervening zones show an orderly progression of change when the young bone is examined in longitudinal section.

The cartilaginous extremity (where an epiphysis usually forms) continues to grow in pace with the rest of the bone by appositional and interstitial mechanisms (p. 267). Where the extremity continues into the cartilaginous shaft, however, a particularly

3.18 A section showing the transformation of cartilage cells and their lacunae as the ossifying front of an early primary centre of ossification is approached (below). Note the cell hypertrophy, lacunar enlargement with matrix partition reduction, and increased density of the partitions following calcification.

3.19 A longitudinal section of a phalanx (from the hand in **3**.17A) showing an early primary ossification centre. The cartilage cells in the shaft centre have hypertrophied and this region is surrounded by a delicate tube or collar of subperiosteal bone (red).



3.20 A longitudinal section of the proximal half of a fetal metacarpal bone (from **3**.17A) at a more advanced stage than the phalanx in **3**.19. The periosteal collar of woven bone is thicker, contains radially disposed vascular spaces, and vascular invasion of the shaft centre has occurred and is proceeding towards its extremities. See text for a detailed description.

rapid and geometrically organized region of cartilage growth becomes prominent, i.e. region of the future *growth plate* between epiphysis and diaphysis (*see* e.g. Siffert 1956; Rang 1969). This region grows both transversely and longitudinally (**3**.18, 20, 21, 22). Transverse or latitudinal growth follows the occasional mitoses of cells in a plane transverse to the long axis of the bone and also by appositional growth from cells derived from the encircling *perichondrial collar* (or *ring*) at this level. By this means the diameter of the future growth plate region increases in concert with the expanding shaft and adjacent future epiphysis. More frequent divisions in the long axis of the bone soon result in the formation of numerous longitudinal columns (palisades) of disc-shaped or wedge-shaped chondrocytes, each in its flattened lacuna. This process of proliferation and longitudinal cell column formation occupies the so-called *zone of cartilage growth* and it is the continued interstitial growth of this zone which is the essential mechanism whereby the whole bone increases in length. As a cell column is traced towards the shaft centre, its component cells are increasing in maturity and their characteristics change. They gradually increase in size and accumulate glycogen in their cytoplasm which also begins to show positive histochemical reactions for oxidative enzymes. The younger chondrocytes of the columns possess a few surface projections which pass into reciprocal recesses in the lacunar walls, but as the cells enlarge and enter the *zone of cartilage transformation*, the number of surface projections increases greatly—possibly associated with removal of the surrounding cartilage matrix and a progressive enlargement of the lacunae across the zone. The largest cells finally withdraw their surface projections, expand to fill their large lacunae and then soon show degenerative changes leading to cell death. As this occurs, the walls of the empty lacunae (now arranged as a series of transverse and longitudinal partitions), become impregnated with hydroxyapatite crystals (sometimes called the zone of calcified cartilage). These calcified partitions now enter the *zone of bone formation* where they are invaded by vascular mesenchyme and its associated osteoblasts and osteoclasts from the adjacent primary ossification centre (**3**.23). The partitions, especially the transverse ones, are now partially eroded, and then on the remaining surfaces of the thinning longitudinal partitions occurs the same processes of osteoid deposition, bone formation, and osteocyte trapping, etc. as described above. (It should be appreciated that the calcifying walls of the enlarging lacunae and the osteoid matrix and sites of bone deposition, have all been shown to exhibit populations of *matrix vesicles*—(*see* Thyberg and Friberg 1970; Anderson and Reynolds 1973; and p. 261.) The erosion (chondrolysis) of the calcified partitions has been variously ascribed to osteoclast (chondroclast) action or to the possible chondrolytic action of the endothelium of the terminal loops of the vascular sinusoids which come to occupy each incomplete, columnar trabecular framework (**3**.22), and *see* Irving (1964). Opinion is divided whether these loops have an intact endothelium or whether they are temporarily fenestrated and the site of a microrupture (Brookes and Landon 1963; Trueta and Morgan 1960; Anderson and Parker 1966). Further, it has been claimed that longitudinal and transverse partitions of matrix are different, both in their structure and chondrolytic mechanisms. Transverse ones are lightly calcified, with sparse collagen, distinctive proteoglycans, and are susceptible to lysosome action, whilst the more resistant longitudinal ones only succumb to osteoclast action (Anderson 1962; Dingle 1962).

B

3.21A and B Low and intermediate magnifications of sections through the cartilaginous growth plate between the epiphysis and metaphysis (below) at the proximal end of a human tibia. Note the transition from hyaline cartilage, through zones of cell multiplication, hypertrophy, column formation, matrix calcification, and partial chondrolysis to the ossifying front. Compare with **3**.22 and consult text for further details.

3.22 A scheme of the main features of an active growth cartilage and the adjacent metaphysis and epiphysis. The different views concerning the mechanism of chondrolysis described in the text are indicated.

3.23A A section through the metaphysis of a fetal bone stained with haematoxylin and eosin showing developing spicules of early bone. Each spicule contains a deeply stained basophilic core of calcified cartilage, which is covered on both aspects by a lightly stained eosinophilic layer of young bone along which are ranged rows of active osteoblasts.

3.23B A transverse section through an epiphysis of a long bone at a more advanced stage of ossification. Note the gradation of cartilage cell lacunae (left) as the ossifying front is approached. The bony trabeculae (light pink) contain dark patches of basophilic calcified cartilage and the inter-trabecular spaces are filled with red bone marrow.

With the continuing division of cells in the zone of growth which adds to the epiphysial ends of the cell columns, the orderly sequence of changes proceeds away from the shaft centre, and the bone grows in length. Simultaneously, continued internal erosion and remodelling combines with further subperiosteal bone deposition, which continues towards the bone ends. By these means the bone grows also in girth and the medullary cavity enlarges both transversely and towards the extremities of the bone.

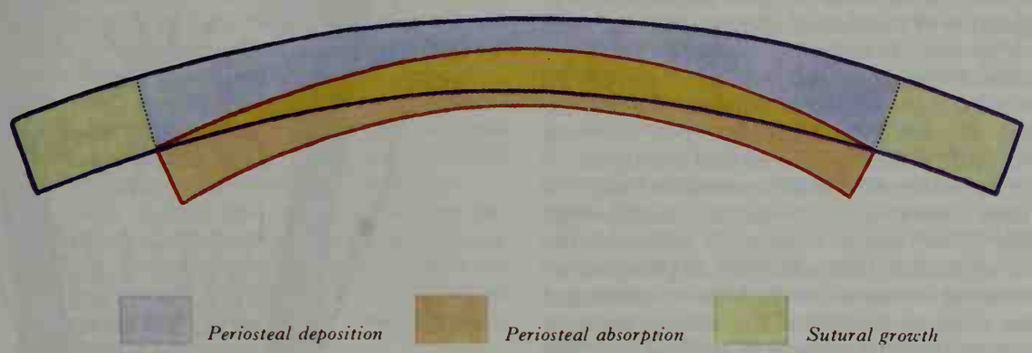
Growth continues in this manner for many months or years, depending upon the bone in question (p. 241), but eventually one or more secondary centres of ossification usually appears in the cartilaginous extremities. Such epiphysial centres (or ossifying bone ends without epiphyses) are not at first characterized by the formation of cell columns. Instead, scattered isogenous groups of cells hypertrophy and die, with matrix calcification and subsequent invasion of this matrix by vascular mesenchyme (sometimes of cartilage canal origin—p. 248). Many irregular bone spicules are formed, with intervening embryonic marrow spaces, in the same manner as above. However, as the epiphysis enlarges, its cartilaginous periphery forms a roughly spherical zone of proliferation and the whole structure gradually assumes a radial organization, with cell column formation and zones of hypertrophy, calcification, erosion and ossification to be found at increasing depths from any point on the surface (**3**.22). In a sense, therefore, the early bony epiphysis is surrounded by a spherical growth cartilage. Soon, however, the growth plate related to the metaphysis becomes a particularly prominent part of this sphere and in this region the enlarging cell columns become directed exclusively towards the metaphysial ossification front, whereas elsewhere in the sphere they are directed towards the underlying epiphysial ossification (Payton 1934; Rang 1969).

When the whole bone is reaching maturity, epiphysial and metaphysial ossification gradually encroach upon this growth plate and final bony fusion occurs with a cessation of growth. In contrast to the numerous investigations on the active growth plate, the histological changes during fusion have attracted much less interest (Rang 1969). However, studies in the rat (Becks *et al.* 1948) revealed the following sequence. After cessation of growth the cartilaginous plate becomes quiescent and for a period thins very gradually. The proliferation, palisading and hypertrophy of chondrocytes ceases and for a while they form very short, irregular cone-shaped masses. Patchy calcification of this cartilage is then accompanied by absorption of the patches and some of the adjacent metaphysial bone. These erosion channels are invaded by vascular mesenchyme and eventually some of the vascular sprouts pass completely through the thin plate of cartilage and at these points metaphysial and epiphysial vessels unite. Final bony fusion occurs by ossification in the walls of these communicating channels, which then spread to involve the intervening zones. The bone formed is particularly dense and is easily recognized on radiographs as a so-called *epiphysial line* (the latter term is also used to indicate the level of the perichondrial ring which surrounds the growth cartilage of an immature bone, or the surface line of junction between epiphysis and metaphysis in a mature bone). More recently, there have appeared some detailed analyses of epiphysio-diaphysial union in the dog and man: for the histological stages, and an extended bibliography consult Haines (1975). The latter author points out that as union approaches new cartilage is added to the epiphysial aspect of the cartilaginous growth plate which initially retains its characteristic histological zoning. Then follows the formation of epiphysial and diaphysial bony plates on the two aspects of the cartilaginous plate: the bony plates being partly formed by calcifying cartilage (termed by the author *metaplastic* bone) and associated patches of lamellar bone. The preliminary union follows the coalescence of one or more columns of mineralized cartilage, accompanied by confluence of the epiphysial and diaphysial marrow spaces. In the smaller earlier-uniting epiphyses there is only one, usually eccentric, initial area of fusion, with thinning of the remaining cartilaginous plate. Subsequently the original site of fusion, now consisting of mineralized cartilage (metaplastic bone), with lamellar bone on its surface and containing marrow, are gradually eroded and replaced by new bone and marrow which extends until the whole cartilaginous plate is replaced, union is complete and no *epiphysial 'scars'* persist. In larger, later-uniting epiphyses, similar processes occur but involve multiple perforations in the growth plate, and in this case *islands* of epiphysial bone often persist as epiphysial scars. (It may also be noted that the special histological features of the so-called *metaplastic bone* that occurs underlying articular cartilage, and at the attachments of tendons, ligaments, and other dense connective tissues, have been reviewed by Haines and Mohuiddin 1968.)

When the cartilaginous surface of the epiphysis is to form the articulating surface of a synovial joint it remains unossified and presents the same sequence of cartilaginous zones as a typical growth plate, but these zones persist throughout life.

Further Development and Remodelling of Bone

In all the situations so far studied, the bone first laid down is spongy in texture and contains a continuous labyrinth of large vascular spaces; the lacunae are irregularly scattered, there is no lamellation and the collagen fibre bundles in the matrix are fairly randomly arranged and form a network. This type of bone is usually termed *woven-fibred*. It is best seen in young fetal bones



but occurs in some situations in the adult (e.g. lining the tooth sockets) and is seen during the repair of fractures. Later, roughly concentric tracts of non-lamellated, parallel-fibred bone, termed *atypical Haversian systems* or *primary osteons* are deposited on the walls of the vascular spaces, which are thereby narrowed and often subdivided by osseous bridges. The collagen fibre bundles in the matrix are arranged in parallel longitudinally orientated spirals. No erosion precedes the deposition of primary osteons, and consequently no cement lines intervene between them and the surrounding woven bone. The circumferential bone which is deposited on both periosteal and endosteal surfaces, is generally composed of parallel-fibred lamelle with the fibres arranged longitudinally and circumferentially in successive lamellae, and where the latter are thin the lamellation is indistinct. Circumferential bone may, however, be non-lamellated or woven-fibred, particularly in some species, and the term *surface bone* is often preferable in these circumstances.

As the bone matures, *typical Haversian systems* (*secondary osteons*) gradually replace the primary osteons and woven-fibred bone. Their formation is always preceded by erosion, usually eccentric, of the walls of the vascular channels, which are composed of primary osteons and woven bone. This is followed by concentric deposition of lamellae of parallel-fibred bone on the walls of the *resorption cavity* and around the vascular channels which are thereby narrowed. A cement line is always deposited at such a site of reversal from erosion to deposition. The formation of secondary osteons does not end with the cessation of growth but continues at varying rates throughout life, and some of the first deposited secondary osteons are eventually involved in the erosive process. The remnants of woven bone, primary osteons, circumferential lamellae and eventually secondary osteons constitute the *interstitial bone* which occupies the crevices between the later formed osteons. (For some quantitative histological data on the ageing of human bone *see* Courpron *et al.* 1973, and for morphometric analyses of ageing effects of osteon remodelling in the human tibia *see* Ortner 1975.)

Implicit throughout the foregoing account of bone development is the fundamental feature of bone growth, that it proceeds exclusively by *appositional mechanisms* in which new layers of bony tissue are simply added sequentially to pre-existing surfaces; and, during the process, bone cells become immovably trapped in lacunae within its substance. Such cells, once within a lacuna, do not divide and, further, the rigidity which follows mineralization of the bone matrix prevents any expansion of the tissue from within. Thus interstitial growth mechanisms, which are so characteristic of many other tissues, including cartilage, are entirely absent in bone. They are, however, of supreme importance in the growth cartilages discussed above.

All remodelling of bone, therefore, whether involving major readjustments of the overall shape of a bone, or the less obvious internal remodelling which occurs throughout life, is dependent upon a delicate and geometrically ordered balance between bone deposition on some surfaces and bone removal from others. The experiments which demonstrated these main features of bone growth have, with increasing refinement, spanned the last two centuries. The earlier anatomists used metal markers in the form of wires encircling the shaft, or pellets embedded in the shaft, of growing bones. The pioneering observation, that when growing pigs were fed with the root of the madder plant, the bone newly formed during the period of feeding was identifiably pink, led to an elegant series of experiments on bone growth by alternating madder feeding with madder-free periods (Brash 1934). More recently the intraperitoneal injection of a solution of alizarin red has been used with greater precision for the same purpose (Hoyte 1960). These studies amply confirmed the accretionary nature of bone growth, and modern techniques have simply increased the resolution of the methods, enabling quantitative histological studies to be made. The latter include the administration of bone-seeking isotopes followed by autoradiography of sections (Leblond 1950); the exhibition of doses of a tetracycline at intervals followed by fluorescence microscopy and finally, historadiography of sections (Amprino and Engström 1952; Amprino 1968).

Relatively gross remodelling, with changes in the general shape of the whole, affects all bones during their growth, but particularly well studied examples are the bones of the skull cap and long bones with expanded extremities.

3.24 A scheme illustrating the gross patterns of growth and remodelling of a bone of the cranial vault, in section. Note the changes in surface area, thickness and curvature. See text for further details.

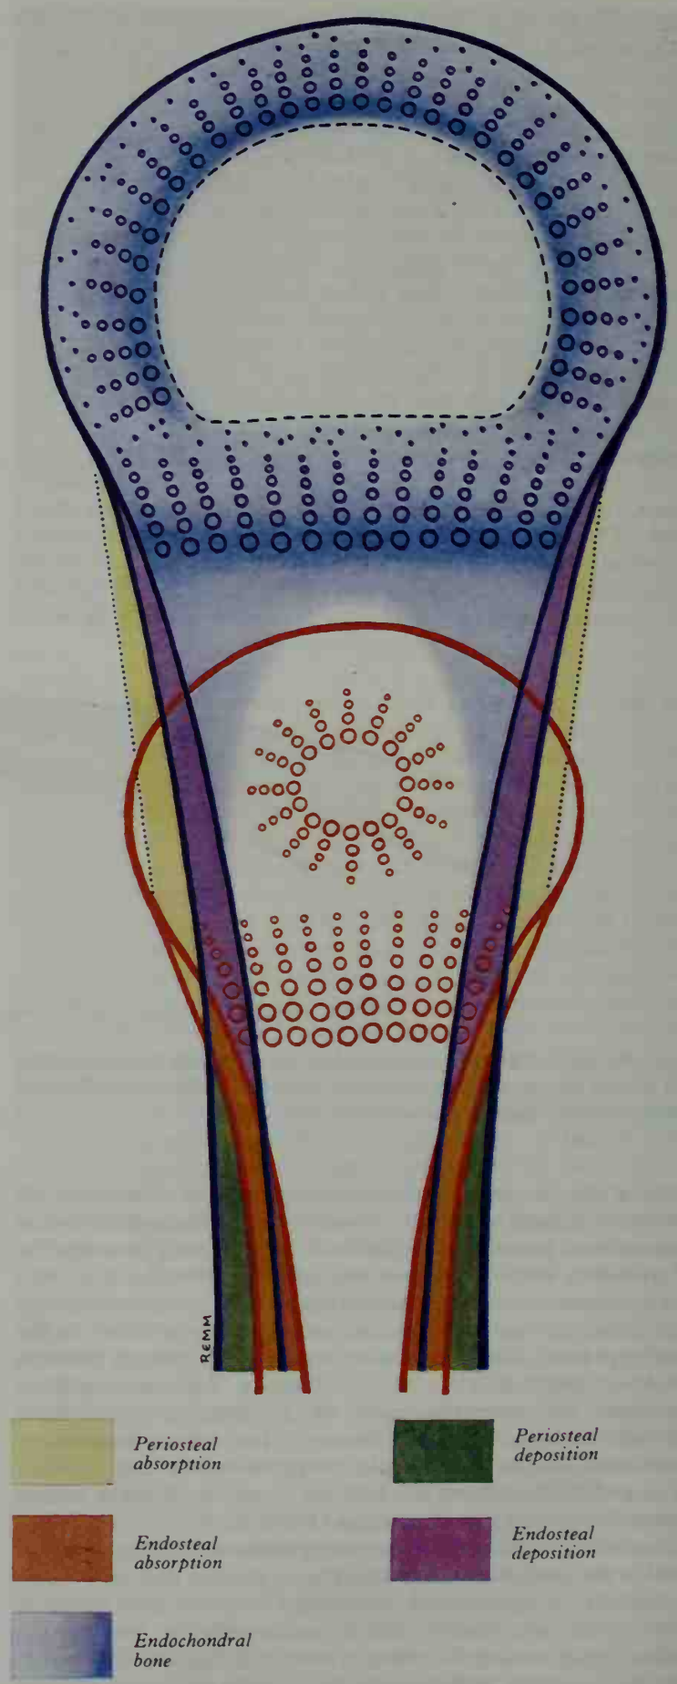
A bone such as the parietal not only increases in thickness and surface area during growth, but its curvature also decreases (**3**.24). Whilst bone growth continues at its margins in association with interstitial growth of periosteal cells at the sutures, periosteal bone is also added on its outer surface and eroded internally. The latter processes, however, do not occur uniformly over the whole bone, but at a rate which increases with the radial distance from the bone centre (**3**.24).

As we have seen, increase in length of a long bone is due mainly to extension of the endochondral ossification process into the calcified zone of adjacent growth cartilages which are continually replaced by longitudinal interstitial growth of their proliferative zones, together with minor additions due to radial growth of the epiphyses. In company with these length increases there occur diametric increases of the growth cartilages and girth increments in the shaft. The latter occur in general by continuing subperiosteal deposition and endosteal erosion of bone. In many bones, however, such processes occur eccentrically, at different rates or even being reversed, at different points on the circumference. By such means a bone initially tubular may be transformed into one which is roughly triangular in cross-section such as the tibia. Meanwhile, the delicate waisted contours of the metaphysis are preserved by a continuous process of periosteal erosion and endosteal deposition (*see* **3**.25).

The tetracycline marker technique has emphasized the dynamic nature of even mature compact bone where at any time in life a single cross-section includes mature relatively quiescent osteons, recently formed osteons and osteons in process of formation, or of resorption. The rate of lamellar bone formation by apposition varies but is on average about 1–2 μm per day, and it has been shown that a resorption canal takes 1–3 months to form

and a new osteon a similar period to regrow (Lee 1964). Such internal remodelling provides a continuous pool of young osteons with their labile calcium reserves (p. 261) and also provides a flexibility of bone architecture which may change in response to altered patterns of mechanical stress (p. 233). Whilst the morphogenetic control systems responsible for overall bone shape are not understood, interesting suggestions have been put forward concerning its responsiveness to altered conditions of stress. In common with many other crystalline substances, bone is piezo-electric; that is, it generates small electric currents when deformed, and the distribution of the potential difference variations, reflects the form of the distortion. It has been proposed that such currents could in some way polarize the cells responsible for osteolysis and bone deposition, so that the bone structure is reorganized in a manner which resists the predominating mechanical stresses (Bassett 1965; Cochran *et al.* 1968). Much work is now in progress concerning the sources, intensities and distributions of the bioelectric phenomena which accompany stressed connective tissues in general, and whilst further results are awaited with great interest, it would be premature to assume that firm causal relationships between such events and the morphogenesis of the tissues have yet been established.

Metabolic and Endocrine Effects on Bone



The role of the bone salts, parathyroid hormone and calcitonin in the homeostatic regulation of circulating calcium levels has been considered elsewhere (p. 261). In addition to these, to ensure the normal development and maintenance of bone there must be an adequate dietary intake and absorption of calcium, phosphorus, vitamins A, C and D and a balanced interplay between somatotrophic hormone, thyroxin, oestrogens and androgens.

Prolonged dietary deficiency of calcium eventually leads to a generalized loss of bone mineral or *osteoporosis*, and consequently an increased fragility of the bones. Vitamin D influences the intestinal absorption of calcium (and indirectly of phosphorus) and therefore circulating calcium levels. Again, prolonged vitamin D deficiency (with or without a low dietary intake of calcium) in the adult, leads to *osteomalacia* or *adult rickets*. The bones are poorly mineralized and often contain large areas of soft, deformable, uncalcified osteoid. Similar deficiencies, before growth has ceased, lead to classical *rickets* with serious disturbances of the growth cartilages and the process of ossification. The regular columnar organization of the growth plate is partially lost, there is a failure of calcification of the cartilage but the chondrocytes continue to proliferate and the cartilaginous plate becomes much thicker and less regular than in the normal bone. In the metaphysial region the cartilage is partially eroded, and osteoblasts secrete thick layers of osteoid which fail to ossify on the uncalcified or poorly calcified cartilage trabeculae. If the condition persists, weight-bearing produces gross deformity of such softened bones. (For a review of the role of vitamin D in bone metabolism, bone remodelling, and calcium homeostasis, with an extensive bibliography, *see* Reynolds 1974.)

Deficiency of vitamin C precipitates *scurvy*, with widespread changes in all the connective tissues of the body, and these are particularly noticeable in the growth cartilages and metaphyses of long bones. Vitamin C appears to be essential for the adequate synthesis of both collagen and mucopolysaccharides of the matrix of connective tissues including bone. The growth plate thins, bone formation almost ceases and metaphysial trabeculae and cortical bone are both excessively narrow, with fragility and delayed healing of fractures.

An adequate intake of vitamin A is also necessary for normal bone growth and is essential for the balanced activities of bone deposition and removal. Deficiency leads to growth retardation with a failure of internal erosion and remodelling, particularly of the skull base. Foramina become narrowed and this may proceed to a pressure degeneration of their contained nerves, while the cranial cavity and spinal canal may fail to expand in step with the central nervous system, leading to gross impairment of nervous function. Conversely, excessive vitamin A intake leads to a more rapid vascular erosion of the growth cartilages, which become thin or totally lost with a complete cessation of growth.

Balanced endocrine activities are essential to normal bone maturation, and endocrine disturbances may have profound effects. In addition to its normal role in calcium metabolism, parathyroid hormone in excess leads to osteocyte and osteoclast stimulation with widespread osteolysis and bone erosion leaving a demineralized framework—a condition known as *osteitis fibrosa*.

3.25 A scheme of the patterns of remodelling which occur during the growth of a long bone. Note the changing shape of the epiphysial ossification centre, the altered organization of the cartilaginous growth plates and the varying zones of bone deposition and absorption. See text for further details.

The eosinophil cells of the anterior part of the hypophysis cerebri secrete *growth hormone* and this is necessary for the continuance of normal proliferative interstitial growth of the growth cartilages and hence normal increase in stature. The mechanism whereby normal growth terminates is imperfectly understood but may result from a fall in hormone production or a lowered sensitivity of the cartilage cells to hormone action. Experimental hypophysectomy or, clinically, a reduction of growth hormone levels in the young, is accompanied by quiescence and thinning of the growth plates resulting in *pituitary dwarfism*. Conversely, continued hypersecretion of growth hormone in the same age group leads to *giantism*, but in the mature individual it results in an overgrowth and thickening of bones by subperiosteal deposition. Characteristically, the mandible and the skeleton of the hands and feet are particularly affected in this condition, known as *acromegaly*.

Whilst continued *growth* of the bones through the agency of their cartilages is dependent upon circulating growth hormone levels, effective remodelling and the assumption of a mature shape depends upon the concomitant action of thyroxin. Finally, the *rate* of growth and overall state of *maturity* is intimately related to the endocrine activities of the ovaries, testes and adrenal glands. High oestrogen levels are associated with an increased deposition of endosteal and trabecular bone, whereas the osteoporosis often seen in women of advanced years may reflect reduced ovarian function. The maturation level and growth rate which vary from phases of rapid change to relatively quiescent periods (p. 243) reflect the circulating levels of adrenal and testicular androgens. With hypogonadism, maturation including growth plate obliteration occurs late and the limbs become excessively long, whereas in hypergonadism, premature synostosis between epiphyses and diaphyses occurs with consequently a diminished stature.

Currently there is much interest and investigation into the natural history and pathology of growth cartilages and a large literature has accumulated. An exhaustive review of this field lies outside the scope of the present work, but several excellent accounts have appeared (Siffert 1956; Rang 1969; Serafini-Fracassini and Smith 1974).

General Features of Bones

The different bones of the skeleton vary amongst themselves not only in their *primary* or basic shape but also in their lesser details of surface structure, the *secondary* markings, which develop for the most part in postnatal life. Nevertheless, certain features, such as elevations and depressions, smooth areas and roughened ridges, appear in many different bones. It is convenient to use a repertoire of common terms for these common features; it is even more important to recognize that the same form of marking or the same surface texture usually has the same functional significance wherever it is encountered. For example, most bones display *articular surfaces* where they form joints with their neighbours; if small, these areas are termed *facets*, or occasionally *foveae*. Knuckle-shaped articular surfaces are called *condyles*, and a *trochlea* is a joint surface grooved like a pulley. Such areas are naturally adapted in shape to the characteristic movements of the joints in which they serve, and they are relatively smooth, though it must be remembered that in life they are covered by articular cartilages and that it is these which are primarily responsible for the smooth surfaces of synovial joints. The texture of articular surfaces is in fact due to another feature, frequently overlooked; they appear almost devoid of the small vascular foramina typical of many bone surfaces, articular cartilage itself being a poorly vascularized tissue. This does not, however, imply that osseous articular surfaces are completely impermeable, although the zone of cartilage contiguous with the subjacent bone is usually calcified, which makes any substantial interchange less probable (as described elsewhere, the nutritive avenue to articular cartilage may be largely via synovial fluid). It should be noted here, however, that with the advent of the scanning electron microscope it is now clear that *all* bony surfaces, including those that appear smooth when examined with the naked eye or hand lens, possess large numbers of minute foramina. What proportion of these are occupied by vascular, nervous, or collagenous elements, is uncertain. (For surface architecture consult **3**.ID and **3**.150C.)

Substantial tendons (e.g. adductor magnus, subscapularis) are attached to bony facets which, though lacking the smooth planes or curves of articular surfaces, are similar to them in texture, and for the same reason, tendons being poorly vascularized. Such tendon facets are sometimes slightly depressed (the adductor tubercle of the femur is quite often replaced by a small pit), or they surmount considerable elevations, for example, the tubercles (tuberosities) of the humerus.

Depressions and elevations, varying in size and shape, frequently interrupt the otherwise featureless surfaces of bones. A depression is termed a *fossa*, and some articular surfaces are in fact fossae (cf. the temporomandibular joint). Elongated depressions are called grooves or *sulci* (e.g. the bicipital sulcus of the humerus); a notch-like depression is an *incisura*, and an actual gap is termed a *hiatus*. A projection of considerable size is usually referred to as a *process*; if particularly elongated, slender or pointed it may be termed a *spine*. A curved or hook-like process is named a *hamulus* or *cornu* (cf. the pterygoid hamuli of the sphenoid bone and the cornua of the hyoid bone). Any localized and roughly rounded projection is styled a *tuberosity* or *tubercle*, occasionally a *trochanter*. Elongated elevations are dubbed *crests*, or *lines* if less developed features; crests are usually wider and therefore may present boundary edges, or *lips*; however, these terms are not carefully differentiated, and one of the most substantial of crests is called the *linea aspera* (cf. femur). An *epicondyle* is a relatively small projection adjacent to a condyle and usually concerned with the attachment of collateral ligaments of the joint in which the condyle is involved (cf. humerus). The terms protuberance, prominence, eminence and torus also have a more limited application to certain bony projections. The expanded proximal ends of many elongated bones are frequently spoken of as the '*head*' or *caput* (cf. humerus, femur, radius, etc.).

A hole through bone is a *foramen*; *foramina* are called *canals* when considerable in length. Larger holes are sometimes called *apertures*. Clefts in or between bones are usually known as *fissures*. A *lamina* is a thin plate of bone; larger laminae may be called *squamae* (e.g. the squama of the temporal bone).

Large areas on many bones are comparatively featureless, and indeed are often smoother to the touch than articular surfaces. They differ from the latter in being liberally speckled with small vascular foramina. Such a surface texture is observed wherever muscle tissue is directly attached, the foramina transmitting numerous small blood vessels which pass uninterruptedly from bone to muscle and perhaps vice versa. The same obtains in areas covered only by periosteum, but the vessels are much less numerous.

Tendons, as already noted, are usually associated at their point of attachment with some degree of roughening of the otherwise smooth bone surface. In the same way, wherever any considerable aggregation of collagen in a muscle reaches bone, the surface displays irregularities corresponding closely in form and extent to the pattern of such 'tendinous fibres', as they are often called. Such markings are almost always elevated to some degree from the general level of the surface, as if ossification were proceeding into the collagen bundles from the periosteal bone. It is, however, not yet certain what is the precise mechanism of production of such secondary markings. The evidence suggests that their prominence may be associated with the power of the muscles involved, and they certainly increase with advancing years, as if the pull of muscles, and indeed ligaments, may exercise an accumulative effect. However this may be, the surface markings on bone faithfully delineate the shape of attached connective tissue structures, whether it be obvious tendon, intramuscular tendon or septum, or aponeurosis, or merely tendinous fibres scattered through an otherwise direct muscular attachment. Hence the markings may be facets, ridges, nodules, roughened areas, or complex mixtures of these. Wherever they occur, they afford most accurate data of the junction of bone with muscle, tendon, ligament or articular capsule. Numerous examples of this will be encountered when the structures are individually considered.

It is important to add that even in a so-called fleshy or direct attachment of muscle to bone, the actual muscle fibres are not themselves adherent to periosteum or bone. The precise mechanism by which tension is transmitted from contracting muscle fibres to bone is, in some details, still uncertain, but it must be effected somehow through the connective tissue which pervades all muscles in the form of perimysium and endomysium. It is not clear how muscle fibres are attached, if indeed they are, to such collagenous elements in their structure; but it is certain that whether the attachment to bone is by tendon or is direct, the actual agent of attachment is connective tissue. (*See*, however, comments on the *myotendinal junction*—p. 515.) The difference between these two extreme forms of attachment—a considerable spectrum of intermediate admixtures exists—is in the amount of collagen fibres intermediating between muscle and bone, and their arrangement. Where collagen is concentrated in visible masses, visible markings appear on the bone surface at localized sites. In contrast, the multitude of microscopic connective tissue ties of a direct attachment of muscle, necessarily over a larger area, do not mark it appreciably. Hence the bone here appears smooth —at least, to unaided vision and to touch. (*See* **3**.1D for magnified views of osseous surfaces.)

THE AXIAL SKELETON

Introduction

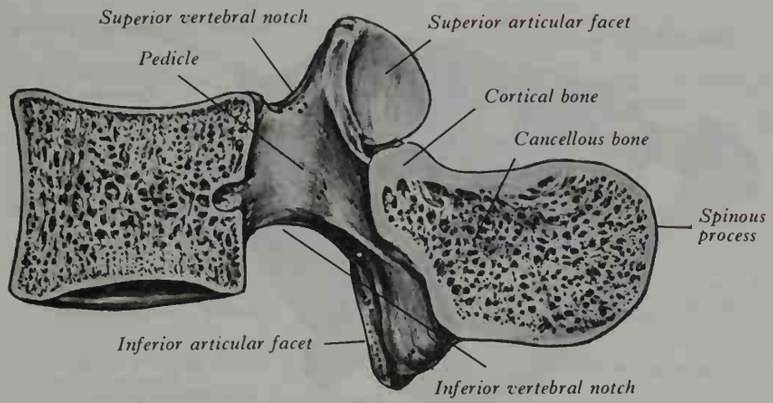
Division of the skeleton into axial and appendicular sections is not a mere arbitrary convenience, for the axial structures, the cranium and vertebral column and their associates, the ribs and sternum, constitute the primary skeleton; the skeletal elements of the appendages, in fins, limbs, or wings were subsequent though early additions, becoming of increasing importance with the elaboration of vertebrate locomotor habits. An axial endoskeleton, first as a notochord and then a vertebral column, provides the basic distinguishing feature of the phylum *Chordata* and its subphylum, the *Vertebrata*, to which, of course, mankind belong. A stiff but flexible axis, in bilaterally symmetrical animals with an early tendency to elongate shape, is an obvious locomotor advantage. It prevents telescoping of the body during the waves of contraction which pass through successive segmental muscles to produce the sinuous side-to-side flapping movements, especially in the tail, which are the basic mode of locomotion in aquatic vertebrates. A chain of ossified elements, flexibly connected by intervening discs of deformable substance, soon replaced the notochord by actually growing around it. It is due to this that notochordal vestiges occur in the vertebrae of many fish, amphibians and reptiles, and in the central part of the intervertebral discs of mammals. This replacement is repeated in every vertebrate embryo. The vertebral elements which grow round the notochord to replace it are complex and variable in pattern in earlier vertebrates, but in the reptiles onwards the most important is the *centrum*, which forms most of the vertebral body, ventral to the spinal cord (or spinal medulla). The plan of a typical vertebra also includes a *neural arch*, encircling the spinal cord, which fuses ventrally with the back of the centrum. The arch usually bears a midline dorsal projection, a *spinous process* or spine, and paired lateral *transverse processes* near the neurocentral junctions. This enclosure of the spinal cord isolates it from the activities of neighbouring axial musculature and affords protection from external forces.

The centrum and each half of the neural arch ossify from separate centres; and when these extend through their cartilaginous precursors to meet and fuse, the dorsolateral parts of the *body* of the fully developed vertebra are in fact formed from the ventral extremities of the neural arch. The terms centrum and body are therefore not synonymous, nor is the *vertebral arch* of a fully ossified vertebra exactly equal to a neural arch. A centrum is somewhat less than a vertebral body, a neural somewhat more than a vertebral arch (p. 282).

The segmental muscles which flex the vertebral axis are only in part attached directly to vertebrae; in the connective tissue septa (*myocommata*) between adjacent myotomes develop ribs as levers for such attachments. Such costal struts evolved in a dorsal position in the axial musculature and extended ventrally into the body wall in early vertebrates, and in fish ventral ribs also appeared, which in the tail enclosed the caudal vessels. It is generally agreed that the ribs of land tetrapods correspond to the dorsal series in fish (Romer 1970).

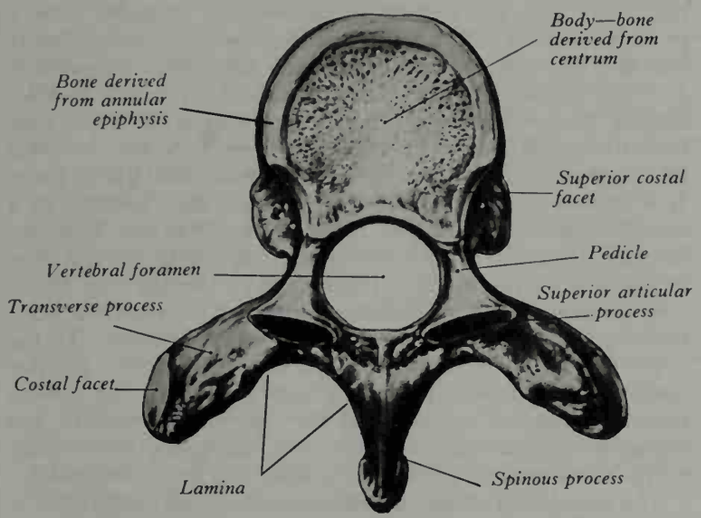
Ribs are intersegmental in position, and since the basic action of segmental muscles derived from myotomes is to bend the vertebral column, vertebrae also become intersegmental, though their embryonic development (p. 138) shows primarily a segmental pattern. In lower vertebrates there are dorsal ribs associated with most of the vertebrae, and the latter themselves show little regional adaptation except in the caudal region, posterior to the anal opening. With the appearance of land vertebrates, and the modification and elaboration of their appendages to various forms of locomotion, the vertebral column was exposed to new patterns of force in the distribution of weight and muscular tensions.

In the case of the hind limbs the pelvic girdle formed an articulation with several vertebrae, which fused with the ribs, or costal elements, of the region to form a sacrum. Such vertebrae lose their individual movement upon each other, and in mammals there are three to five *immovable sacral vertebrae*; distal to these are a variable number of *caudal vertebrae*, reduced to four degenerate elements which become fused into a common mass, the coccyx, in mankind during adult life.



The presacral vertebrae show considerable variation in mammals, in numbers and differentiation; but there is always a distinction into *cervical* (neck) vertebrae, *thoracic* vertebrae where ribs persist, and *lumbar* vertebrae devoid of mobile ribs. In the neck, ribs are small or 'absent' (but *vide infra*); their disappearance in the cervical and lumbar regions is in both cases linked to the change from gill to lung breathing and to the development of a neck for rapid and independent movements of the head upon the trunk. There is no true neck in fish, the immediate postcranial region being occupied by the branchial apparatus. The caudal shift of the respiratory apparatus in land vertebrates was a necessary precursor to the development of a neck, whose vertebrae became early stabilized to a series of seven in the mammals (except in tree sloths and manatees), despite such extremes of external form as whales and giraffes, which both conform. With the adaptation of ribs to respiratory function in land animals, and the development of a diaphragm in mammals, ribs as well-formed functional entities, articulating with but separate from vertebrae, become limited to the region thus defined as thoracic. It is not, however, true to state that ribs disappear completely in the *cervical* and post-thoracic, *lumbar* regions, because small vestiges, called *costal elements*, can be identified in association with the transverse processes of all these vertebrae, as will be apparent when they are individually considered (see also **2**.50, and **3**.29).

In primate mammals there is a general reduction in the total number of vertebrae, excluding the tail, from the lemuroid and tarsioid to the anthropoid primates. The latter suborder, including monkeys, apes and men (extinct and extant species), shows some uniformity of arrangement. The cervical, thoracic, lumbar and sacral vertebrae number respectively 7, 11 to 15, 4 to 7, and 3 to 6, the figures for mankind being 7, 12, 5 and 5.



With these brief preliminary remarks on the origin of the human vertebral column it is now appropriate to consider the individual elements in detail, beginning with the form and structure of a typical vertebra. Some reference to the phylogeny of the other components of the axial skeleton, the ribs and sternum, will be found in the sections describing them.

General Vertebral Characteristics

A typical vertebra (3.26) consists basically of an anterior or ventral part, the *body*, and a posterior or dorsal *vertebral (neural) arch* which is extended by lever-like processes and encloses a *vertebral foramen*, occupied in life by the spinal cord, the meninges, and associated vessels. The opposed surfaces of adjacent vertebral bodies are strongly bound to each other by *intervertebral discs* of fibrocatilage. In the complete column the bodies and discs form a continuous, flexible pillar which is the central axis of the body and supports, in a biped such as man, the weight of the head and trunk. It also transmits considerably greater forces due to the muscles attached to it directly and otherwise. The foramina afford a *vertebral canal* in which is the spinal cord. Between the arches of adjacent vertebrae, on each side, near their junction with vertebral bodies, are *intervertebral foramina* which transmit the spinal nerves and vessels.

3.27 A median sagittal section through a lumbar vertebra.

3.26 A typical thoracic vertebra. Superior aspect.

The vertebral body is roughly cylindrical, but varies widely in size, shape and proportions in different animals and in the different regions of the column of the same species. Its two surfaces are flattened and display a peripheral smooth zone formed from the annular epiphysial disc (p. 283), within which the surface is roughened. These differences in surface texture correspond to variations in the early structure of the intervertebral discs (p. 140). In the transverse plane the body is convex except where its dorsal aspect completes the vertebral foramen; here it is concave. Vertically it is concave except on its dorsal aspect, where it is flat. Small venous foramina show on the front and sides of the body; posteriorly there are a number of small foramina for arteries (Willis 1949) and a large irregular orifice (sometimes double) for the exit of basivertebral veins (3.27). It should be noted that the adult vertebral *body* is *not* coextensive with the developmental *centrum* (p. 140) but in addition, posterolaterally, includes parts derived from the neural arch.

The vertebral arch has on each side a vertically narrower anterior part, the *pedicle* and behind this the broader *lamina*. Projecting from it are seven processes, paired transverse and superior and inferior articular processes, and a single spinous process.

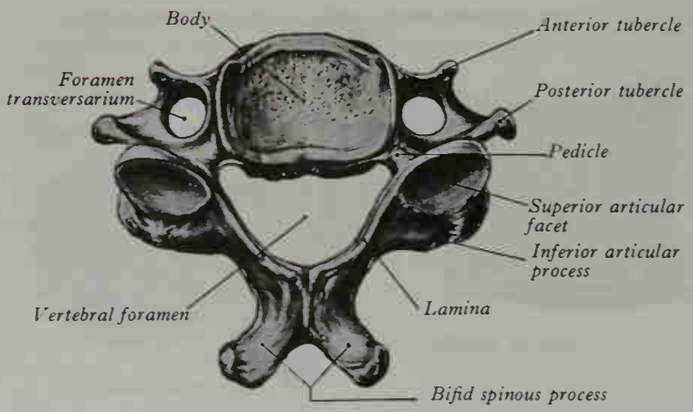
The two *pedicles* are short, thick and rounded bars projecting back from the body at the junction between its lateral and dorsal surfaces, and nearer the superior surface, so that the concavity above the pedicle is shallower than the one below it (3.27). These concavities are the *vertebral notches*; when vertebrae are articulated together by their discs, adjacent notches enclose an *intervertebral foramen*.

The two *laminae* are vertical, broad and plate-like, and are, of course, directly continuous with the pedicles. They curve backwards and medially to fuse in the midline with the spinous process, thus completing the vertebral foramen.

The *spinous process* or spine projects dorsally and often downwards from the junction of the laminae. Spines vary much in size, shape and direction. They are levers for muscles which extend the vertebral column or, to a lesser extent, rotate it.

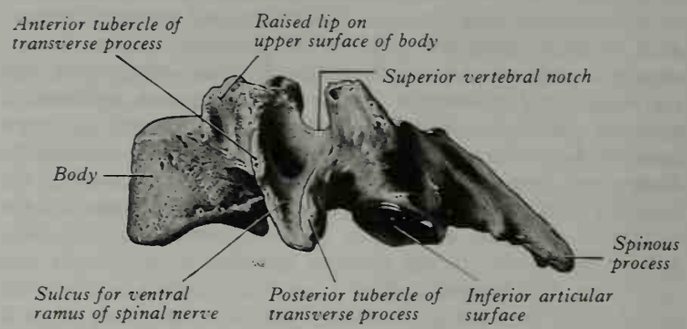
The *articular processes* (*zygapophyses*), paired superior and inferior, project from the vertebral arch at the junctions of pedicles and laminae. The superior articular processes jut upwards and bear surfaces which face dorsally and often laterally; the inferior processes bulge downwards and their articular facets are directed forwards and often somewhat medially. Thus, the articular processes of adjoining vertebrae meet to form small synovial joints (p. 445) which, while permitting a limited degree of movement, are particularly concerned in guiding and restricting the range of movement between vertebrae.

The *transverse processes* project laterally from the junctions of pedicles and laminae, and they serve as levers for the muscles and ligaments concerned in rotation and lateral bending of the spinal column. In the thoracic region they also articulate with ribs. In other parts of the vertebral column, the transverse process of mature vertebrae is a compound structure composed of the 'true' transverse process (*diapophysis*) and the incorporated costal element.



Costal elements (or *pleurapophyses*) develop as basic constituent parts of each vertebral arch in mammalian embryos, but they become independent units, ribs, only in the thoracic region. Elsewhere they remain less prominently developed and unrecognizable as ribs, fusing with their vertebrae, as part of the 'transverse process' of descriptive adult anatomy (*see*, for example, 3.29).

Internally, vertebrae are composed throughout of trabecular bone (*see* 3.1B), covered by an external shell of compact bone, which is traversed by numerous vascular foramina. The cortical bone is relatively thin on the upper and lower surfaces of the body but rather thicker in the arch and its processes. The trabecular interior of the body is traversed antero-posteriorly by one or two large canals containing the commencement of basivertebral veins.

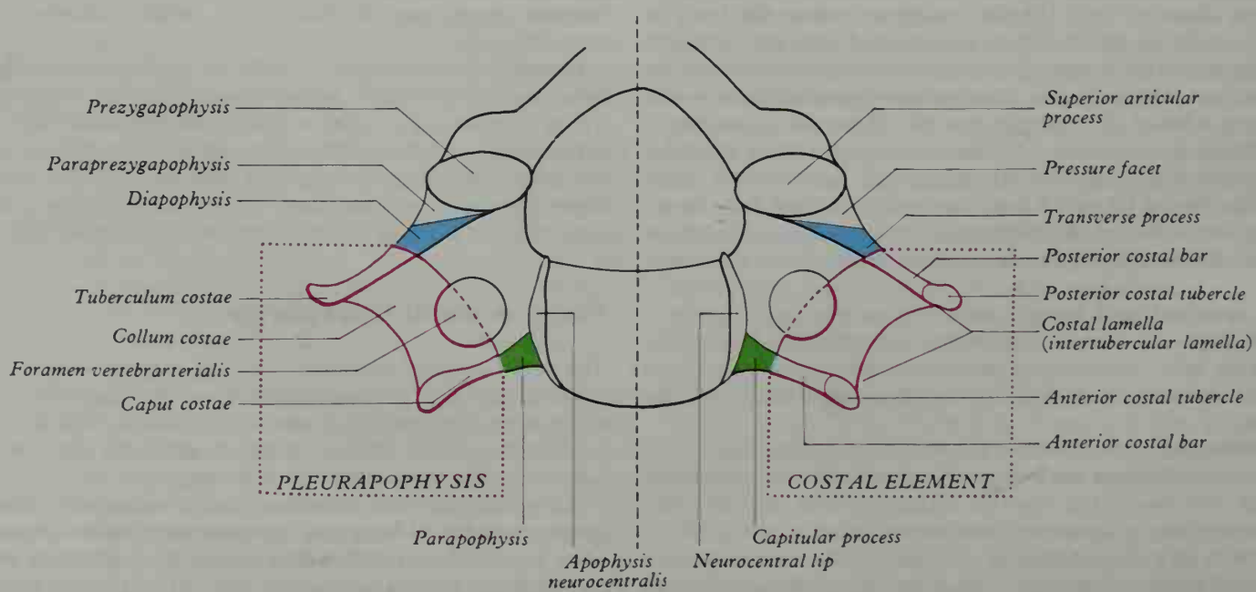


The Cervical Vertebrae

The seven cervical vertebrae (3.28, 29, 34, 35) are the smallest movable vertebrae and identifiable by their transverse processes, which are perforated by a foramen. The first, second, and seventh vertebrae present special features and will be considered separately; the rest conform to a common type.

A typical cervical vertebra has a relatively small and transversely broad body; the *vertebral foramen* is comparatively large and triangular rather than round. In conformity with this the *pedicles* project somewhat laterally (3.28A) as well as backwards, and the *laminae* are angled markedly from them in a medial direction. Superior and inferior vertebral notches are almost equal in depth, the pedicles being attached about midway

3.28A A typical cervical vertebra. Superior aspect.



3.28B A typical cervical vertebra. Left lateral aspect.

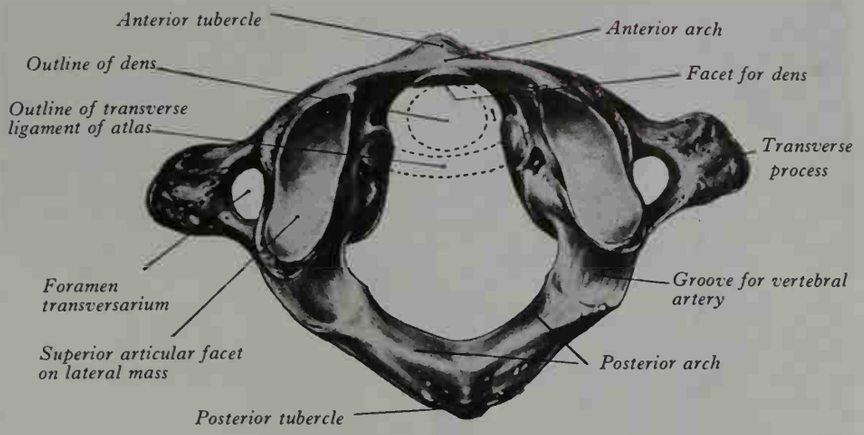
between upper and lower borders of the body. The *laminae* are relatively long and narrow, with a thin upper border. The *spinous process* is short and bifid, with terminal tubercles often unequal in size. The *superior* and *inferior articular processes* form an *articular pillar*, which bulges laterally at the junction of pedicle and lamina. The '*transverse process*' of adult anatomy is morphologically a compound structure containing the *foramen transversarium*. It displays anterior and posterior *roots* or *bars* which terminate laterally as anterior and posterior *tubercles*. The roots are connected lateral to the foramen by an *intertubercular lamella* of bone (often, quite incorrectly, called the costotransverse bar). Of these separately named parts of the transverse process, all except the medial portion of the posterior root constitute the homologue of a *rib*. The medial moiety of the posterior root is homologous with a true transverse process (*diapophysis*) such as exists in a thoracic vertebra (**3**.26). Cave (1975) has examined the morphology of the mammalian, including the human, cervical 'costal element' or *pleurapophysis*, and has defined its extent more precisely, especially in relation to cervical ribs (*see* **3**.29, and p. 140). It should also be noted that the foramen transversarium may be divided into two in any of the cervical vertebrae.

The anterior surface of the body, convex transversely, is marked at its upper and lower margins by the attached fibres of the anterior longitudinal ligament, and on each side of the midline a slight depression shows the point of union of the vertical part of the longus colli. The flattened posterior surface displays centrally two or more large foramina for basivertebral veins. To its upper and lower borders the posterior longitudinal ligament is united in life. The superior surface is transversely concave with a prominent lip on each side, and its anterior rim may be slightly bevelled. The inferior surface is reciprocally convex transversely and also slightly concave anteroposteriorly, i.e. it is saddle-shaped. Its bevelled lateral edge is separated in the living state from the lateral lip of the subjacent vertebra by a small synovial joint, oblique and cleft-like, which develops at about 9 to 10 years. It is limited medially by the intervertebral disc, laterally by a capsular ligament (Cave *et al.* 1955). Some authorities, however, describe the cleft as being in the fibrocartilage of the disc and deny its status as a synovial joint (Tondury 1943; Orofins *et al.* 1960). The anterior rim of the inferior surface of the vertebral body projects downwards in front of the intervertebral disc. To the upper borders of the laminae and the lower part of their anterior surfaces are bound the paired ligamenta flava. To the cervical spinous processes are attached the ligamentum nuchae and numerous deep extensors of the neck, including semispinalis thoracis and cervicis, multifidus, spinalis and the interspinales.

The dorsal rami of the cervical spinal nerves turn back close to the anterolateral aspects of the articular pillars and actually groove those of the third and fourth vertebrae. Their superior facets are oval and flat, and are directed backwards and upwards; in conformity the inferior facets, similar in shape, are turned forwards and downwards. In all but the seventh cervical vertebra the transverse foramen transmits the vertebral artery and its accompanying venous and sympathetic plexuses. The anterior root of the transverse process ends in a roughened tubercle to which are attached tendinous slips of scalenus anterior, longus

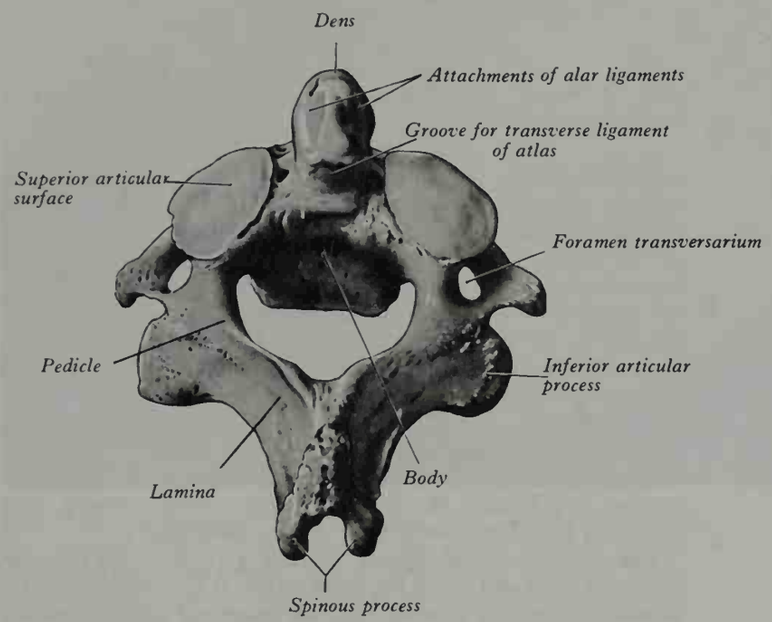
3.29 The morphology of a generalized cervical vertebra, with particular reference to the pleurapophyses. On the left the terms are zoological, on the right are alternatives for human anatomy suggested by Professor A. J. E. Cave. (Reproduced by kind permission of the author, the *Journal of Zoology* and Cambridge University Press.)

capitis, and longus colli (5.36). The anterior tubercle of the sixth vertebra is particularly large, and the common carotid artery, being immediately anterior to it, can be effectively compressed here. It is hence called the *carotid tubercle*. The intertubercular lamella is oblique in the third and fourth cervical vertebrae, passing downwards, backwards and laterally; it is increasingly grooved from the fourth to the sixth by the emerging anterior rami of the spinal nerves. The groove across the intertubercular lamella of the sixth vertebra is conspicuously wide and shallow. The posterior root of the transverse process also ends in a rounded tubercle which is lateral to the anterior tubercle and at a slightly lower level in all except the sixth vertebra, in which the two tubercles are approximately level. Attached to the posterior tubercles are splenius, longissimus and iliocostalis cervicis, levator scapulae, and scalenus posterior and medius (the latter extending forwards along the intertubercular lamella).



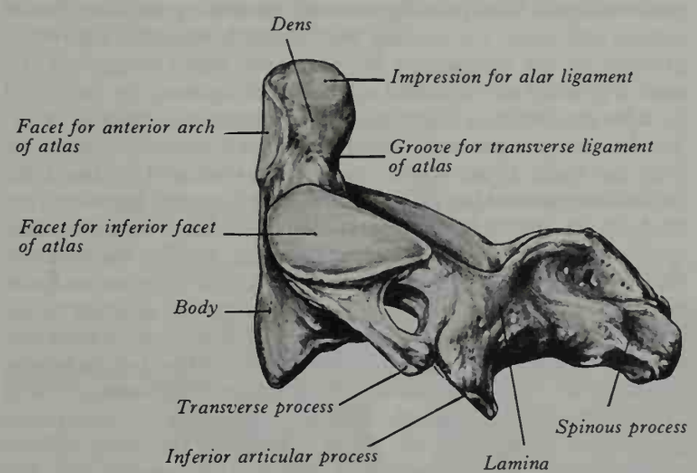
The atlas, the first cervical vertebra (3.30), supports the 'globe' of the head and hence its name. It differs from all other vertebrae in lacking a body; its topographic position is occupied by the *dens* of the axis which forms a projecting pivot around which the atlas turns (p. 447). Moreover, it has no true spine, consisting of two bulky *lateral masses*, connected in front by a short *anterior arch* and posteriorly by a longer curved *posterior arch*. It is thus somewhat annular. When the atlas and axis are articulated together, the upward projection of the latter, the *dens*, is behind the anterior arch and is retained there in life by a *transverse ligament* (4.28). Some comparative morphological and developmental studies have thrown much doubt on the traditional view that the centrum of the atlas is secondarily fused with the axis as its dens (for discussion and bibliography *see* Jenkins 1969).

The anterior arch is slightly curved, its forward convexity being accentuated by a roughened, medially placed *anterior tubercle*. Attached to this is the anterior longitudinal ligament, and on each side of this the superior oblique part of the longus colli. The upper and lower borders of the arch provide attachment respectively to the anterior atlanto-occipital membrane and the lateral parts of the anterior longitudinal ligament.



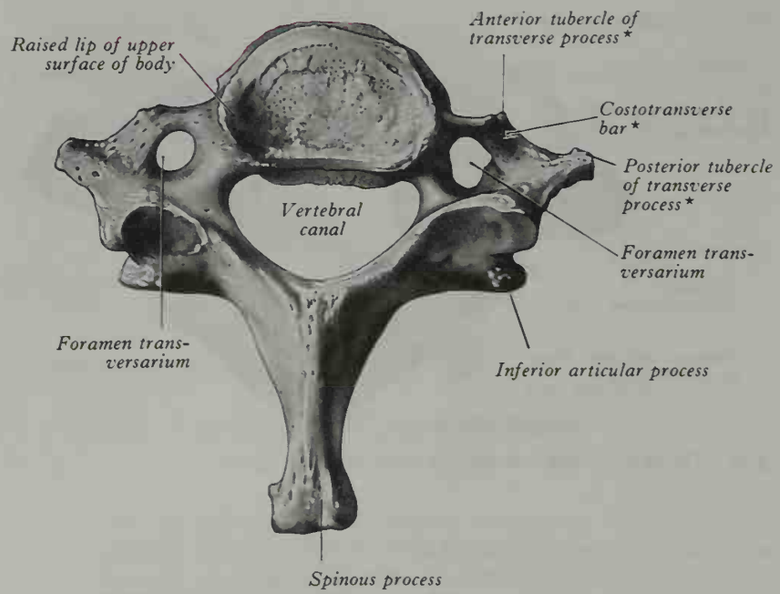
The *lateral masses* converge, their long axes running forwards and medially. Each bears on its upper surface an elongated, somewhat reniform, concave facet jointing with the corresponding occipital condyle. The facet is usually constricted near its middle and may be divided into two. It faces upwards and medially and is adapted to nodding and lateral movements of the head which occur at these two atlanto-occipital joints. The inferior surface of each lateral mass presents an almost circular facet, flat or slightly concave, which articulates with a similar superior articular facet of the axis. The inferior facets of the atlas face down, medially, and slightly backwards. Attached to the edges of superior and inferior facets are the corresponding articular capsules. The medial aspect of each lateral mass has a small, rough tubercle for the transverse ligament of the atlas (3.30), which passes behind the dens and retains it in place. This ligament divides the cavity of the atlas into a smaller, anterior part, containing the dens, and a larger, posterior region, occupied by the spinal cord and meninges. The anterior aspect of the lateral mass has the rectus capitis anterior attached to it.

The *posterior arch* accounts for about two-fifths of the ring of the atlas. Its upper surface shows a wide groove behind each lateral mass, behind the overhang of which the vertebral artery winds (3.30). Quite frequently (about 37 per cent of 66 macerated specimens) the groove is partly or wholly converted into a foramen by a spicule of bone arching backwards from the upper surface of the lateral mass (for details *see* Lamberty and Živanović 1973). The first cervical spinal nerve also lies in the groove, between the artery and bone. Behind the two grooves the posterior atlanto-occipital membrane joins the posterior arch, and to its lower margin are attached the highest pair of ligamenta flava. The posterior tubercle of the arch represents a spinous process; to its roughened surface are attached the ligamentum nuchae and flanking this the two recti capitis posteriores minores.



The *transverse processes* are unusually long (3.34), and hence the width of the atlas exceeds that of all cervical vertebrae save the seventh. The length and strength of these processes makes them adequate levers for the muscles which aid in rotation of the head.

3.30 The first cervical vertebra, or atlas. Superior aspect.



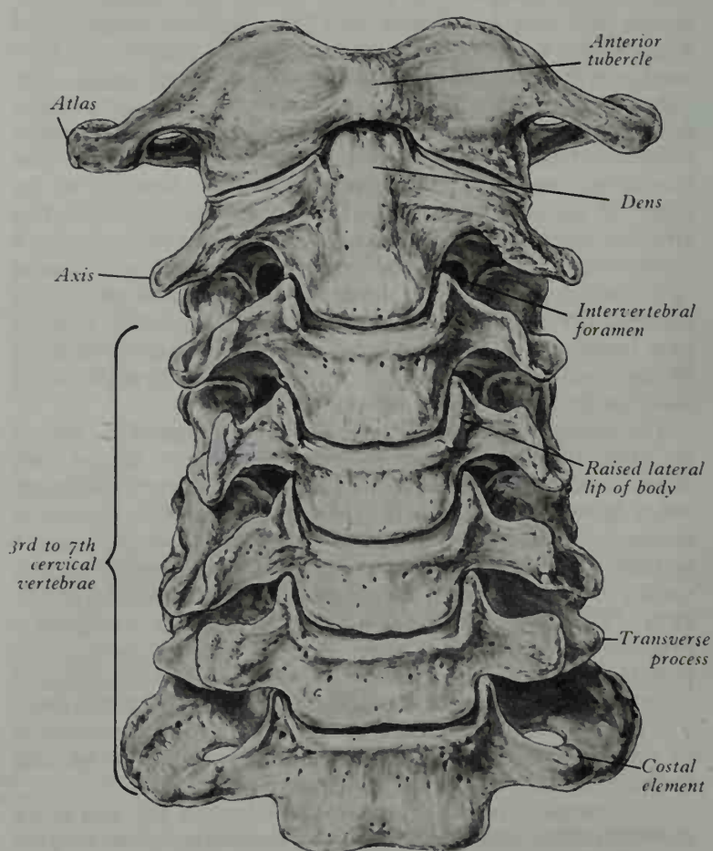
3.31 The second cervical vertebra, or axis. Posterosuperior aspect.

3.32 The second cervical vertebra, or axis. Left lateral aspect.

(The maximal width of the atlas shows a range of 74 to 90 mm in the male and 65 to 76 mm in the female of European and American whites, providing a useful criterion of sex in identifying human remains.) The apex of the transverse process is homologous with the *posterior* tubercle in a typical cervical vertebra; it can be felt through the overlying tissues between the mastoid process and

3.33 The seventh cervical vertebra. Superior aspect. (*See text and **3**.29 for alternative terms.)

mandibular angle. On the anterior aspect of the lateral mass a minute tubercle is sometimes perceptible, and this is the homologue of an *anterior* tubercle. Hence the transverse process of the atlas is the equivalent of the posterior root and intertubercular lamella only, the anterior root being absent, save for the minute tubercle mentioned above. Numerous muscles are attached to the transverse processes of the atlas; superiorly, the rectus capitis lateralis in front of the superior oblique, at the tip, the inferior oblique, laterally and below, slips of levator scapulae, splenius cervicis, and scalenus medius. The ventral ramus of the first cervical spinal nerve passes forwards on the lateral surface of the lateral mass and then turns down in front of the transverse process and behind the internal jugular vein, crossed here anteriorly by the accessory nerve and occipital artery.



The axis, the second cervical vertebra (**3**.31, 32), is the pivot on which the atlas and hence the head rotate. It is distinguished by the strong toothlike process, the *dens* (odontoid process), which juts vertically upwards from the body. On the front of the dens is a small oval articular facet which forms a joint with the similar facet on the back of the anterior arch of the atlas; posteriorly the dens is grooved by the transverse ligament of the atlas (**3**.31). The dens is conical and about 1·5 cm long and distinctly waisted, where it is grooved by the ligament, a bursa usually being interposed. Its apex is pointed and is joined by the apical ligament (p. 449), and its sides are flattened where the alar ligaments are attached (**3**.31, 32). In structure the dens contains relatively more compact bone than the body. From above, the body is obscured by the dens, flanked by a pair of large, oval facets, which extend laterally from the body on to the adjoining parts of the pedicles. These articulate in life with the inferior facets of the atlas. Unlike the superior facets of other cervical vertebrae, they do not form an articular pillar with the inferior facets, being considerably anterior to the latter. The anterior aspect of the body is hollowed out on each side of the midpoint by the attachment of the vertical part of the longus colli muscles. The anterior longitudinal ligament is connected to the lower border, which has a characteristic downward projection. Posteriorly the lower border of the body affords attachment to the posterior longitudinal ligament and the membrana tectoria (p. 449). The pedicles are stout, the inferior vertebral notches deep, and the superior ones scarcely discernible. The laminae are thicker than in any other cervical vertebra and provide attachment to ligamenta flava. They fuse behind with a large and powerful spinous process which takes the pull of muscles which extend, retract, and rotate the head. The inferior oblique arises from a rough impression on each side of the spine, and the rectus capitis posterior major a little posterior to this. The ligamentum nuchae is attached to the broad gap at the apex of the spine, together with slips of the semispinalis and spinalis cervicis, interspinalis, and multifidus.

The transverse processes of the axis are small; their blunt tips present a single tubercle, a homologue of the posterior tubercle at other levels. The anterior tubercle is at or near the junction of the anterior root of the transverse process with the body, as in the atlas. To the tip of the process is attached levator scapulae, between scalenus medius in front and splenius cervicis behind. To its upper and lower surfaces are attached the corresponding intertransverse muscles (p. 545). Each transverse foramen is directed superolaterally, because the vertebral arteries must deviate laterally as they pass up to the more widely separated foramina in the atlas. The inferior articular facets are carried at the junction of pedicles and laminae and face downwards and forwards, as in a typical cervical vertebra. The vertebral foramen is relatively large.

In a study of 60 cervical vertebral series (Krmpotić-Nemanić and Keros 1973) the longitudinal axis of the dens relative to the body of the vertebra varied according to the cervical vertebral curvature, and also showed changes with age.

For a discussion concerning the homologies of the transverse processes of the atlas and axis, and of the atlanto-occipital and atlanto-axial joints and their neuromuscular relationships, consult Cave (1975).

The seventh cervical vertebra (**3**.33) is sometimes called the *vertebra prominens*; its long spinous process is visible through the skin at the lower end of the nuchal furrow. (In fact, the spine of the first thoracic vertebra is usually just as prominent and sometimes more so.) The seventh cervical spine is thick, almost horizontal, and ends in a single tubercle, to which the lower end of the ligamentum nuchae is tied. Also attached near the tip of the spine are trapezius, rhomboideus minor, serratus posterior superior, splenius capitis, spinalis cervicis, semispinalis thoracis, multifidus, and interspinales. The transverse processes are large, particularly their prominent posterior parts. Anterior to the transverse foramina, which are relatively small and may be reduplicated, the anterior part of the process is slender and shorter. It is the costal element and may be a separate bone, a cervical rib. The intertubercular lamella anterolateral to the foramen (**3**.33), is grooved superiorly by the ventral ramus of the seventh cervical nerve; it is often partly deficient. The prominent posterior tubercle of the transverse process provides attachment

3.34 The cervical vertebrae. Anterior aspect.

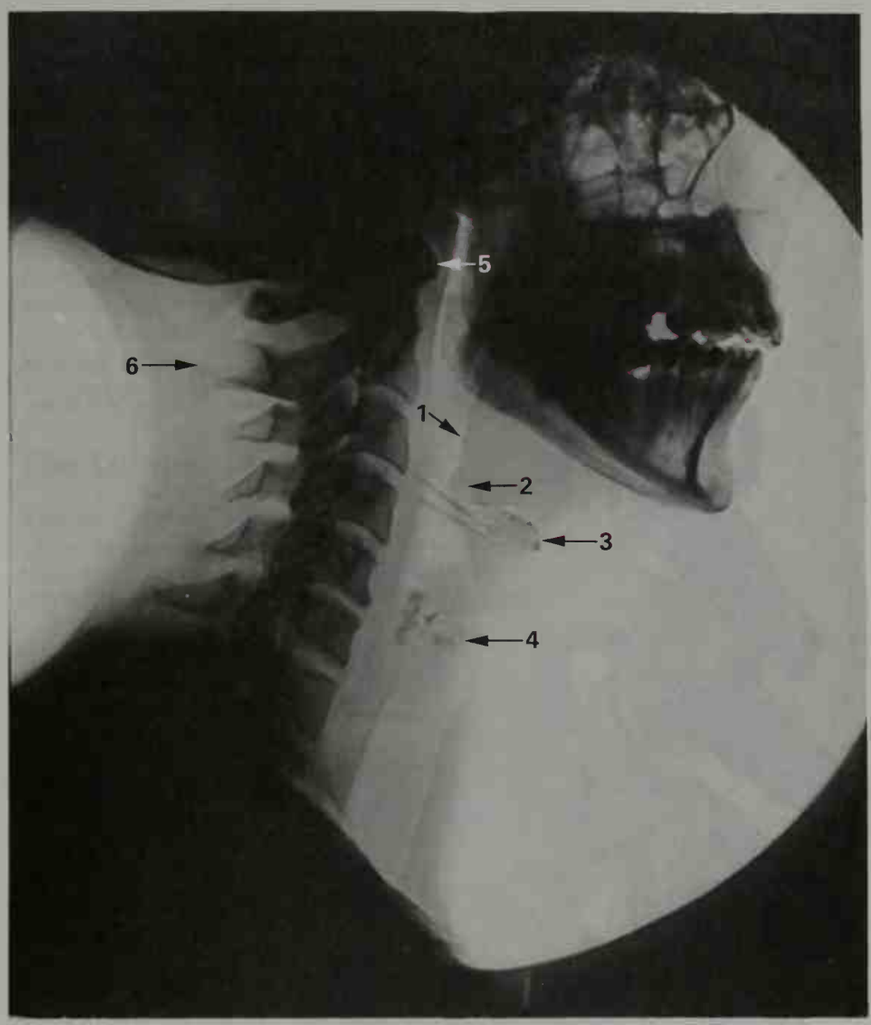
for scalenus minimus, when present, and also to an aponeurotic layer which covers the cervical dome of the pleura, the suprapleural membrane. The first pair of levatores costarum are connected to the lower edge of the transverse processes.

The Thoracic Vertebrae

The twelve thoracic vertebrae (**3**.26, 36, 37, 38) show a gradual increase in size downwards, like other vertebrae, an expression of the increasing load carried from head to sacrum. All are distinguished by costal facets on the sides of their bodies, and all but the last two or three by facets on their transverse processes. These articulate respectively with the heads and tubercles of ribs. The first and the ninth to twelfth thoracic vertebrae possess certain peculiarities and will be considered separately; the rest, despite minor differences, may be regarded as 'typical'.

The body of a typical thoracic vertebra is a waisted cylinder except where the vertebral foramen encroaches upon it behind; its transverse and anteroposterior dimensions are therefore almost equal. On each side it bears two *costal facets*; the superior pair are usually larger and are at the upper border in front of the root of the pedicle; the inferior facets are at the lower border immediately in front of the vertebral notch (**3**.36). The *vertebral foramen* is relatively small, and its circular outline can be linked with the fact that the *pedicles* do not diverge as in cervical vertebrae and that the thoracic part of the spinal cord is smaller and more nearly circular. The *laminae* are hence also short, and they are thick, broad, and overlap each other from above downwards. The typical *spinous process* slants back and downwards. The superior *articular processes*, thin plates of bone, project upwards at the junctions of pedicles and laminae; they are almost flat and face back, and a little laterally and upwards. The *inferior processes* are downward projections of the laminae, their facets directed forwards and a little medially and upwards. The *transverse processes* are substantial and club-shaped projections from the vertebral arch at junctions of pedicles and laminae. They point laterally and somewhat backwards; they bear, anteriorly near their tips, oval facets which articulate with the tubercles of the numerically corresponding ribs.

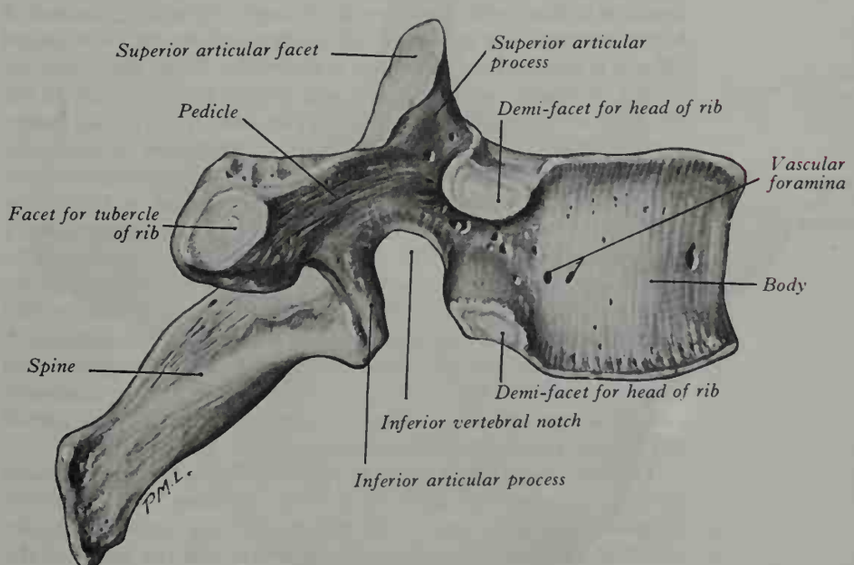
The first thoracic vertebra (**3**.37) is distinguished by the upper costal facets on its body, for these are circular, articulating with the whole of the facet on the head of each first rib, whereas the inferior facets are smaller and semilunar; they articulate, as is usual through the thoracic series, with a demifacet on the head of a rib. The spine is thick, long and horizontal, and is commonly as prominent as that of the seventh cervical vertebra.



The ninth thoracic vertebra (**3**.37), though otherwise typical, often fails to form joints with the tenth ribs, and the inferior demifacets on the body are then absent.

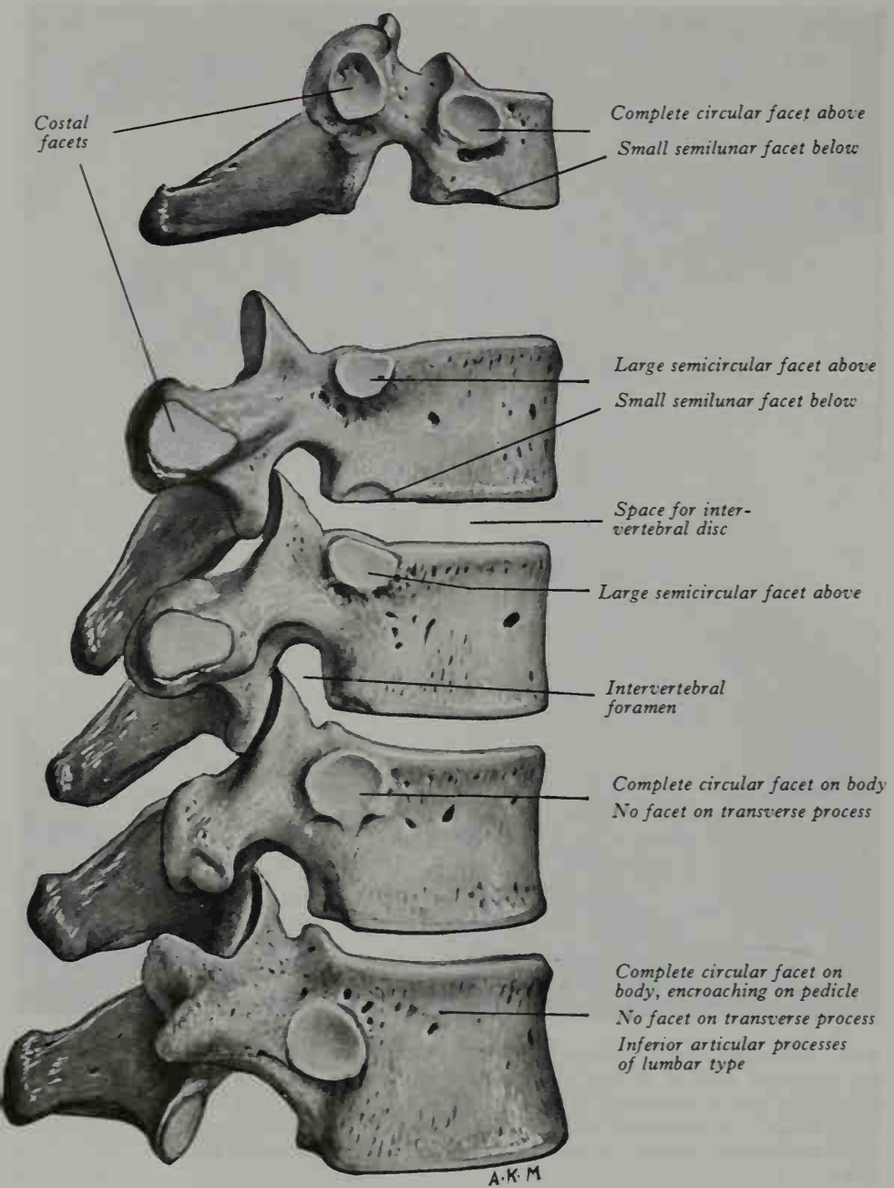
The tenth thoracic vertebra (**3**.37) articulates only with the tenth pair of ribs, taking no part in the costovertebral joints of the eleventh pair. Superior facets only are therefore present on the body, and these are usually large and semilunar, but they are oval when the tenth ribs fail to reach the ninth vertebra and intervening disc. The transverse process may or may not present a facet for the tubercle of the tenth rib.

The eleventh thoracic vertebra (**3**.37) articulates only with the eleventh ribs by their heads. The circular costal facets are close to the upper border of the body and extend slightly on to the pedicles. The transverse processes are small and lack articular facets.

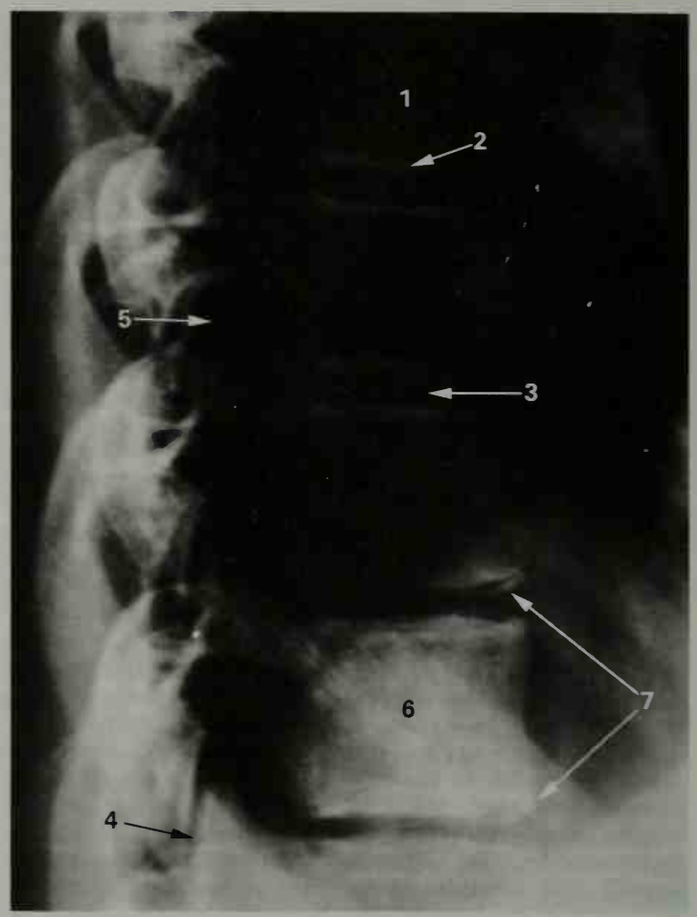


The twelfth thoracic vertebra (**3**.37) forms joints with the heads of the twelfth ribs by circular facets somewhat below the upper border of the body and spreading on to the pedicles. The body is large and approximates to the lumbar type. The transverse processes are insignificant and present lumbar features (*vide infra*).

The bodies of the upper thoracic vertebrae show a gradual transition from cervical to thoracic type, while the bodies of the lower thoracic vertebrae show a similar transition from thoracic to lumbar characteristics. The body of the first is cervical in form, its transverse is nearly twice as great as its anteroposterior measurement. The body of the second retains the cervical shape,



3.35 Lateral radiograph of the neck. Positive print. The cervical curve of the vertebral column is well shown. The arrows point (1) to the pharyngeal part of the tongue; (2) to the epiglottis; (3) to the body of the hyoid bone; (4) to the thyroid cartilage, which is undergoing calcification; (5) to the anterior tubercle of the atlas; (6) to the spinous process of the axis.



In front of the body of the first thoracic vertebra, a small part of the apex of the lung shows as a narrow, clear area which crosses the opacity caused by the oesophagus and encroaches very slightly on the broad clear area caused by the presence of air in the trachea.

but its breadth is less and the disproportion between its two measurements is diminished. The body of the third is actually the smallest of the thoracic bodies, but its anterior aspect, instead of being flattened like the bodies of the first and second, is rounded off and is convex forwards from side to side. From this point the bodies gradually increase in size and, owing to an increase in the anteroposterior measurement, that of the fourth is typically heart-shaped. The bodies of the fifth to eighth show a gradually increasing anteroposterior dimension while the transverse shows little alteration. These four vertebrae, when seen on transverse section, are asymmetrical, for the left side of each body shows a flattening produced by the pressure of the thoracic aorta. The remaining vertebrae increase in size more rapidly, the increase affecting all the measurements of the body, so that the twelfth approximates closely to the shape of a typical lumbar vertebra. A geometrical analysis of these regional differences suggests that they are adaptations to a greater range of flexion-extension activity at the cervical and lumbar extremes of the thoracic part of the vertebral column (Veleanu *et al.* 1972).

The upper and lower borders of the bodies in front and behind give attachment respectively to the anterior and posterior longitudinal ligaments; to the margins of the costal facets are attached the capsular and radiate ligaments of the joints of the heads of the ribs. The longus colli arises from the bodies of the first three thoracic vertebrae, lateral to the anterior longitudinal

3.39 A lumbar vertebra. Left lateral aspect.

ligament. The psoas major and minor arise from the lateral aspect of the body of the twelfth near its lower border.

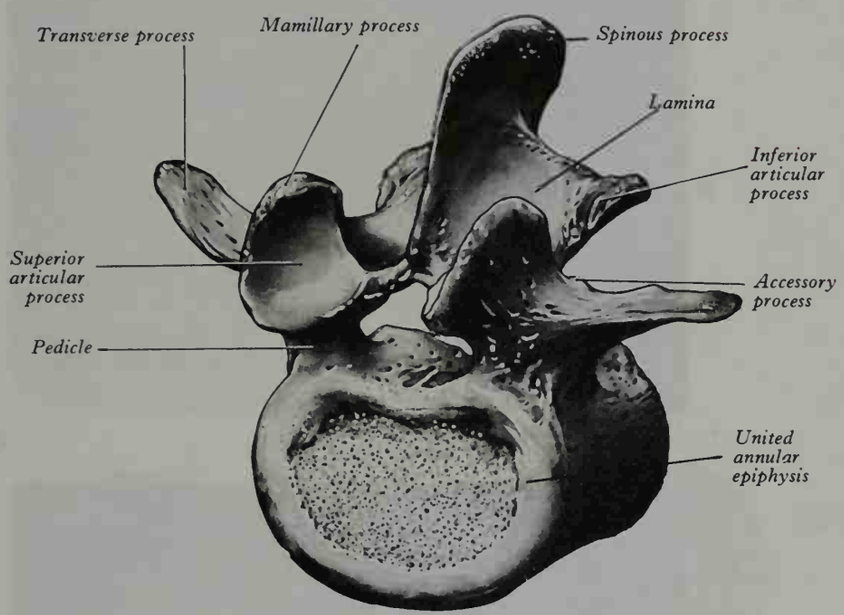
The pedicles increase in thickness from above downwards. The superior vertebral notch is scarcely recognizable except in the first thoracic vertebra, but the inferior notch is deep and conspicuous. The upper borders of the laminae and the lower parts of their anterior surfaces serve for attachment of the ligamenta flava; their dorsal aspects give insertion to the rotatores muscles.

The transverse processes gradually diminish in length from above downwards. In the upper six (sometimes five) the costal facets are concave and face forwards and laterally; in the others the facets are flattened and face upwards, laterally, and slightly forwards. The anterior surface of the process medial to the facet gives attachment to the costotransverse ligament, its tuberculated extremity to the lateral costotransverse ligament and its lower border to the superior costotransverse ligament. In addition, the upper and lower borders of the transverse process provide attachment for intertransverse muscles or their fibrous vestiges, and the posterior surface for the deep muscles of the back, the levator costae arising from the dorsal aspect of the tuberculated extremity under cover of the longer muscles.

The spines overlap from the fifth to the eighth, which is the longest and most nearly vertical of the thoracic spines. Above and below they are less oblique in direction. (In quadrupeds the majority of the spines of the thoracic vertebrae project dorsally and caudally, while those in the lumbar region are directed dorsally and cranially. The change in inclination is effected in one of the lower thoracic vertebrae, the spine of which points almost straight dorsally. This vertebra is known as the *anticlinal*, and in man its representative is the eleventh thoracic.) In man the supraspinous and interspinous ligaments, the trapezius, rhomboideus major and minor, latissimus dorsi, the serratus posterior superior and inferior, and many of the deep muscles of the back are attached to the thoracic spines.

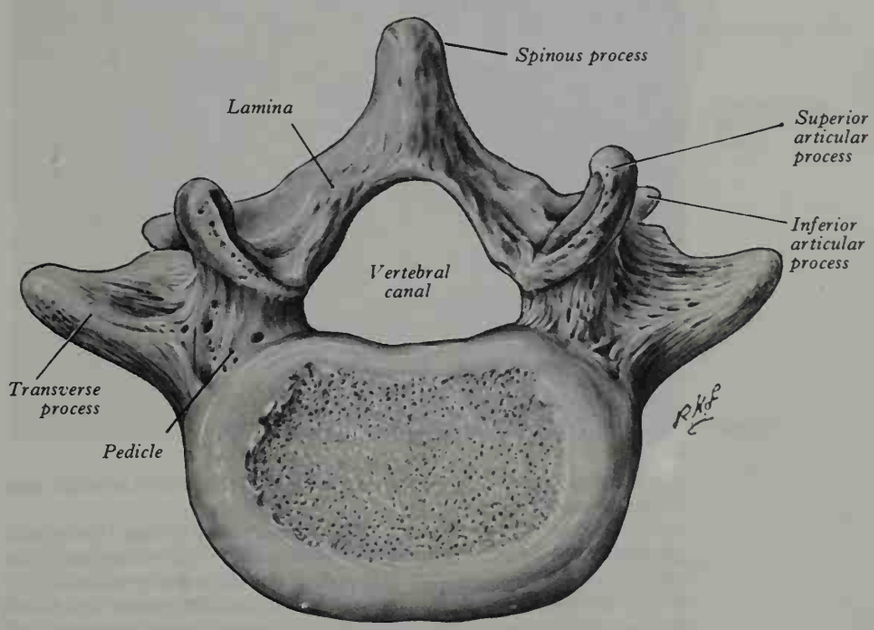
The first thoracic resembles a cervical vertebra in the shape of its body. In addition, the posterolateral parts of its upper border are raised, as they are in the cervical region, and this projection forms the anterior border of the superior vertebral notch, which is a distinctive feature of this vertebra. The upper facet on the side of the body is not always complete, as the head of the first rib often articulates with the intervertebral disc between the seventh cervical and the first thoracic vertebra. Immediately below the facet there is frequently a small, deep depression in the bone.

In the eleventh and twelfth thoracic vertebrae the spinous processes are characteristically triangular, with blunted apices. In each case, the lower border is horizontal, or nearly so, and the upper border is oblique. In the region of the transverse process of the twelfth thoracic vertebra three small tubercles can be distinguished. Of these the superior is the largest and juts upwards. It corresponds to the mamillary process of a lumbar vertebra, but it is not so closely connected with the superior articular process. The lateral tubercle is small and corresponds to the true transverse process. The inferior tubercle, directed downwards, corresponds to the accessory process of a lumbar vertebra.



Usually these two vertebrae can be distinguished by the size and character of the transverse process and the distance between the costal facet and the upper border of the vertebra (p. 275).

The change in the character of the articular processes from the thoracic to the lumbar type occurs suddenly, usually in the eleventh thoracic vertebra, but sometimes in the twelfth or tenth, at one of which the articular processes commonly interlock in tenon and mortice fashion. In the transitional vertebra the superior articular processes are thoracic in type; their articular facets are directed backwards and a little laterally and upwards, while the inferior articular processes are turned laterally and their facets are slightly convex from side to side, facing laterally and forwards. This vertebra marks the site of a sudden change in function (*see* p. 446, and Davis 1955).



The Lumbar Vertebrae

The five lumbar vertebrae (3.39, 40, 41) differ from other vertebrae in their greater size and absence of costal facets and transverse foramina.

The *body* is large, wider from side to side and a little deeper in

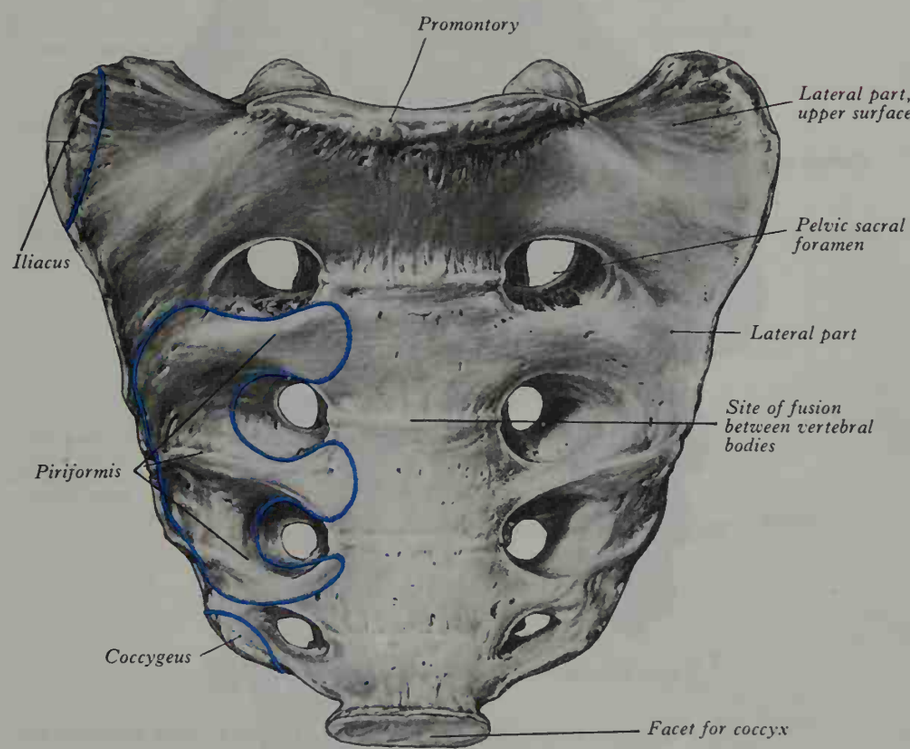
front. The *vertebral foramen* is triangular, larger than in the thoracic but smaller than in the cervical region. The *pedicles* are short. The *spinous process* is almost horizontal, quadrangular, and thickened along its posterior and inferior borders. The *superior articular processes* bear slightly concave vertical articular facets which face medially and backwards. The posterior border of each has a rough elevation, the *mamillary process*. The *inferior articular processes* have slightly convex vertical articular facets which face laterally and forwards. The *transverse processes* are thin and long, except those of the fifth vertebra, which are more substantial. A small, rough *accessory process* marks the postero-inferior aspect of the root of each transverse process. (Measurement of the third and fourth lumbar vertebrae in 338 skeletons, male and female, aged 20–90 years demonstrates that the *breadth* of the body increases with age. In males, the posterior height shows a relative decrease, and in both sexes the anterior height of the vertebral body decreases relative to breadth—Ericksen 1976.)

The fifth lumbar vertebra (3.41) is distinguished by its massive *transverse process;* it is connected to the *whole of the lateral suface of the pedicle and encroaches on the side of the body.* Its body is usually the largest of the lumbar vertebrae and it is markedly deeper in fronter than behind, in association with the prominence of the sacrovertebral angle.

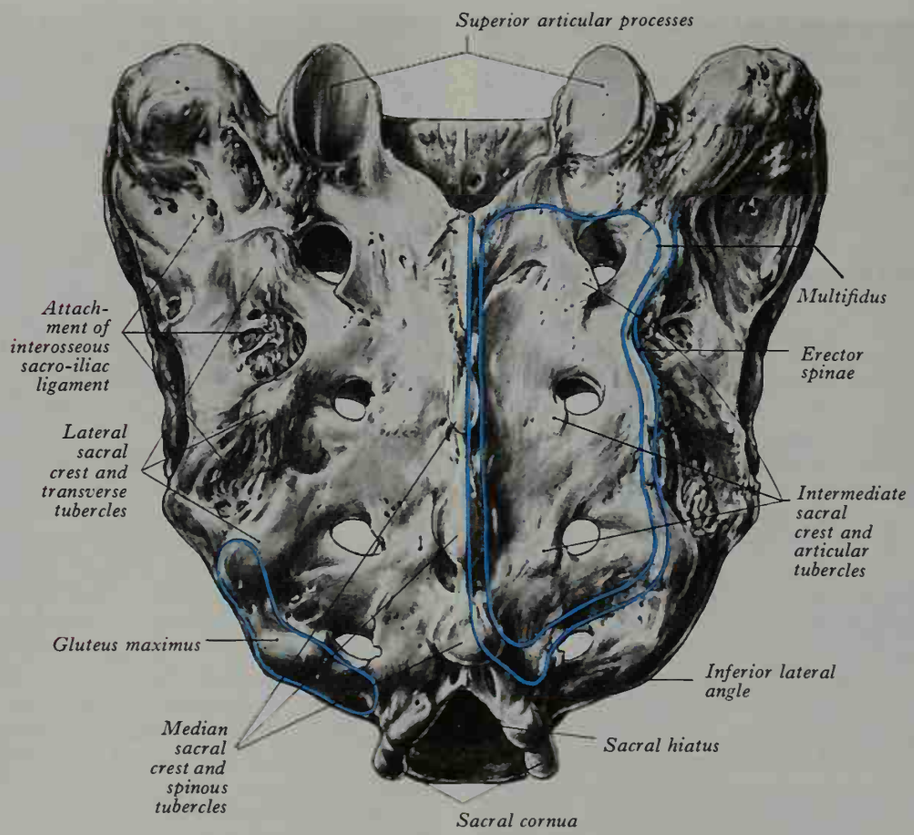
The upper and lower borders of lumbar *bodies* in front and behind give attachment to the anterior and posterior longitudinal ligaments. Lateral to the anterior longitudinal ligament, the bodies of the upper lumbar vertebrae (three on the right side, two on the left) give origin to the crura of the diaphragm. Behind this the psoas major arises from the upper and lower margins of the bodies of all the lumbar vertebrae; tendinous arches carry its attachments across the concave sides of the bodies. The vertebral foramen of the first lumbar vertebra contains the lower part of the spinal cord—the conus medullaris; the lower foramina contain the cauda equina and the spinal meninges. The pedicle is strong, and springs from the posterolateral aspect of the body just below its upper border. The superior vertebral notch is shallow; the inferior notch is deep. The laminae are broad, short and strong, but do not overlap one another to the same extent as in the thoracic region. They give attachment to the ligamenta flava. The spinous processes provide attachment for the posterior lamella of the thoracolumbar fascia, the erector spinae, spinalis thoracis, multifidus, interspinal muscles and ligaments and supraspinous ligaments. The spinous process of the fifth lumbar vertebra is the least substantial and its extremity is often rounded and down-turned. The superior articular processes are wider apart than the inferior in the upper lumbar region, but the difference is very slight in the fourth, and in the fifth the two measurements are approximately equal. The articular facets are reciprocally concave (superior) and convex (inferior), so that they permit some rotation as well as flexion and extension. The transverse processes, with the exception of the fifth, are compressed from before backwards and pass laterally and slightly backwards. In the fifth lumbar vertebra the lower border of the transverse process is angulated and passes at first laterally and then upwards and laterally to a blunt tip, giving the whole process the appearance of a greater upward inclination than those of the vertebrae above. The blunt angle on the inferior border is said to represent the tip of the costal element and the outer extremity, the tip of the true transverse process. The transverse processes increase in length from the first to the third—which are the longest of all transverse processes—and then become shorter. The fifth incline *upwards*, passing laterally and slightly backwards. A faint, vertical ridge marks the anterior surface of the transverse process nearer the tip than the root. It gives attachment to the anterior layer of the thoracolumbar fascia and separates the surface into a medial area for the psoas major and a lateral area for the quadratus lumborum. To the tip of the process is attached the middle layer of the thoracolumbar fascia, but, in addition, the tip of the first gives attachment to the medial and lateral arcuate ligaments and the tip of the fifth to the iliolumbar ligament. The posterior surfaces of the transverse processes are covered by the deep muscles of the back and give origin to fibres of the longissimus thoracis. The upper and lower borders of the process give attachment to lateral intertransverse muscles. The mamillary process is homologous with the superior tubercle in the twelfth thoracic vertebra. It gives attachment to the multifidus and to the medial intertransverse muscle. The accessory process varies in prominence and may be difficult to identify. It gives attachment to the medial intertransverse muscle. The costal element is incorporated in the transverse process. (For a discussion concerning the possible homologies of the accessory, transverse and mamillary processes consult Wood Jones 1912.)



The Sacrum

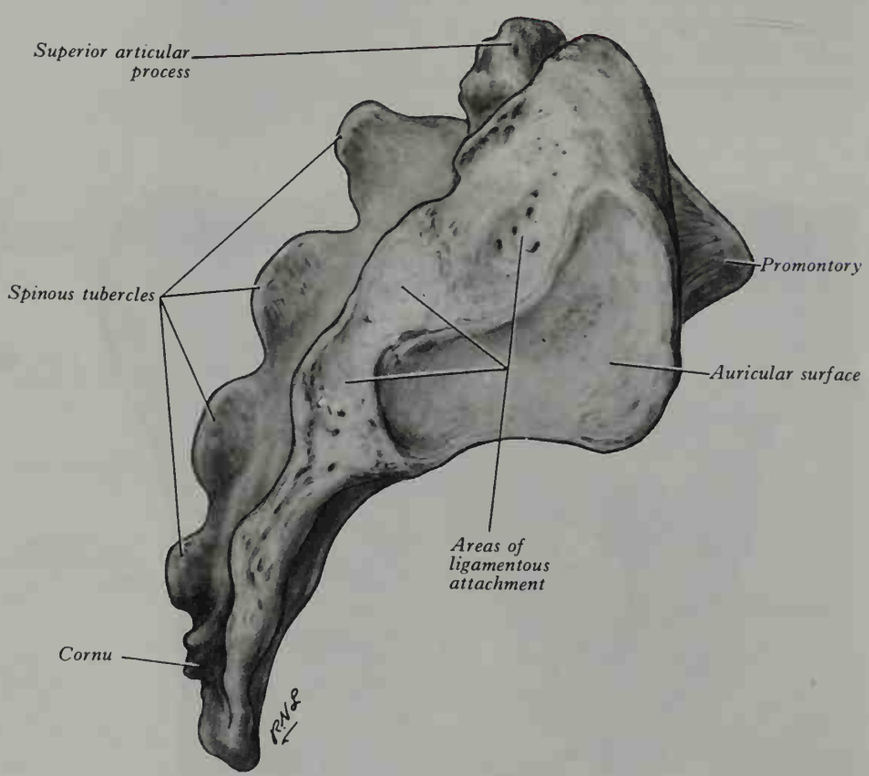
The sacrum (3.43–7) is large, triangular and formed by fusion of the five sacral vertebrae. It is situated at the upper and posterior part of the pelvic cavity, inserted like a wedge between the two innominate bones. Its narrow, blunted *apex* is at the inferior end of the bone and articulates with the coccyx. At the opposite end the wide *base* articulates with the fifth lumbar vertebra, with which it forms the *sacrovertebral angle.* In the erect position the bone is very oblique and is also curved longitudinally so that its dorsal surface is convex and its pelvic surface is concave (3.45). This ventral concavity increases the capacity of the true pelvis. In addition to a base and an apex the sacrum possesses *dorsal*, *pelvic*, and *lateral surfaces* and encloses the *sacral canal.*

In childhood the individual sacral vertebrae are connected by cartilage and can be separated by maceration. The adult bone shows many signs of its vertebral constitution, especially on its basal aspect.



The base (3.46) is formed by the upper surface of the *first sacral vertebra* and presents all the features of a typical vertebra in a slightly modified form. The *body* is large and much wider transversely. Its anterior projecting edge is the *sacral promontory.* The vertebral foramen is triangular, because the *pedicles* are short, widely separated, and are directed backwards and laterally. The *laminae* are very oblique and incline downwards, medially and backwards. Where they meet, the spinous process is represented by a *spinous tubercle.* The *superior articular processes* project upwards, with concave articular facets directed dorsomedially to articulate with the inferior articular processes of the fifth lumbar vertebra. The posterior part of each process projects backwards, and its lateral aspect bears a roughened area which corresponds to the mamillary process of a lumbar vertebra. The region of the *transverse process* shows marked modifications. A broad, sloping mass of bone projects from the lateral side of the body, pedicle and superior articular process (3.46)—a feature which is not found in any other vertebra, although foreshadowed in the fifth lumbar. It consists of the transverse process and the costal element fused to each other and to the rest of the vertebra, and forms the upper surface of the *lateral part* or *ala* of the sacrum.

The pelvic surface (3.43) faces downwards and forwards. Overall it is concave from above down and from side to side, but occasionally the body of the second sacral vertebra protrudes to produce a convexity in this region. It displays four pairs of *pelvic sacral foramina,* which communicate through intervertebral foramina with the sacral canal. They transmit the ventral rami of



3.43 The sacrum. Pelvic surface.

(The reader should appreciate that the old terms 'origin' and 'insertion' are functionally obsolete in terms of modern myokinetics. Accordingly they have been abandoned in the present volume: likewise the need for distinguishing colours has also disappeared. Thus, here and elsewhere in this edition, *all muscle attachments* are outlined in a single colour—a full blue line.)

3.44 The sacrum. Dorsal surface.

3.45 The sacrum. Right lateral aspect.

the upper four sacral spinal nerves. The large area between the foramina of the right and left sides is formed by the flattened pelvic surfaces of the bodies of the sacral vertebrae, and their lines of fusion are clearly visible as four raised *transverse ridges*. The bars of bone between the foramina on each side are the *costal elements*, which are fused to the vertebrae. Lateral to the foramina the costal elements unite with one another and, posteriorly, with the transverse processes to form the *lateral part* of the sacrum.

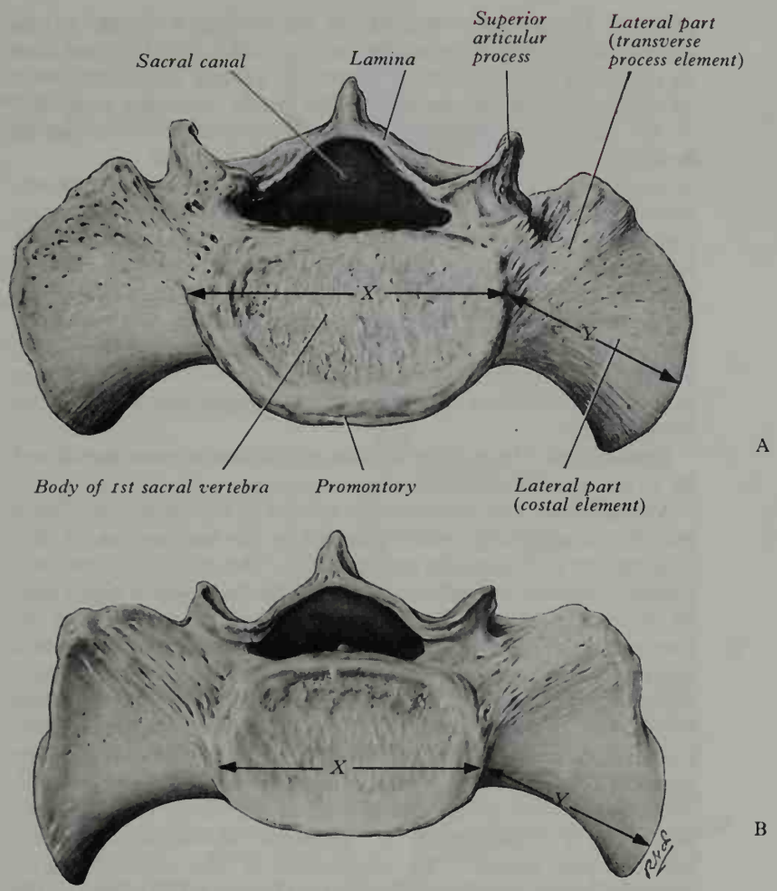
The dorsal surface (3.44) is convex backwards and upwards. In the median plane is a raised interrupted *median sacral crest*, which bears four (sometimes only three) *spinous tubercles*. The crest represents the fused spines of the sacral vertebrae. Below the fourth, or sometimes the third, there is a ∩-shaped gap in the posterior wall of the sacral canal, the *sacral hiatus*. This is due to the failure of the laminae of the fifth sacral vertebra to meet in the median plane; as a result, the posterior surface of its body is exposed on the dorsal aspect of the sacrum. Lateral to the median crest the posterior surface is formed by the fused laminae. Lateral to this area on each side are four *dorsal sacral foramina*. Like the pelvic foramina they communicate with the sacral canal through the intervertebral foramina; each transmits the dorsal ramus of a sacral spinal nerve. Medial to the foramina, and vertically below each superior articular process of the first sacral vertebra, is a row of four small tubercles, which together constitute the *intermediate sacral crest*; the tubercles are sometimes termed *articular* since they represent contiguous articular processes fused together. The inferior articular processes of the fifth sacral vertebra project downwards at the sides of the sacral hiatus. They are the *sacral cornua* and are connected to the cornua of the coccyx by the intercornual ligaments. The interrupted crest lateral to the dorsal sacral foramina is the *lateral sacral* crest; it is formed by the fused transverse processes, the tips of which appear as a row of tubercles sometimes called the *transverse tubercles*.

The lateral surface (3.45) of the sacrum is formed by fused transverse processes and costal elements. It is wide above but rapidly diminishes in breadth in its lower part. The broad, upper part bears an ear-shaped surface, termed the *auricular surface*, for articulation with the ilium, and the area behind it is rough and deeply pitted by the attachment of ligaments. The auricular surface is borne by the costal elements and is shaped like an inverted letter L. The cephalic limb is shorter and restricted to the first sacral vertebra; the caudal limb extends downwards to the middle of the third sacral vertebra. The lower part of the lateral surface is not articular and consequently reduced in breadth. At its lower end it curves medially to reach the side of the body of the fifth sacral vertebra. The point at which the change of direction occurs is the *inferior lateral angle*. Below the angle the lateral surface becomes a thin border. An *accessory* sacral articular facet, of variable disposition, sometimes occurs.

The apex of the sacrum is formed by the inferior surface of the body of the fifth sacral vertebra and bears an oval facet for articulation with the coccyx.

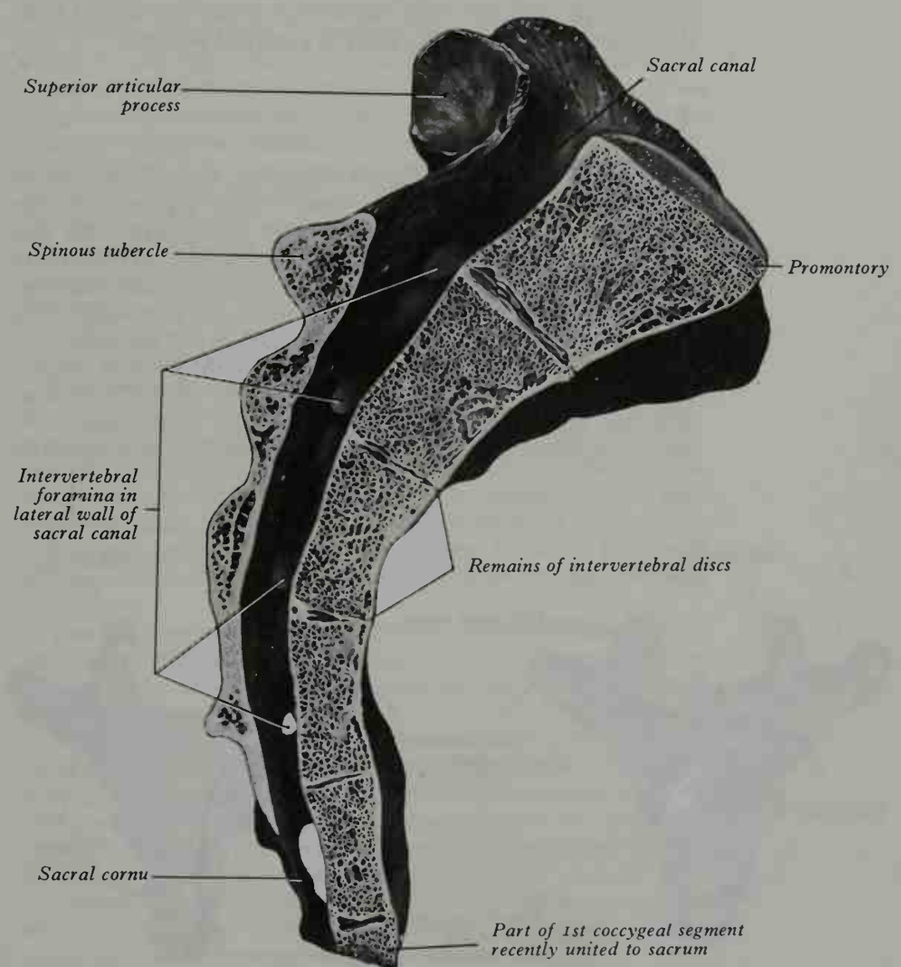
The sacral canal (3.47) is formed by the vertebral foramina of the sacral vertebrae and is triangular on transverse section. Its upper opening, seen on the basal surface, is set obliquely but, owing to the inclination of the sacrum, it is directed upwards in the erect position. The lateral wall of the canal presents four intervertebral foramina (3.47), through which the canal is connected with both the pelvic and the dorsal sacral foramina. The lower median opening is the *sacral hiatus*.

To the ventral and dorsal surfaces of the body of the first sacral vertebra are attached the lowest fibres of the anterior and posterior longitudinal ligaments. The upper borders of the laminae of the first sacral vertebra give attachment to the lowest pair of ligamenta flava. The upper surface of the lateral part is smooth and slightly concave in its medial part but is irregularly roughened laterally. It is covered almost entirely by the psoas major. The smooth area is marked by an oblique, shallow groove which lodges the lumbosacral trunk. The rough area gives attachment to the lower band of the iliolumbar ligament (p. 447) which lies lateral to the fifth lumbar spinal nerve, and to the ventral ligament of the sacro-iliac joint. The anterolateral part of the area affords attachment to a portion of the iliacus (3.43).



The pelvic surface of the sacrum gives origin on each side to the piriformis (3.43). On emerging from the pelvic sacral foramina the ventral rami of the first three sacral nerves pass at once on to the anterior surface of the muscle. Along the medial margins of the foramina, on each side, the sympathetic trunk descends in contact with bone, and in the median plane the median sacral vessels are a direct relation. Lateral to the foramina the lateral sacral vessels bear a variable relation to the bone. The ventral surfaces of the bodies of the first and second and part of the third sacral vertebra are covered with parietal peritoneum and crossed obliquely, to the left of the median plane, by the root of the sigmoid mesocolon. The rectum lies in contact with the pelvic surfaces of the bodies of the third, fourth and fifth sacral vertebrae, but the bifurcation of the superior rectal artery into right and left branches intervenes between it and the third sacral vertebra.

The dorsal surface of the sacrum is rough and irregular. The erector spinae arises by an elongated U-shaped origin from the spinous and transverse tubercles, and covers the multifidus, which arises from the intervening area (3.44). The dorsal rami of the upper three sacral spinal nerves pierce these muscles after they emerge from the dorsal sacral foramina.



The auricular surface is covered with hyaline cartilage in the recent state and is formed entirely by costal elements. It shows cranial and caudal elevations and an intervening central depression; in the elderly a third elevation is found dorsal to this depression. The rough area behind the auricular surface shows two or three well-marked depressions and gives attachment to the strong interosseous sacro-iliac ligaments. Below the auricular surface to the lateral aspect of the sacrum are attached the gluteus maximus, the sacrotuberous and sacrospinous ligaments and the coccygeus, the structures being enumerated from behind forwards.

The sacral canal (3.47) contains the cauda equina (including the filum terminale) and the spinal meninges. Near the mid level of the sacrum the subarachnoid and subdural spaces become closed, and the lower sacral nerve roots and the filum terminale pierce the arachnoid and dura mater at that level. The filum terminale emerges below at the sacral hiatus and passes downwards across the dorsal surface of the fifth sacral vertebra and the sacrococcygeal joint to reach the coccyx. The fifth sacral spinal nerves also emerge through the sacral hiatus close to the medial side of the sacral cornua and groove the lateral aspects of the fifth sacral vertebra.

No difficulty will be experienced in distinguishing typical male or female sacra, but, as the characters are not always pronounced, there are many cases in which this is by no means easy. In the female the sacrum is shorter and wider than in the male, producing the wider pelvic cavity. Sacral width expressed as a percentage of vertical length is known as the *sacral index* (*see*

3.46 The base of the sacrum in the male (A) and in the female (B). The body of the first segment (X) forms a larger part of the breadth of the base in the male than it does in the female. In the latter the body is relatively smaller and the lateral, costal part (Y) is relatively broader.

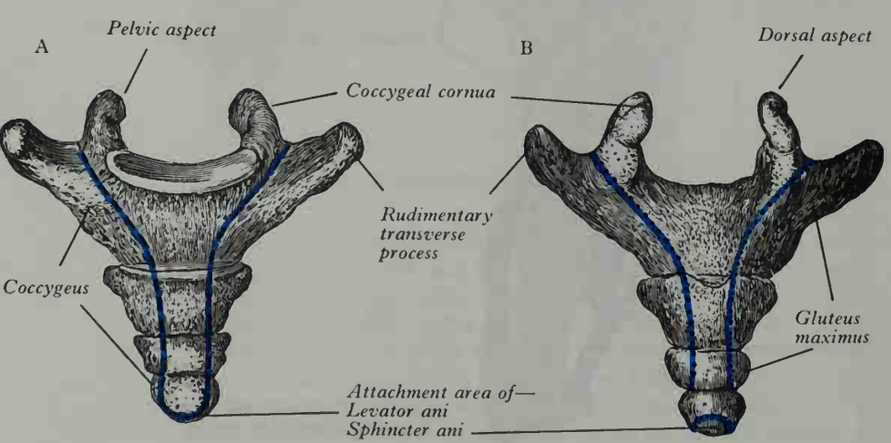
3.47 A median sagittal section through the sacrum.

p. 389). The ventral concavity of the sacrum is deeper in the female and its deepest point is usually placed at a higher level than in the male; the curvature is somewhat greater above this point in the female than in the male. The dorsal convexity produced by the protrusion of the second sacral vertebra (p. 389) occurs in both sexes but is usually less prominent in the male.

In the female the pelvic surface of the bone faces downwards more than in the male; this increases the size of the pelvic cavity and renders the sacrovertebral angle more prominent. In the female the auricular surface for articulation with the ilium is shorter than that in the male but in both sexes it usually extends along the sides of the first three sacral vertebrae. Owing to the great size of the body of the fifth lumbar vertebra the upper surface of the body of the first sacral vertebra occupies a larger proportion of the base of the sacrum in the male than it does in the female (**3**.46).

Structure. The sacrum consists of trabecular bone enveloped by a thin layer of compact bone.

Variations. The sacrum may consist of six vertebrae. There may be an additional sacral element or the last lumbar or first coccygeal vertebra may be incorporated. The inclusion of the fifth lumbar vertebra (*sacralization*) is usually incomplete and it may be limited to one or other side. In the most minor degree of the abnormality the transverse process of the fifth lumbar vertebra is unusually large, and articulates, sometimes by a synovial joint, with the sacrum at the dorsolateral angle of the base. Reduction of the number of the constituents of the sacrum is less common, but *lumbarization* of the first sacral vertebra does occur; it remains partially or completely separate from the rest of the sacrum. A considerable part of the dorsal wall of the sacral canal may be deficient, in consequence of imperfect development of the laminae and spines. The orientation of the superior sacral articular facets (and hence the relation between the planes of the two zygapophysial joints made with the fifth lumbar vertebra) displays wide variation according to Cihák (1970). The chords of the concave sacral facets formed an angle with the sagittal plane which varied from 20° to 90° in 132 sacra, the majority lying between 40° and 60°. The curvatures of the facets, and their degree of asymmetry, also varied to a marked extent.



The Coccyx

The coccyx (**3**.48A, B) is a small triangular bone, which consists usually of four rudimentary vertebrae fused together, but the number varies from five to three. Not infrequently, the first coccygeal vertebra is separate. The bone is directed downwards and ventrally from the apex of the sacrum, so that its pelvic surface faces up and forwards and its dorsal surface down and backwards. This orientation is, of course, varied by the mobility of the coccyx.

The *base*, formed by the upper surface of the body of the *first coccygeal vertebra*, presents an oval, articular facet which joints with the apex of the sacrum. Dorsolateral to the facet, two processes, the *coccygeal cornua*, project upwards to articulate with the sacral cornua; they are the homologues of the pedicles and superior articular processes of fully formed vertebrae. A rudimentary *transverse process* projects laterally and slightly upwards from each side of the body of the first coccygeal vertebra and may ascend to articulate or fuse with the inferior lateral angle of the sacrum. In that event five pairs of foramina exist in the sacrum.

The *second*, *third* and *fourth coccygeal vertebrae* diminish successively in size and are usually fused together. They are mere nodules of bone, which represent rudimentary vertebral bodies, although the second may show traces of transverse processes and pedicles.

The lateral parts of the *pelvic surface*, including the rudimentary transverse process, have attached to them the levatores ani and the coccygei. The ventral sacrococcygeal ligament is attached to the front of the body of the first, and may extend downwards to reach the second coccygeal vertebra (**4**.56). To the *cornua* are connected the intercornual ligaments. The interval between the body of the fifth sacral vertebra and the articulating sacral and the coccygeal cornua on each side represents the intervertebral foramen between the fifth sacral and the first coccygeal vertebrae, and transmits the fifth sacral nerve. The dorsal ramus of that nerve descends behind the rudimentary transverse process, but its ventral ramus passes forwards through a foramen between the transverse process and the sacrum, bounded laterally by the lateral sacrococcygeal ligament, which connects the process to the inferior lateral angle of the sacrum. The *dorsal surface* of the coccyx gives origin, on each side, to the gluteus maximus and, at its tip, to the sphincter ani externus. The median area gives attachment to the deep and superficial dorsal sacrococcygeal ligaments. The latter extends downwards from the margins of the sacral hiatus and may close the lower end of the sacral canal. The filum terminale, which is situated between the two ligaments, blends with them on the dorsal surface of the first coccygeal vertebra.

Ossification of the Vertebral Column

For the earlier stages of vertebral development consult p. 138 and illustration **2**.50.

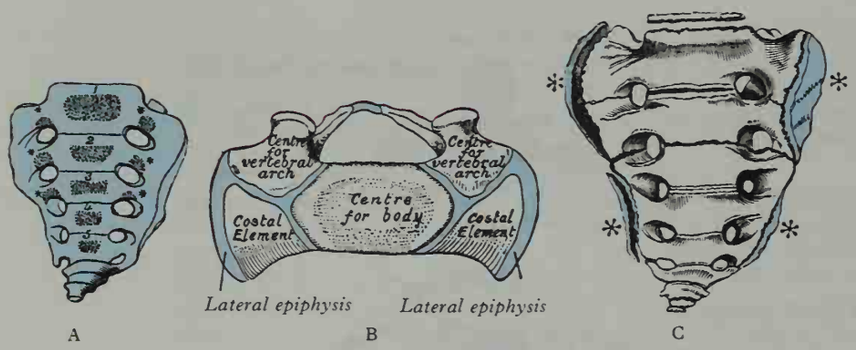
Each typical vertebra is ossified from three primary centres (**3**.49A), one in each half of the vertebral arch and one in the body. The primary centres in the vertebral arch appear at the roots of the transverse processes; ossification spread backwards into the laminae and spine, forwards into the pedicles and posterolateral portions of the body, laterally into the articular processes and upwards and downwards into the articular processes. The classical view has been that the centres in the *vertebral arches* appear first in the upper cervical vertebrae at the ninth to tenth week of intrauterine life, and subsequently in successively lower vertebrae, reaching the lower lumbar about the end of the third month. However, in a radiographic study of 195 unsexed human fetuses, of which 33 proved to lie in the age range appropriate to the present study (Bagnall *et al.* 1977), a pattern was found which differed substantially from the simple cranio-caudal sequence described above. A regular progression was not present in the cervical region. A group of centres first appeared in the lower cervical/upper thoracic region, quickly followed by a second group in the upper cervical region. After a short interval a third group appeared in lower thoracic/upper lumbar region, and the remaining centres then appeared, spreading regularly and rapidly in both cranial and caudal directions. The remaining, major portion of the body constitutes the *centrum* and is ossified from a primary centre which appears dorsal to the notochord. (The centrum is occasionally ossified from bilateral centres which sometimes fail to unite. The suppression of one of these centres leads to the formation of a wedge-shaped vertebra, and is well-recognized cause of lateral curvature of the vertebral column. The condition is frequently multiple.) This centre is first seen in the lower thoracic region at the ninth to tenth week of intrauterine life and then develops at successively higher and lower levels, reaching the second cervical vertebra by the end of the fourth month. In the study referred to above (Bagnall *et al.* 1977), the

3.49A–F Ossification of the vertebral column. A A typical vertebra. B A typical vertebra at puberty. C Body of a typical vertebra at puberty. D The atlas. E The axis. F A lumbar vertebra.

account just given was largely confirmed, but the earliest centres were found in the lower thoracic *and* upper lumbar regions; cranial progression was rather faster than caudal progression, the last centre to appear being for the centrum of the fifth sacral vertebra. (The latter, of course, ignores the much later and erratic ossification of the coccyx—*vide infra*.) During the first few years of life the centrum is connected to each half of the vertebral arch by a synchondrosis, termed the *neurocentral joint*. In the thoracic region the costal facets on the bodies lie behind the neurocentral joints. At birth a vertebra consists of three ossified elements, the centrum and the halves of the vertebral arch, united, of course, by cartilage. During the first year the halves of the arch unite behind, first in the lumbar region and then upwards through the thoracic and cervical regions. In the upper cervical vertebrae centra unite with arches about the third year, but in the lower lumbar vertebrae union is not completed until the sixth year. Until puberty the upper and lower surfaces of the bodies and the ends of the transverse and spinous processes are cartilaginous, but about this time five secondary centres appear, one for the tip of each transverse process, one for the end of the spinous process, and two annular epiphysial rings for the circumferential parts of the upper and lower surfaces of the body (**3**.38, 49B and C). The costal articular facets are extensions of the annular epiphysial rings (Dixon 1920). These secondary centres fuse with the rest of the bone about the age of 25 years. In the bifid spinous processes of the cervical vertebrae there are two secondary centres. It is doubtful whether the annular 'epiphyses' of vertebrae can be equated with the epiphyses of long bones. In most mammals the vertebral epiphyses are complete osseous discs. For discussion of these arrangements consult François and Dhem (1974).

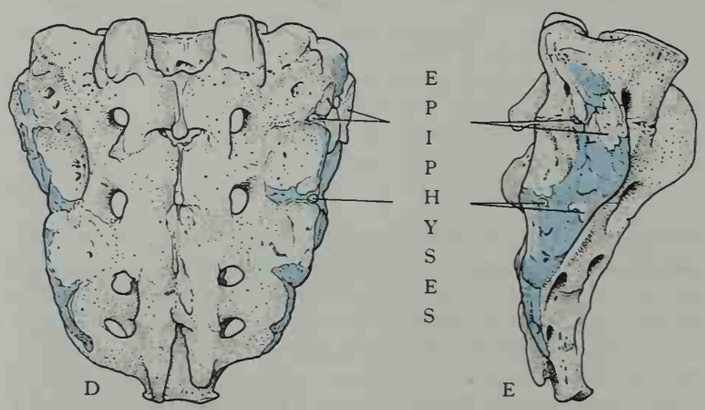
Exceptions to this mode of ossification occur in the first, second and seventh cervical, and in the lumbar vertebrae.

The atlas is usually ossified from three centres (**3**.49D). One appears in each lateral mass about the seventh week of intrauterine life, and gradually extends into the posterior arch, where the two unite between the third and fourth years, either directly or through the medium of a separate centre. At birth, the anterior arch consists of fibrocartilage; in this a separate centre appears about the end of the first year, and unites with the lateral masses between the sixth and eighth years—the lines of union extending across the anterior portions of the superior articular facets. Occasionally the anterior arch is formed by the forward extension and ultimate union of the centres for the lateral masses; sometimes it is ossified from two laterally placed centres.



The axis is ossified from five primary and two secondary centres (**3**.49E). The vertebral arch is ossified from two primary centres, and the centrum from one, as in a typical vertebra; the centres for the arch appear about the seventh or eighth week of intrauterine life, the centre for the centrum about the fourth or fifth month. The dens is ossified almost entirely from two laterally placed centres; these appear about the sixth month of intrauterine life, and join before birth to form a conical bony mass, deeply cleft by cartilage above. A wedge-shaped piece of cartilage fills the cleft and forms the summit of the process: in this cartilage a centre appears about the second year and unites with the main mass of the process about the twelfth year. It is regarded as representing a part of the cranial sclerotome half of the first cervical segment or the *pro-atlas* (Gadow and Green 1933). The base of the process is separated from the body of the axis by a cartilaginous disc, the circumference of which ossifies, but the centre remains cartilaginous until advanced age; in this cartilaginous disc what are possibly rudiments of the lower epiphysial lamella of the atlas and the upper epiphysial lamella of the axis may sometimes be found. In addition a thin epiphysial plate is formed on the under surface of the body of the bone about the time of puberty. It has long been held, almost universally, that the dens represents the centrum of the atlas, secondarily fused with cranial aspect of the centrum of the axis. Considerable doubt has now been cast on this traditional view following comparative morphological and developmental studies on a variety of mammals by Jenkins (1969), who regards the dens as a new formation. On the other hand, Ganguly and Singh-Roy (1965) consider that the apical centre for the dens is derived from the *pro-atlas*, and the latter may also contribute to the lateral masses of the atlas. Torklus and Gehle (1968) consider that the dens is the centrum of the pro-atlas.

The seventh cervical vertebra shows an additional feature in that the costal processes are usually ossified from separate centres, which appear about the sixth month of intrauterine life, and join the body and transverse processes between the fifth and sixth years. As already stated (p. 274), the costal processes may remain separate, and grow laterally and forwards, as cervical ribs.



Separate ossific centres have also been found in the costal processes of the fourth, fifth and sixth cervical vertebrae. (See also p. 292.)

The lumbar vertebrae (**3**.49F) have two additional centres, one for each mamillary process. In the fifth lumbar vertebra there is also a pair of scale-like epiphyses on the tips of the costal elements.

The sacrum (**3**.50A–E) resembles a typical vertebra in the ossification of each of its vertebral segments. Primary centres for the centrum and each half of the vertebral arch appear between the tenth and twentieth weeks. Primary centres for the costal elements of the upper three or more sacral vertebrae appear, above and lateral to the pelvic sacral foramina, between the sixth and eighth months of intrauterine life. The costal element unites with its half of the vertebral arch between the second and fifth years, and the conjoined element so formed unites ventrally with the centrum and dorsally with its fellow of the opposite side about

3.50D and E The epiphyses of the costal and transverse process of the sacrum at the eighteenth year.

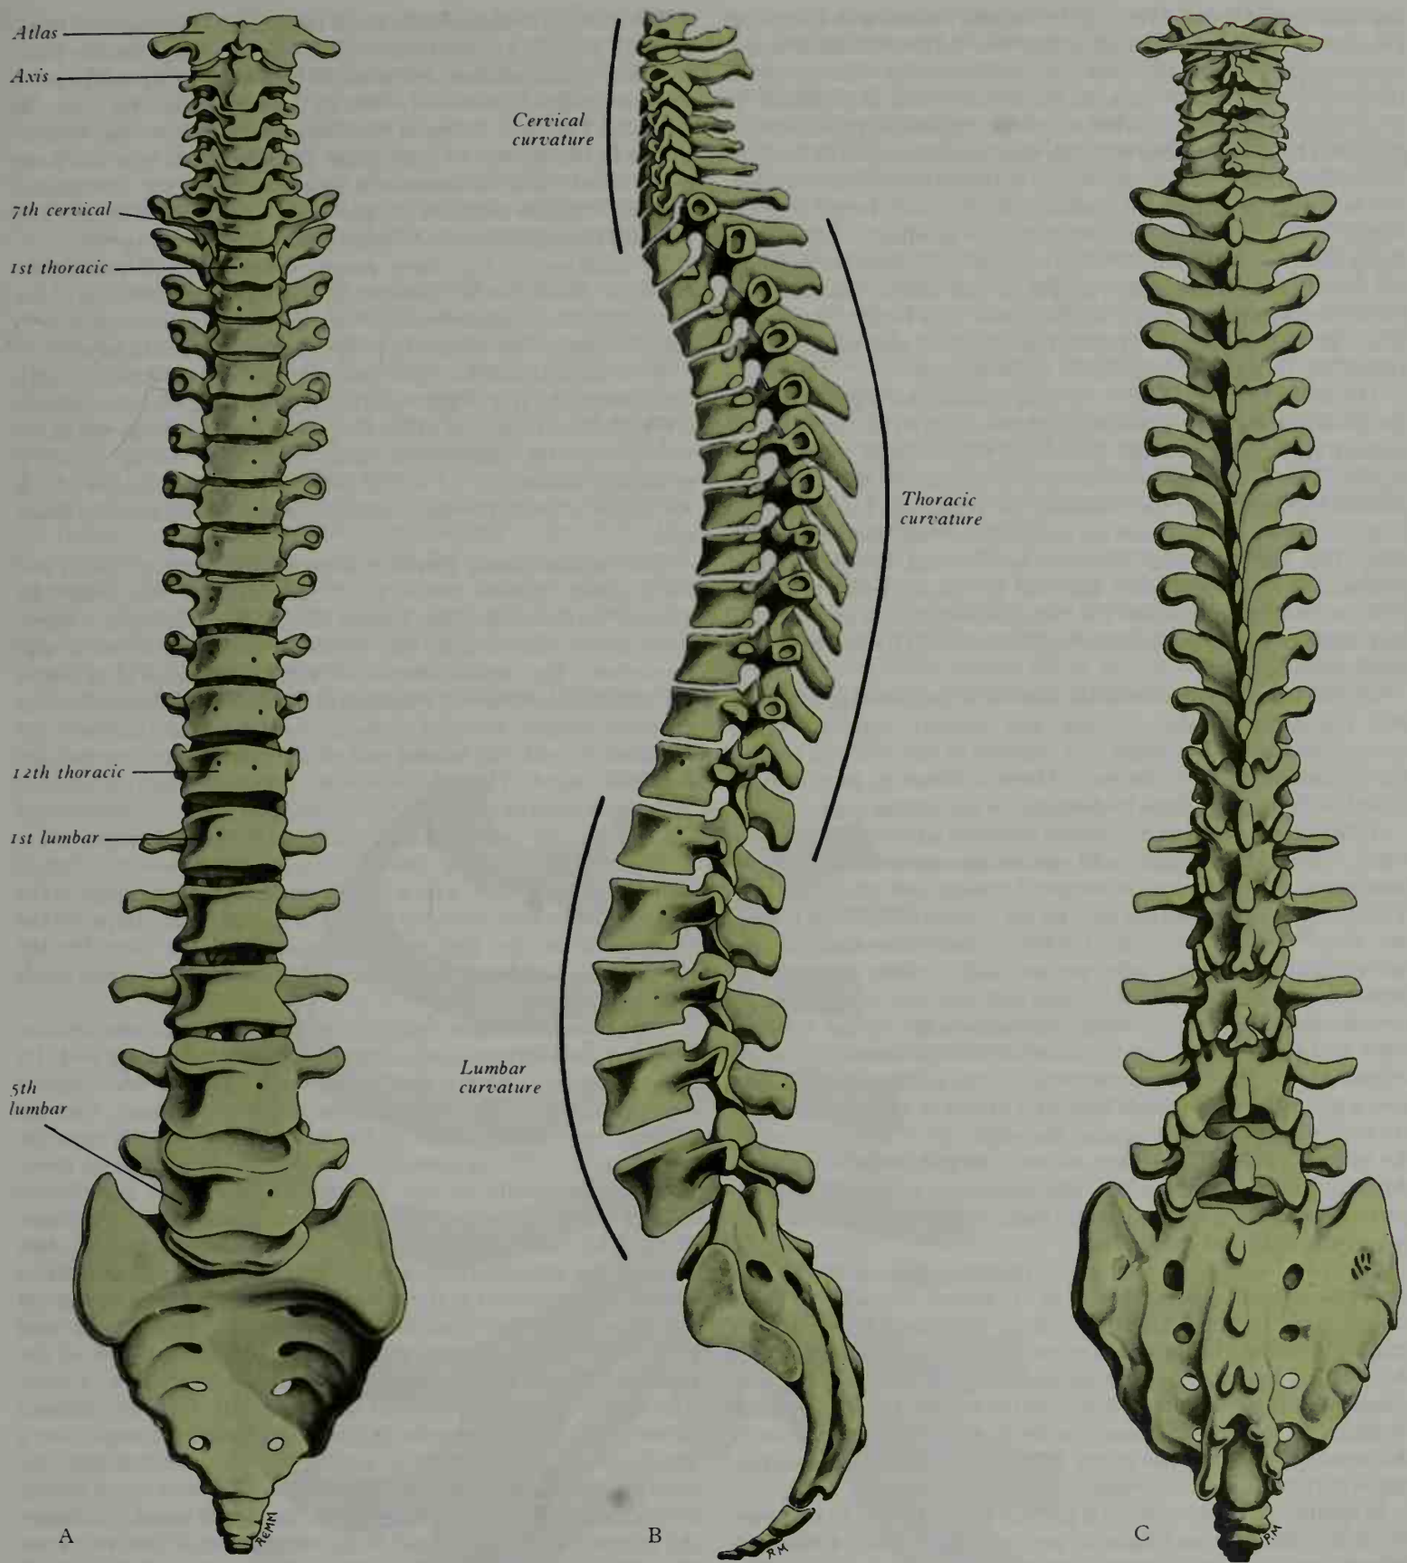
the eighth year. When this has occurred the upper and lower surfaces of the body of each sacral vertebra are covered by an epiphysial plate of cartilage which is separated from its neighbour by a plate of fibrocartilage representing an intervertebral disc. Laterally the successive conjoined vertebral arches and costal elements are separated by hyaline cartilage and there is a cartilaginous epiphysis, sometimes divided into upper and lower parts, on the auricular surface and lower part of the lateral surface of the bone. Soon after puberty the conjoined vertebral arches and costal elements of adjacent vertebrae begin to fuse with one another from below upwards. At the same time epiphysial centres develop (1) for the upper and lower surfaces of the bodies, (2) for the spinous tubercles, (3) fo r the transverse tubercles and (4) for the costal elements. The costal epiphysial centres appear at the lateral extremities of the hyaline cartilages which intervene between adjacent costal elements. Two such centres, placed anteriorly and posteriorly, appear in each of the intervals between the first and second and the second and third sacral vertebrae. From these ossification spreads into the epiphysial plate covering the auricular surface. One costal epiphysial centre, placed anteriorly, appears in each of the remaining intervals and from them ossification spreads to the epiphysial plate covering the lower part of the lateral surface of the sacrum.

The bodies of the sacral vertebrae unite with one another at their adjacent margins after the twentieth year but the central area and greater part of each intervertebral disc remains unossified up or or even after middle life; available information is based on relatively few specimens (Fawcett 1907; McKern and Stewart 1957).

The coccyx. Each segment of the coccyx is ossified from one primary centre but the incidence and times of ossification are imperfectly known. The centre for the first segment appears about birth and its cornua may ossify from separate centres appearing soon after birth. The remaining segments ossify at widely separated intervals up to the twentieth year or later. As age advances, the segments unite with one another, the union between the first and second being frequently delayed until the age of 30 years. At a late period of life, esp ecially in females, the coccyx often fuses with the sacrum.

The Vertebral Curvatures

The vertebral column is median and dorsal in the body—the common vertebrate plan. In the human male its length is about 70 cm, its cervical part measuring approximately 12 cm, thoracic 28 cm, lumbar 18 cm, and sacrum and coccyx 12 cm. In the female the total length is about 60 cm.



The curves of the vertebral column viewed from the side (**3**.51B), are cervical, thoracic, lumbar and pelvic. The thoracic and pelvic curves are *primary*; they are concave ventrally during fetal life and retain the same curvature after birth. The cervical and lumbar curves are *secondary* or compensatory; the cervical curve appears in intrauterine life and is further accentuated when the child is able to hold up its head (at three or four months), and to sit upright (about nine months); the lumbar curve appears at twelve to eighteen months, when the child begins to walk; its development is neccessary to bring the centre of gravity of the trunk over the legs. This change in the mechanics of the lumbar region appears to be a potent factor in the necessary alterations in the proportions of the vertebral bodies and the intervertebral discs, especially in the fifth lumbar vertebra and the disc below it (Taylor 1975). It should be noted that although it has long been held that the secondary cervical curve first appears either late in intrauterine life, or early in postnatal life, this view has recently been challenged (Bagnall *et al.* 1977). In a careful radiographic study of 195 human fetuses ranging in conceptual age from 8 to 23 weeks, it was shown that 83 per cent already possessed a cervical curve as soon as the ossification centres became sufficiently radio-opaque—namely 9½ weeks. Further, these authors emphasized the importance of the early onset of *fetal movements*, in relation to the emergence of an identifiable cervical curve.

In the adult, the *cervical* curve is convex forwards, and is the least marked; it begins at the atlas, and ends at the second thoracic vertebra. The *thoracic* curve is concave forwards, and reaches from the second to the twelfth thoracic vertebra; it is caused by the greater depth of the posterior parts of the vertebral bodies. The *lumbar* curve is convex forwards and is more pronounced in the female than in the male; it reaches from the last thoracic vertebra to the lumbosacral angle, and the convexity of the lower three segments is greater than that of the upper two; it is caused mainly by the greater depth of the anterior parts of the intervertebral discs, but the shape of the vertebral bodies also helps to produce it. Sex differences in the lumbar curvature, and also in the cervical region, are confirmed by Knussman and Finke (1977). The *pelvic* curve extends from the lumbosacral joint to the apex of the coccyx; its concavity faces downwards and forwards.

In the upper part of the thoracic region of the vertebral column there is often a slight *lateral* curvature, with its convexity directed towards the right side in right-handed persons, and to the opposite side in the left-handed.

When viewed from the front (**3**.51A), the width of the vertebral bodies is seen to increase from the second cervical to the third lumbar vertebra. This change is associated with the increase in weight bearing from above downwards. There is some variation in the size of the bodies of the last two lumbar vertebrae, but thereafter the width diminishes rapidly to the apex of the coccyx. In the last two lumbar vertebrae there is an inverse relation between the areas of the upper and lower surfaces of the bodies and the size of the pedicles and transverse processes which suggests that the latter transmit some of the vertebral compressive forces from the spine to the pelvis (Davis 1961). In a detailed dimensional study of primate lumbar vertebrae, human and otherwise, Rose (1975) considered that the size of their bodies is as much concerned with bending as compressive stresses. He also indicated that in man only the *fifth* body *regularly* displays a greater depth ventrally, concluding that other factors must also contribute to the lumbar curvature: as noted above this is principally the conformation of the intervertebral discs.

The posterior surface of the column presents the spinous processes of the vertebrae in the median plane (**3**.51C). In the cervical region (with the exception of the second and seventh vertebrae) these are short and nearly horizontal, with bifid ends. In the upper part of the thoracic region they are directed obliquely downwards; in the middle part they are long and almost vertical; in the lower part of the thoracic region and in the lumbar region

3.51A–C The vertebral column. A Anterior aspect. B Lateral aspect. (Note curvatures.) C Dorsal aspect. (Note slight thoracic curvature to left.)

they are nearly horizontal. They are separated by considerable intervals in the cervical and lumbar regions, but are closely approximated in the middle of the thoracic region. Occasionally a spinous process may deviate from the median plane—a fact to be remembered in practice, as irregularities of this sort occur also in fractures or dislocations of the vertebral column. The seventh cervical can be felt at the lower end of the nuchal furrow, and below it the first and the second thoracic are prominent. The third thoracic lies opposite the root of the scapular spine and the seventh lies opposite the inferior angle of the scapula, provided that the arm is at rest by the side. The spine of the fourth lumbar vertebra lies on a level with the highest parts of the iliac crests and that of the second sacral vertebra with the posterior superior iliac spines. At the sides of the spinous processes the *vertebral grooves* contain the deep muscles of the back. In the cervical and lumbar regions these grooves are shallow and are formed by laminae; in the thoracic region they are deep and wide, and are formed by laminae and transverse processes. Lateral to the laminae are the articular processes, and still more lateral the transverse processes. In the thoracic region the transverse processes lie on a plane considerably behind that of the same processes in the cervical and lumbar regions. In the cervical region the transverse processes are placed in front of the articular processes, lateral to the pedicles, and between the intervertebral foramina. In the thoracic region

they are behind the pedicles, intervertebral foramina and articular processes. In the lumbar region they are in front of the articular processes, but behind the intervertebral foramina. The size of the transverse processes of the atlas has already been emphasized (p. 273), and the breadth from the tip of one transverse process to the other has been contrasted with the same measurement in the axis. Breadth varies little from the second to the sixth cervical vertebra, but in the seventh it shows a substantial increase. In the thoracic region it is greatest in the first and then gradually diminishes, being least in the twelfth, where the transverse process elements are usually reduced to mere vestiges. In the first lumbar vertebra the measurement is greater; in the second it is further increased; while in the third it is greater than it is in any of the other vertebrae. In the fourth and fifth it diminishes.

The *lateral aspects* of the vertebral column are separated from the posterior surface by the articular processes in the cervical and lumbar regions, and by the transverse processes in the thoracic region. The anterior part of the lateral surface of the column is formed by the sides of the bodies of the vertebrae, marked in the thoracic region by the facets for articulation with the heads of the ribs. The intervertebral foramina are behind the bodies and between the pedicles; they are oval in shape, smallest in the cervical and upper part of the thoracic regions, and gradually increasing in size to the last lumbar; they contain the spinal nerves and vessels.

The *vertebral canal* follows the curves of the column; it is large and triangular in the cervical and lumbar regions, where movement is free, but small and circular in the thoracic region, where motion is more limited. These differences may also be linked with the variations in diameter of the spinal cord.

Although the range of movement between adjacent vertebrae is small, these small ranges add up to considerable degrees of bending or rotation over the vertebral column as a whole (p. 445). The intervertebral discs not only tie the vertebrae together but are the sites of all movement between them. By their elastic deformability they not only permit slight tilting and torsion between adjoining vertebral bodies, but they also provide a very considerable element of compressibility in the spinal column. This ability to absorb and neutralize compression stresses is augmented by the sinuous curvature of the column itself; forces which would be transmitted from end to end of a straight column are expended completely against the slight 'give' and recovery of the spinal curves. The effects of body weight, muscle pull and thrust due to impact of the feet, whether trivial as in walking, or of greater magnitude, in running and jumping, are largely smoothed out by the discs and curvatures.

Applied Anatomy. Fractures or fracture dislocations of the vertebral column are the result of (1) forced flexion, e.g. by a violent blow on the back from a large object, and (2) violence transmitted along the long axis of the column, e.g. by falling on to the feet from a height, or by diving on to the head. In the first group the injury commonly occurs at the level of the fifth or sixth thoracic. In the second group, owing to the normal curvature of the vertebral column, the injury is also a flexion fracture and its site is between the ninth thoracic and second lumbar.

In spondylolisthesis, which is present in 5 per cent of skeletons, the spine, laminae and inferior articular processes of the fifth (sometimes the fourth) lumbar vertebra are united to one another but are separate from the rest of the bone. The condition may give rise to low back pain and is usually regarded as due to a congenital defect. It has been suggested that each part of the vertebral arch ossifies from two primary centres which fail to fuse but there is no evidence for this.

The Sternum

The sternum is probably confined to land vertebrates; it is absent in fish. The elongate form seen in the human skeleton is typical of mammals, the sternum being more of a complex plate in amphibians and reptiles. It has been associated with both the shoulder girdles and the ribs from its earliest appearance, but is usually considered to be axial in nature. The details of its embryonic development, including its ossification, indicate a separate origin from the ribs.

The human sternum, as is usual in mammals, consists of three parts (**3**.52, 53): a cranial element, the *manubrium*; a middle part, the *body* or *mesosternum*; and a caudal element, the *xiphoid process*. Its total length in males is about 17 cm and considerably less in females. The ratio between manubrial and mesosternal lengths differs in the sexes, but clear racial characteristics have not been established. Such estimates are complicated by the probability that the sternum continues to grow beyond the third decade and perhaps throughout life (Ashley 1956, Rother *et al.* 1976).

In addition to the three major sections noted above, the sternum shows further division in its body, which in early life consists of four segments or *sternebrae*; from their relationship to the ribs sternebrae appear to be intersegmental in character.

In its natural position the sternum is inclined downwards and a little forwards. It is slightly convex in front, and concave behind; it is broadest at the level of the first costal cartilages, narrow at the junction of the manubrium with the body, below which it gradually widens as far as the level of the articulations of the cartilages of the fifth ribs, and then narrows quickly to its lower end.

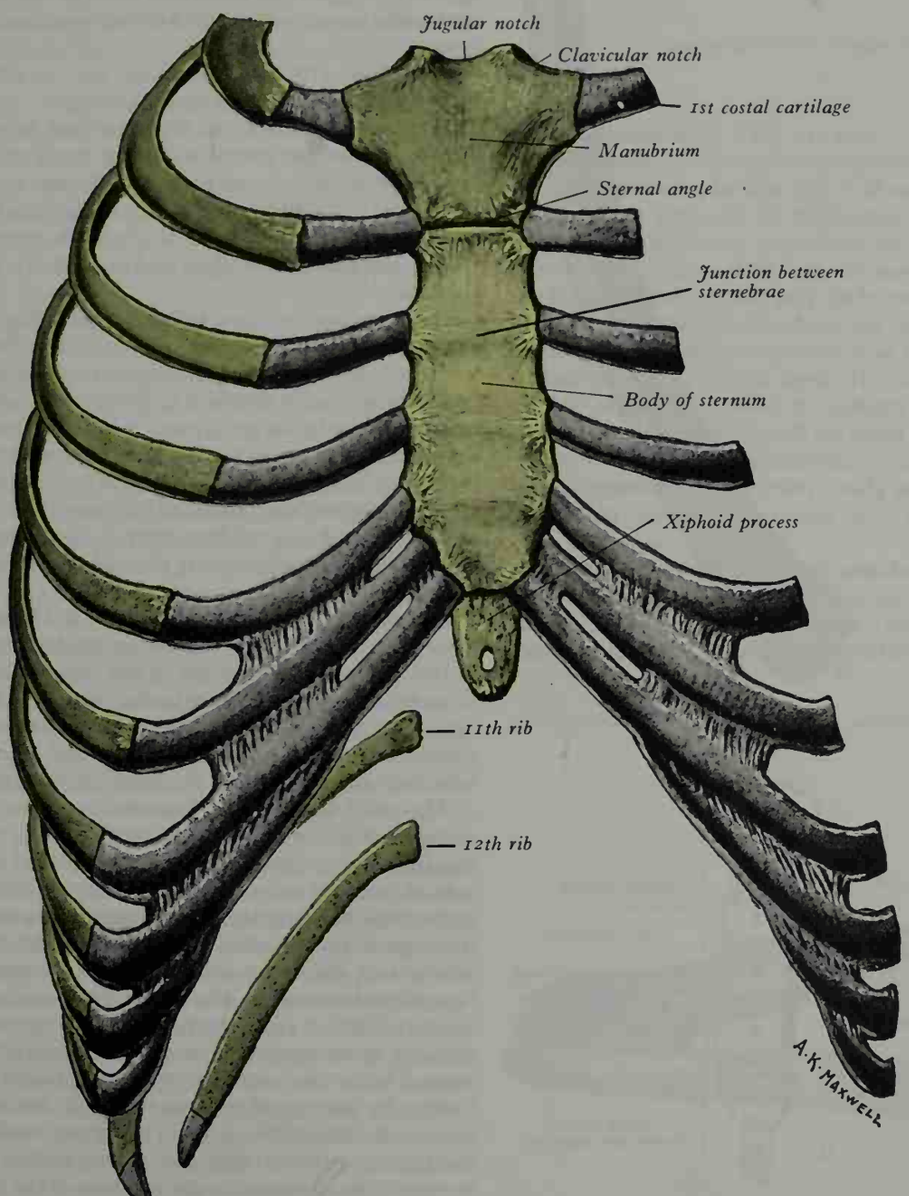
The manubrium sterni is somewhat triangular, broad and thick above, narrow below at its junction with the body. Its *anterior surface* is smooth, convex from side to side and concave from above downwards. Its *posterior surface* is concave and featureless. The *superior border* is thick, and presents at its centre the *jugular (suprasternal) notch*; on each side of this there is an oval articular surface, directed upwards, backwards and laterally, for articulation with the sternal end of the clavicle, and termed the *clavicular notch*. The *inferior border*, oval and rough, is covered with a thin layer of cartilage, for articulation with the upper end of the body. The *lateral borders* are each marked above by a depression for the first costal cartilage, and below by a small articular facet, which, with a similar one on the upper angle of the body, forms a joint with the second costal cartilage. Between the depression for the first costal cartilage and the facet for the second, the narrow curved edge slopes from above downwards and medially.

The mesosternum (body) is longer, narrower and thinner than the manubrium, and is broadest close to its lower end. Its *anterior surface*, nearly flat, is directed forwards and slightly upwards, and is marked by three transverse ridges, variably defined, marking the lines of fusion of four originally separate *sternebrae* (p. 288). A *sternal foramen*, of varying size and form, occurs occasionally at the junction of the third and fourth sternebrae (p. 288). The *posterior surface*, slightly concave, is also marked by three transverse lines, less distinct, however, than those on the anterior surface. The *upper end* is oval and articulates with the manubrium at the *sternal angle*, which forms a ridge on the anterior surface that can usually be felt through the skin without difficulty. On the posterior surface the position of the manubriosternal joint is marked by a transverse groove (**3**.53A). The *lower end* is narrow, and is continuous with the xiphoid process. Each *lateral border* (**3**.53B), at its superior angle, has a small notch, which, with a similar one on the manubrium, receives the second costal cartilage; below this, four *costal notches* articulate with the third, fourth, fifth and sixth costal cartilages; the inferior angle has a small facet, which, with a similar one on the xiphoid process, forms a notch for the reception of the seventh costal cartilage. These articular depressions are separated by a series of curved edges, which diminish in length from above downwards, and correspond to the anterior ends of the intercostal spaces.

The xiphoid process is the smallest and most variable part of the sternum. It may be broad and thin, pointed, bifid, perforated, curved or deflected to one side or the other. It is cartilaginous in youth, but, at its upper part, more or less ossified in the adult. Above, it is continuous with the lower end of the body of the bone, and on the front of each superior angle there is a facet for a part of the cartilage of the seventh rib (**3**.53).

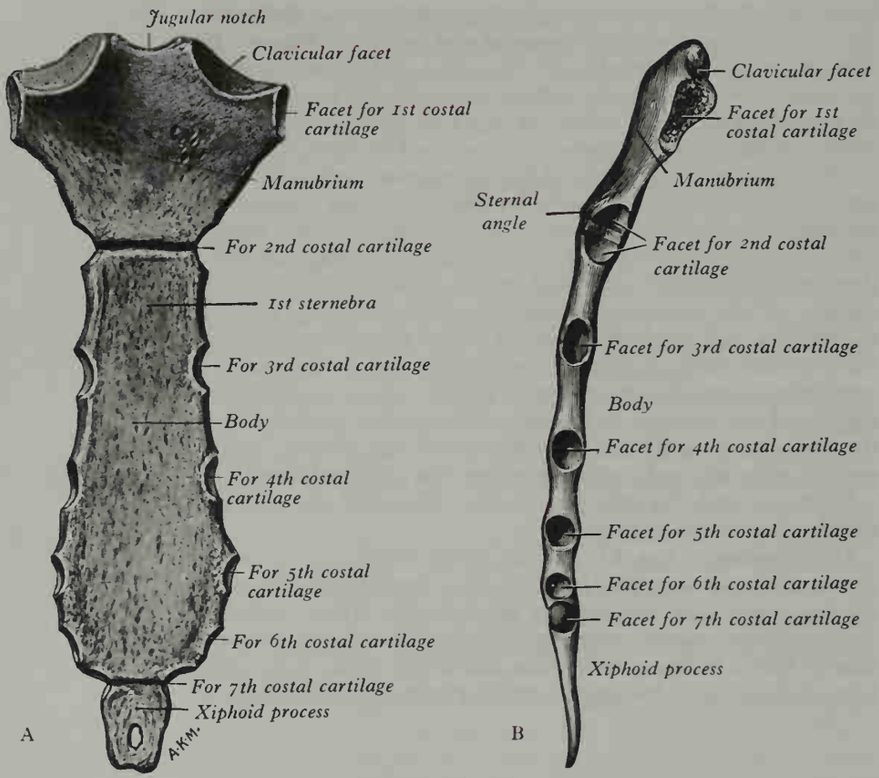
The manubrium is level with the third and fourth thoracic vertebrae. Its *anterior surface*, on each side, gives attachment to the sternal origins of the pectoralis major and sternocleidomastoid. To its *posterior surface* are attached the sternothyroid, opposite the first costal cartilage; above this level the most medial

fibres of the sternohyoid usually arise from the bone. This surface forms the anterior boundary of the superior mediastinum; its lower part is related to the arch of the aorta, and its upper part to the left brachiocephalic vein and the brachiocephalic, left common carotoid and left subclavian arteries. Its lateral portions are related to the lungs and pleurae. The *jugular notch* gives attachment to some of the fibres of the interclavicular ligament. On the *lateral border* the junction between the manubrium and the first costal cartilage is a synchondrosis in contrast to the other sternocostal joints.



The sternal body lies opposite the fifth to ninth thoracic vertebrae. Its *anterior surface* gives attachment, on each side, to the articular capsules of the sternocostal joints and to the sternal origin of the pectoralis major. Its *posterior surface* affords origin inferiorly to the transversus thoracis (sternocostalis), and has numerous important relationships. On the right of the median plane it is related to the right pleura and the thin, anterior border of the right lung, which intervene between it and the pericardium. To the left the upper two sternebrae are related to the left pleura and lung, but the lower two are directly related to the pericardium. The *borders* give attachment to the external intercostal membranes in the intervals between the costal notches. With the exceptions of the first and the sixth, the cartilages of the true ribs articulate with the sternum at the lines of junction of its primitive component segments.

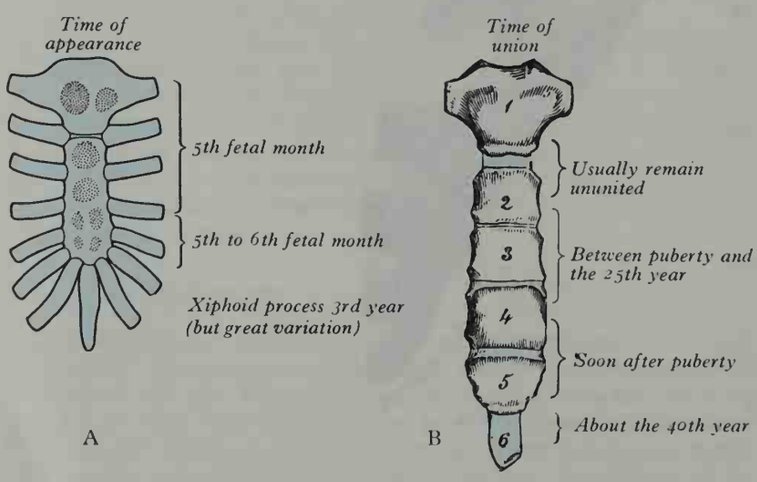
The xiphoid process lies in the epigastric region. To its *anterior surface* are attached the most medial fibres of the rectus abdominis and the aponeuroses of the external and internal obliques. Its *lower end* gives attachment to the linea alba, and its *borders* to the aponeuroses of the internal oblique and transversus abdominis. Its *posterior aspect* gives origin, on each side, to some of the fibres of the diaphragm, and is related to the anterior surface of the liver.



The sternum is composed of highly vascular trabecular bone covered by a compact layer which is thickest in the manubrium between the clavicular notches. The spaces in the spongy substance contain *red* marrow. The internal trabecular pattern of the manubrium and the first and second sternebrae has been the subject of an intensive examination by scanning electron microscopy and computer analysis of its metrical parameters (Whitehouse 1975). Centrally the bone is lightly constructed, trabeculae being thicker and more widely spaced in the lateral regions of the sternum. No mechanical or other explanation of these variations, or of the noted differences in the patterns already studied in the ribs and lumbar vertebrae, has yet been formulated.

Pismenov and Zapetski (1977) have described the vascular supply of the sternum in detail.

Ossification (3.54A, B). The sternum is formed by the fusion of two cartilaginous *sternal plates* (p. 141), one on each side of the median plane. The number and arrangement of the centres of ossification are variable and are related to the completeness and time of fusion of the sternal plates and to the width of the adult bone (Ashley 1956). Incomplete fusion results in the presence of a



3.52 The sternum and costal cartilages. Anterior aspect.

3.53 The sternum. A Posterior aspect. B Lateral aspect.

sternal foramen in the adult bone (p. 286). The manubrium is ossified from one, two or even three centres which appear in the fifth month of fetal life. The first and second sternebrae usually ossify from single centres appearing in the fifth month. The centres of ossification in the third and fourth sternebrae are generally paired and appear in the fifth and sixth months respectively, but one member of the pair may be delayed until the seventh or even eighth month, and the fourth sternebral centre may be absent (Paterson 1904). The xiphoid process begins to ossify in the third year or much later. In some sterna all the centres of ossification are single and median; in others the centre for the manubrium is single whilst those for the sternebrae are all paired, and may be symmetrical or asymmetrical. Union between the centres for the body begins about puberty, and proceeds from below upwards; by the age of 25 they are all united (see also p. 452).

Suprasternal ossicles, which may be paired or single, are present in about 7 per cent of sterna. They may be fused to the manubrium or articulate with it at the lateral border of the jugular notch posteriorly. When well formed they are pyramidal in shape,

3.54A and B The ossification of the sternum. A Before birth. B At puberty.

the base of the pyramid forming the articular surface. Cartilaginous at birth, they become ossified during adolescence.

The Ribs

The ribs are elastic arches of bone, which are connected behind with the vertebral column, and form a large part of the skeleton of the thorax. There are twelve pairs, but this number may be increased by the development of a cervical or a lumbar rib, or may be reduced to eleven by the absence of the twelfth pair. The first seven pairs are connected in front, through the costal cartilages, to the sternum (**3**.52); they are called *true* ribs. The remaining five are so-called *false* ribs; of these the cartilages of the eighth, ninth and tenth are joined to the cartilage of the rib immediately above; the eleventh and twelfth are free at their anterior ends, and are *floating* ribs. (The latter statement requires qualification: the tenth rib is also *usually* 'floating' in Japanese, a condition also recorded in other races: *see* p. 291.)

The ribs are situated one below the other in such a manner that *intercostal spaces* intervene. These are deeper in front than behind, and deeper between the upper than between the lower ribs. The ribs vary in direction, the upper ones being less oblique than the lower; the obliquity reaches its maximum at the ninth rib, and gradually decreases to the twelfth. The ribs increase in length from the first to the seventh, and then diminish to the twelfth. In breadth they decrease successively from above downwards; in the upper ten the greatest breadth is at the anterior extremity. The first two and the last three ribs present special features, but the remaining seven conform to a common plan and are referred to as typical.

A typical rib has a posterior and an anterior end, and an intervening portion—the shaft (**3**.55, 56).

The *anterior end* can be distinguished by a small cup-shaped depression, for the lateral end of the costal cartilage. The shaft is curved with the convexity outwards, and is grooved along the lower part of its inner surface so that the lower border of the shaft is thin and sharp in contrast to the thick, rounded upper border.

The *posterior or vertebral end* possesses a head, a neck and a tubercle.

The *head* presents two facets, separated by a transverse ridge, named the *crest*. The lower facet, which is the larger, articulates with the body of the numerically corresponding vertebra, and the crest of the head is attached to the intervertebral disc.

The *neck* is the flattened portion which succeeds the head; it lies in front of the transverse process of the corresponding vertebra. It is oblique, so that its anterior surface faces forwards and upwards. Its posterior surface is directed backwards and downwards, and is roughened and pierced by numerous foramina. Its upper border is sharp and forms the *crest of the neck of the rib*: its lower border is rounded.

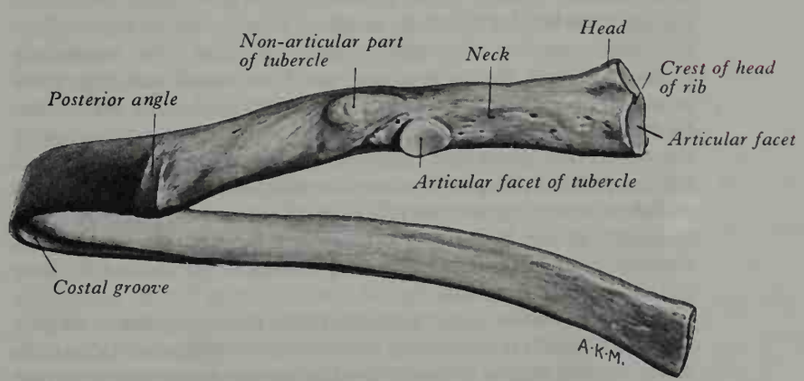
The *tubercle* is on the outer surface of the posterior part of the rib, at the junction of the neck with the shaft; it is more prominent in the upper than in the lower ribs and is divided into a medial articular and a lateral non-articular portion. The articular portion bears a small, oval facet for articulation with the transverse process of the numerically corresponding vertebra; the non-articular portion is rough for ligamentous attachments.

The *shaft* is thin and flattened, with external and internal surfaces, superior and inferior borders. It is not only curved but also bent, the *posterior angle* (often simplified to 'the angle'), being 5–6 cm from the tubercle. The shaft is twisted in its long axis, as is apparent if the rib is placed on a horizontal surface. The part behind the angle inclines medially and upwards, and its outer surface faces downwards and backwards; in front of the angle the outer surface faces slightly upwards. The *external surface* is convex and smooth. A short distance from the tubercle it is crossed by a rough line, directed downwards and laterally, the position of the (posterior) *angle*. The *internal surface* is smooth and is marked along its lower border by the *costal groove*, which is bounded below by the inferior border of the shaft. The upper border of the groove is continuous behind with the lower border of the neck, but anteriorly it terminates at the junction of the middle and anterior thirds of the shaft; in front of this point, the groove is absent. (*Vide infra* concerning the *anterior angle*.)

The first rib (3.57) is the most curved and usually the shortest of the ribs; it is broad and flat, its surfaces facing 'upwards' and 'downwards' and its borders inwards and outwards. It is placed very obliquely in the body, sloping downwards and forwards from its vertebral to its sternal end. The *head* is small and rounded, and bears a single, nearly circular, articular facet, which articulates with the body of the first thoracic vertebra. The *neck* is rounded, and directed upwards, backwards and laterally. The *tubercle*, wide and prominent, is directed upwards and backwards; medially an oval facet articulates with the transverse process of the first thoracic vertebra. At the tubercle the rib is bent, so that the head of the bone is directed slightly downwards; the angle and the tubercle therefore coincide. The *upper surface* of the shaft is crossed obliquely by two shallow grooves, separated from each other by a slight ridge, which ends at the inner border of the rib in a small projection, the *scalene tubercle*. The *under surface* is smooth and has no costal groove. The *outer border* is convex, thick behind, but thin in front. The *inner border* is concave and thin, and marked near its centre by the scalene tubercle. The *anterior end* is larger and thicker than in any other rib.

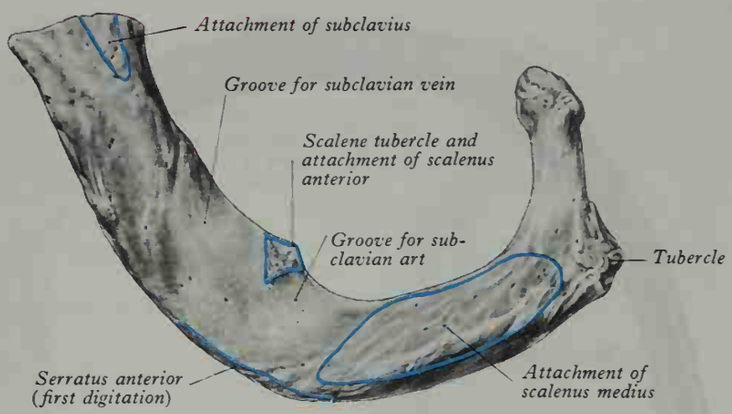
The second rib (3.58) is about twice the length of the first, but has a similar curvature. The non-articular portion of the *tubercle* is often small. The *angle* is slight, and close to the tubercle. The *shaft* is not twisted, so that both ends touch any plane surface upon which the rib may be laid; but at the tubercle there is an upward convexity, similar to, but smaller than, that in the first rib. The *external surface* of the shaft is convex, and looks upwards and a little outwards; near its middle it is marked by a rough, muscular impression. The *internal surface*, smooth and concave, is directed downwards and a little inwards; on its posterior part there is a short costal groove.

The tenth rib has a single articular facet on its head, which may articulate with the intervertebral disc above as well as with the upper border of the tenth thoracic vertebra close to its pedicle.



The eleventh and twelfth ribs (3.59) each have a single, relatively large, articular facet on the head; they have no necks or tubercles; their anterior ends are pointed and tipped with cartilage. The eleventh has a slight angle and a shallow costal groove. The twelfth has neither; it is much shorter than the eleventh, and its vertebral end is directed slightly upwards. The inner surfaces of both ribs look *upwards* as well as inwards, the upward inclination being more marked in the twelfth.

The *head of a typical rib* gives attachment along its anterior border to the radiate ligament, and on its crest to the intra-articular ligament. The anterior surface of the head is related to the costal pleura, and, in the lower ribs, to the sympathetic trunk. The *anterior surface* of the neck is divided into an upper and a lower area by a faint ridge, which affords attachment to the internal intercostal membrane and is continuous with the inner of the two lips of the superior border of the shaft. The upper area, of varying size and more or less triangular in shape, is separated from the internal intercostal membrane by some fatty tissue; the lower area is smooth and covered with the costal pleura. The *posterior surface* of the neck gives attachment to the costotransverse ligament and is pierced by numerous vascular foramina. The *crest of the neck* is rough for the attachment of the superior costotransverse ligament, and it can be traced laterally into the outer lip of the superior border of the shaft. The *inferior border* of the neck is rounded and can be traced laterally into the upper border of the costal groove; it gives attachment to the internal intercostal membrane. The *articular part of the tubercle* in the upper six ribs is convex and faces backwards and medially; in the succeeding three or four ribs it is flattened and faces downwards, backwards and slightly medially. The *non-articular part of the tubercle* gives attachment to the lateral costotransverse ligament.



The ridge which marks the (posterior) *angle* on the *external surface* of the *shaft* of a typical rib gives attachment to the upward continuation of the thoracolumbar fascia and the most lateral fibres of the iliocostalis thoracis. From the second to the tenth ribs the distance between the angle and the tubercle becomes progressively greater. Medial to the angle, the external surface gives attachment to the corresponding levator costae and is covered by the erector spinae. Near the sternal end of this surface an indistinct, oblique line (which marks the *anterior 'angle'*)

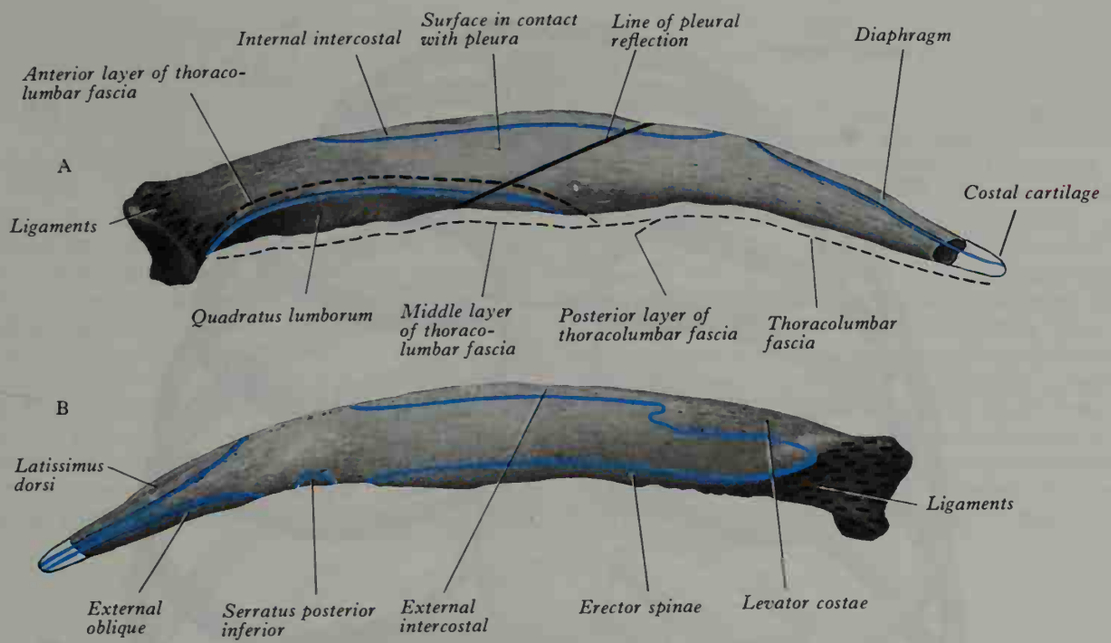
3.58 The second rib of the left side. Superior aspect.

separates the origins of the external oblique and the serratus anterior (or latissimus dorsi, in the cases of the ninth and tenth ribs). The *costal groove* on the *internal surface* gives attachment to the internal intercostal muscle, which intervenes between the bone and the intercostal vessels and nerve. At the vertebral end the groove faces downwards, as its borders lie on the same plane. Near the posterior angle the shaft broadens and the groove passes on to the internal surface. The upper edge of the groove gives attachment to the intercostalis intimus, which rarely extends on to the anterior fourth of the rib. Posteriorly this edge is continuous with the lower border of the neck. The sharp lower border of the rib gives origin to the external intercostal muscle. Its upper border is marked, posteriorly, by inner and outer lips: the inner gives attachment to both the intercostalis internus and intimus; the outer only to the intercostalis externus.

The first rib (**3**.57) presents the *tubercle for the scalenus anterior*, which also extends on to the adjoining part of the *upper surface*, on the internal border about its middle. The groove in front of the tubercle contains the subclavian vein, and the irregularly roughened area between it and the first costal cartilage gives attachment to the costoclavicular ligament and, more anteriorly, to the subclavius. The groove behind the tubercle is occupied by the subclavian artery and, as a rule, the lower trunk of the brachial plexus. Behind this groove a rough area which extends as far as the costal tubercle gives insertion to the scalenus medius. The obliquity of the first rib is responsible for the obliquity of the thoracic inlet and accounts for the presence of the apex of the lung in the root of the neck.

The outer border of the first rib is thin anteriorly but is thicker behind, where it is covered by the scalenus posterior as it descends to the second rib for its insertion. It gives origin to the upper part of the first digitation of the serratus anterior, behind and opposite to the groove for the subclavian artery. The *inner border* gives attachment to the suprapleural membrane, which covers the cervical dome of the pleura.

The *second rib* (**3**.58) bears a rough *tubercle for the serratus anterior* on its external surface just behind its midpoint; to this tubercle the lower part of the first and the whole of the second digitation are attached. The *costal groove* is very poorly marked on the *internal surface* and is restricted to its posterior part. The second intercostal nerve lies between the second rib and the pleura in most of its course. The inner and outer lips of the upper border are distinct and are widely separated behind. Immediately in front of the poorly marked angle the outer lip is roughened above for the insertion of the scalenus posterior and, below this, of the serratus posterior superior.



The *twelfth rib* (**3**.59), although short, has attached to it numerous muscles and ligaments. The lower part of its *anterior surface*, in its medial half to two-thirds, gives insertion to the quadratus lumborum and its covering fascia. Superior to these attachments the surface is related to the costodiaphragmatic recess of the pleura. At or close to the upper border are the attachments of the internal intercostal medially and the diaphragm laterally. The *lower border* affords attachment to the middle lamella of the thoracolumbar fascia and, at the lateral border of the quadratus lumborum, to the lateral arcuate ligament (p. 549). Posteriorly, close to the head, is attached the lumbocostal ligament (p. 451), by which it is connected to the transverse process of the first lumbar vertebra. The *external surface* has attached to it the lowest levator costae, the longissimus thoracis, and the iliocostalis in its medial half; more laterally, it gives insertion to the serratus posterior inferior, and origin to the latissimus dorsi and the external oblique muscle of the abdomen. Along the *upper border* is the insertion of the external intercostal. These muscle attachments show considerable variation. The insertions of the internal intercostal, levator costae and erector spinae merge and are difficult to define. The attachments of the latissimus dorsi, diaphragm and external oblique may extend on to the costal cartilage. The lower limit of the pleural sac crosses the anterior aspect of the twelfth rib, approximately at the point where the rib is crossed by the lateral border of the iliocostalis. The lateral extremity of the rib usually lies below the line of pleural reflection and is therefore not covered with pleura.

The ribs consist of the highly vascular trabecular bone, enclosed in a thin layer of compact bone and containing a large proportion of red marrow (*see* **3**.10B).

Ossification. Each rib, with the exception of the first and the last two, is ossified from four centres—a primary centre for the shaft, and three secondary centres, one for the head and one each for the articular and non-articular parts of the tubercle (Fawcett 1911). No epiphysis is usually present on the non-articular part of the tubercle below the sixth or seventh rib. The primary centre appears near the angle, towards the end of the second month of intrauterine life, first in the sixth and seventh ribs. The secondary centres for the head and tubercle appear about puberty, and unite with the shaft soon after the twentieth year. The first rib has three centres, viz.: a primary one for the shaft, a secondary centre for the head, and one for the tubercle. The eleventh and twelfth ribs, being destitute of tubercles, have each only two centres.

The Costal Cartilages

The costal cartilages (**3**.60) are flattened bars of hyaline cartilage which extend forwards from the anterior ends of the ribs and contribute materially to the mobility and elasticity of the walls of the thorax. The first seven pairs are connected with the sternum; the eighth, ninth and tenth articulate with the lower border of the cartilage immediately above; the lowest two are pointed, and end in the muscular wall of the abdomen. The cartilages increase in length from the first to the seventh, and then gradually decrease to the twelfth. They diminish in breadth from the first to the last, like the intervals between them. They are broad at their attachments to the ribs, and taper towards their medial extremities, with the exception of the first and second which are of the same breadth throughout, and the sixth, seventh, and eighth which are enlarged where their margins are in contact. The first cartilage descends a little, the second is horizontal, the third

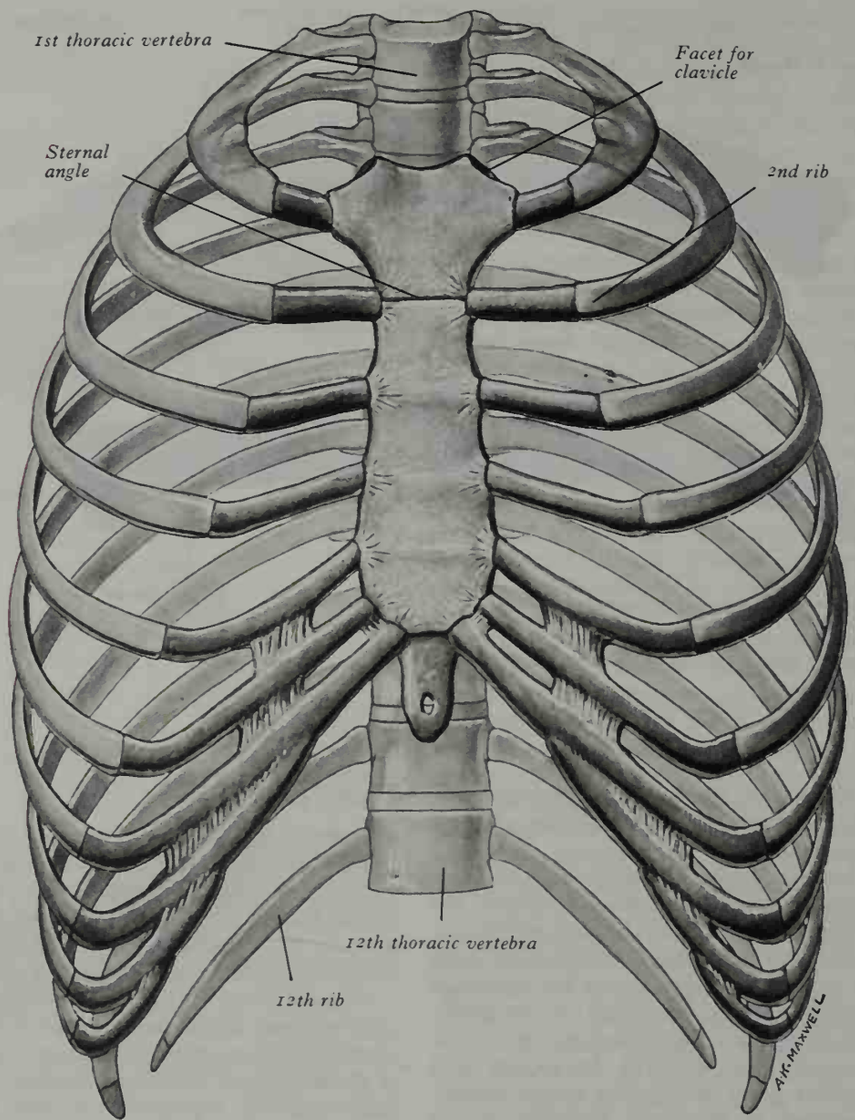
3.59 The twelfth rib of the left side. A anterior aspect and B, posterior aspect.

ascends slightly, while the others are angular, continuing the course of the ribs for a short distance, and then inclining upwards to the sternum or cartilage above.

Each costal cartilage has two surfaces, two borders, and two ends. The *anterior surface* is convex, and faces forwards and upwards; that of the first gives attachment to the sternoclavicular articular disc, the costoclavicular ligament and subclavius; those of the first six or seven at their medial ends, to the pectoralis major. The others are covered by, and give partial attachment to, some of the flat muscles of the anterior abdominal wall. The *posterior surface* is concave, and directed backwards and downwards; that of the first gives attachment to the sternothyroid, those of the second to the sixth inclusive to the transversus thoracis, and the six lower ones to the transversus abdominis and the diaphragm. The *superior border* is concave, and the *inferior* convex; they afford attachment to the internal intercostal muscles, and the external intercostal membranes. The inferior borders of the sixth, seventh, eighth and ninth cartilages present heel-like projections at the points of greatest convexity; a similar projection is frequently present on the lower border of the fifth cartilage. On these projections are oblong facets which articulate respectively with facets on slight projections from the superior borders of the sixth, seventh, eighth, ninth and tenth cartilages. The *lateral end* of each cartilage is continuous with the osseous tissue of the corresponding rib. The *medial end* of the first is continuous with the sternum; the medial ends of the six succeeding cartilages are rounded and articulate with the shallow costal notches on the lateral margins of the sternum. The medial ends of the eighth, ninth and tenth costal cartilages are pointed, and each is connected with the cartilage immediately above. Those of the eleventh and twelfth are pointed and free. With the exception of the junction of the first rib with the sternum, all these articulations are synovial (p. 451).

The tenth rib is usually described as united, at its ventral extremity, with the ninth by a fibrous joint (p. 452); but it is frequently not so connected, presenting a free pointed extremity like the eleventh and twelfth ribs. The incidence of a 'floating' tenth rib varies from 35 to 70 per cent in different racial studies (Shimaguchi 1974).

In old age the costal cartilages are prone to undergo superficial ossification, losing their pliability and becoming brittle. The histology (Amprino and Bairati, 1933), histochemistry (Quintarelli and Delaro, 1966) and ultrastructure of senile changes in costal cartilage have been reviewed by Dearden *et al.* (1974). An increase in keratan sulphate is noted, maximally in the subperichondrial zone.



The Thorax

The skeleton of the thorax or chest (3.60), is an osseocartilaginous framework within which are the principal organs of respiration and circulation. It is conical in shape, narrow above and broad below, flattened from before backwards, and longer behind than in front. It is reniform on horizontal section on account of the forward projection of the vertebral bodies.

Posteriorly the thoracic skeleton includes the twelve thoracic vertebrae and the posterior parts of the ribs. At each side of the vertebral column there is a wide and deep groove in consequence of the lateral and backward direction which the ribs follow from their vertebral extremities to their angles. *Anteriorly* are the sternum, the anterior ends of the ribs and the costal cartilages, and this aspect is flattened or slightly convex. *Laterally* the thorax is convex, and is formed by the ribs. The ribs and costal cartilages are separated from each other by the intercostal spaces, eleven in number, which are occupied by the intercostal muscles and membranes, and neurovascular bundles and lymphatics.

The *inlet* of the thorax is reniform in shape; its anteroposterior diameter is about 5 cm, its transverse about 10 cm. Its plane slopes downwards and forwards, and it is bounded by the first thoracic vertebra behind, the superior border of the manubrium sterni in front, and the first rib on each side. The *outlet* is bounded by the twelfth thoracic vertebra behind, by the twelfth and eleventh ribs at the sides, and in front by the cartilages of the tenth, ninth, eighth and seventh ribs, which ascend on each side and form an angle, termed the *infrasternal angle*. The outlet is wider transversely than from before backwards, and slopes obliquely downwards and backwards; it is closed by the diaphragm, which forms the floor of the thoracic cavity.

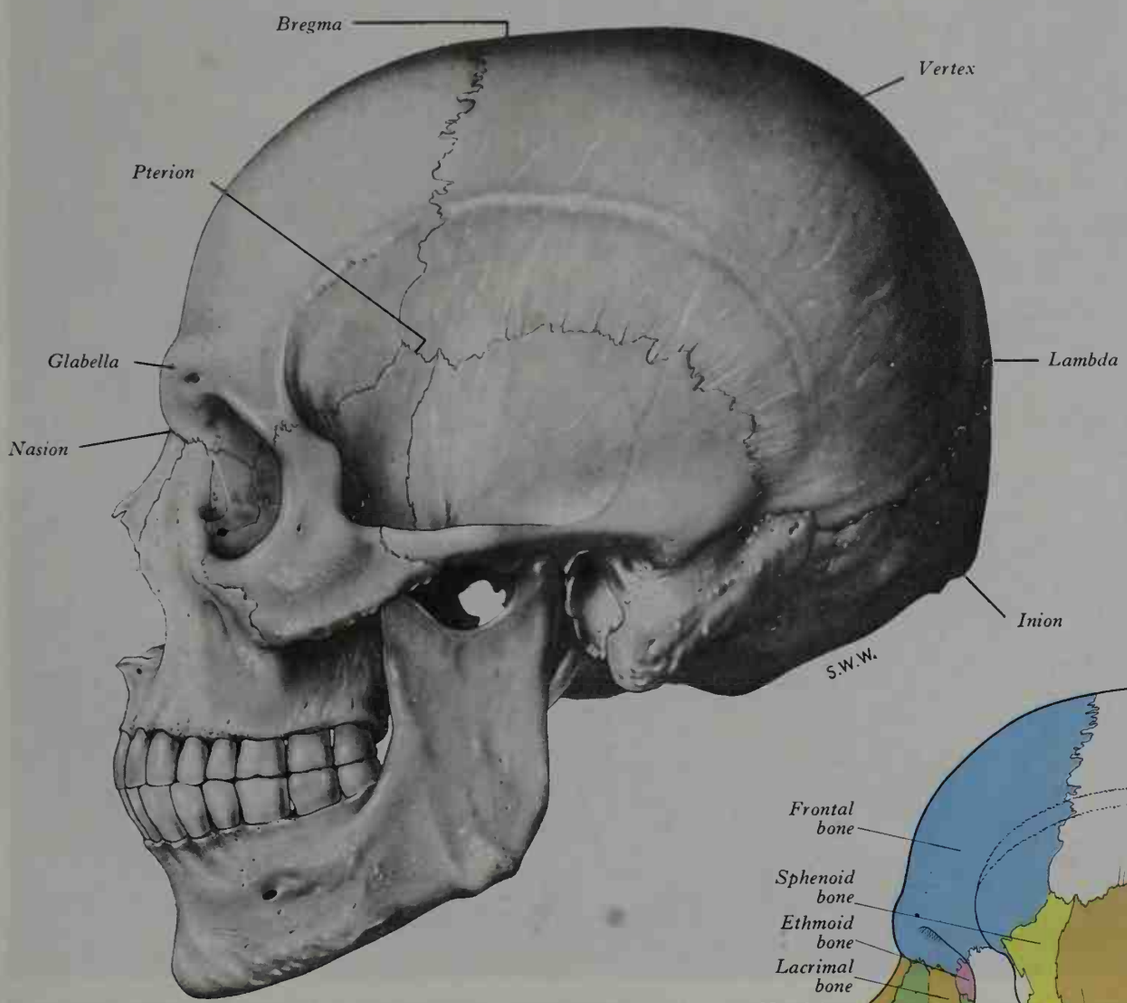
Like any other part of the skeleton, the thorax displays variation in dimensions and proportions which are partly individual and also linked to age, sex and race. In the newborn the transverse diameter is relatively less, but a change to adult proportions occurs when the child begins to walk. In the female the capacity is less, absolutely and proportionately; the sternum is relatively shorter and the thoracic inlet more oblique, the suprasternal notch being level with the third thoracic vertebra, rather than the second, as in the male. The upper ribs are also more movable in females, permitting comparatively greater expansion of the upper thorax. In tall and thin individuals the thoracic skeleton usually shows similar proportions, as also in the short and broad. Racial variations are likewise chiefly linked to stature and general proportions. In a race which is characteristically short and broad, the thorax shares in these proportions.

3.60 The skeleton of the thorax. Anterior aspect.

The outstanding functional significance of the thorax is in respiration (p. 453). The obvious protection afforded is perhaps best regarded as fortuitous, but a large number of muscles are attached to the thoracic skeleton, not all of which are primarily concerned with respiratory movements, though they may also share in these. The muscles of the arm, especially those acting on its girdle, those of the abdominal wall, and also those of the spinal column have widespread thoracic attachments.

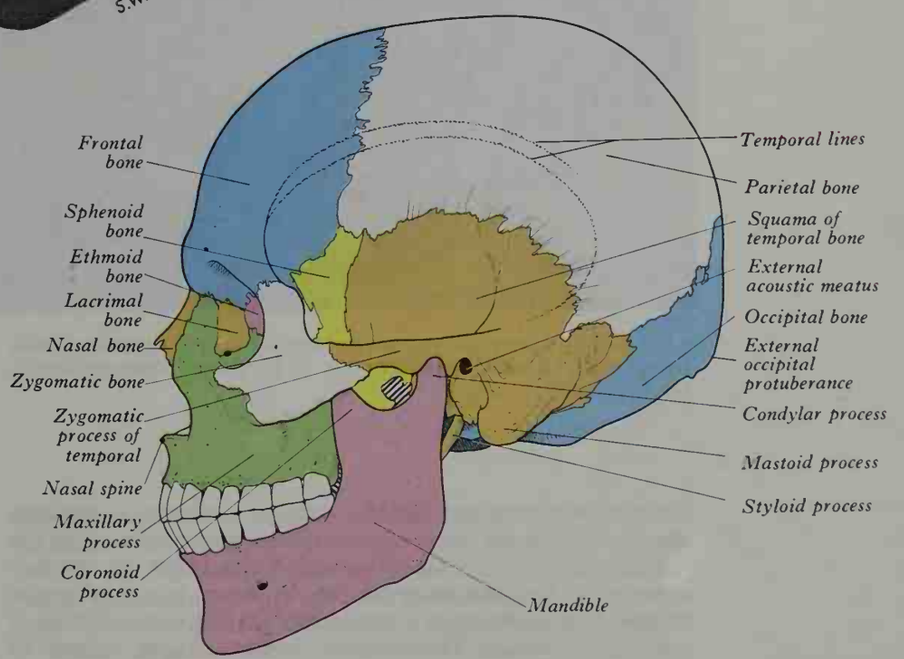
Applied Anatomy. The elastic recoil of the ribs, which suspend the sternum, may account for the comparative rarity of sternal fractures. Despite their ability to bend under stress, ribs are much more frequently broken. The middle ribs are most liable; and since the stress is usually of a bending nature, due to compression of the thorax, the weakest point, which is just in front of the angle, is the most frequent site of fracture. Direct impact may fracture a rib anywhere and in this case in particular the broken ends of the bone may be driven inwards, with the possible complication of injury to thoracic or upper abdominal viscera.

A *cervical rib*, derived from the costal element of the seventh cervical vertebra, may be a mere epiphysis articulating only with its transverse process; more commonly it has a definite head, neck and tubercle, with or without a shaft. According to the length of the shaft it extends laterally and forwards into the posterior triangle of the neck, where it may have a free end or join the first rib or costal cartilage, or even the sternum. It may be in part a fibrous cord, but the effects of its presence are not necessarily related to the size and development of its osseous part. If it reaches far enough forwards its relations are like those of a first thoracic rib: part of the brachial plexus (usually the lower trunk) and the subclavian vessels are *superior* to it, and they are apt to suffer some degree of compression here, being confined in a narrow angle between the cervical rib and the scalenus anterior. As a result, cervical ribs may first be discovered after the onset of nervous and vascular symptoms. In particular, pressure on the fibres of the eighth cervical and first thoracic spinal nerves may lead to motor and sensory effects in the structures which they supply.



According to Cave (1975) a cervical rib or pleurapophysis may show a variety of forms of junction—synostosis or diarthrosis—with either the anterior (parapophysial) or posterior (diapophysial) 'roots' of the so-called transverse process of a seventh cervical vertebra, or, more usually, with both of them. (*See* **3**.29 for a recent morphological analysis of the cervical pleurapophysis.)

THE SKULL



Introduction

The vertebrate skull is the most highly modified region in the axial skeleton. Whatever truth may reside in the hypothesis that the skull is partly derived from metameric elements, in the form of modified vertebrae, the evidence of palaeontology and comparative anatomy clearly indicates that from the earliest times it has been a complex of skeletal elements, adapted to support and contain the brain and special senses and to secure and devour food. The siting of special receptors, especially those of the chemical senses and of vision, and the feeding orifice, at the leading or head end of an elongate creature such as a vertebrate, offers advantages so fundamental that they are often overlooked. Associated with this concentration of functions is the enlargement of the fore end of the central nervous system into a brain, whose relative size and dominance have increased throughout the vertebrate series. The very size of the human brain focuses attention upon the *cerebral* function of the skull, and tends to exclude other considerations. Even in this limited regard the role of the cranium is by no means so simple as to be dismissed as merely protective. Sporadic protection of the brain from potentially damaging external impacts is of undoubted value; the need of a barrier against the stresses and pressures due to the play of powerful masticatory and axial musculature is perhaps less obvious, but is habitual and frequent. Quite apart from these extraneous forces, the rigid walls of the cranium afford a continuous isolation to the cerebral circulation. Moreover, the reputed buffering mechanism, due to the meninges, subarachnoid space and its contained fluid, could only work effectively within such a rigid container.

The extreme dependence of the brain upon an uninterrupted flow of blood is well known; the independence of the cerebral arterial pressure from extracranial variations in vascular pressures, due to some form of auto-regulation as yet unidentified, is also well established. It appears likely that the situation of the brain in a rigidly contained space is a factor of some importance in these arrangements, though it appears to have evaded any exact assessment. Of course, the cranial cavity is not completely closed; cerebrospinal fluid passes freely through the foramen magnum and can be displaced in either direction. The brainstem itself can also be displaced downwards to some extent through the same orifice under the influence of raised intracranial pressure. Variability in the volume of fluid in the cerebral

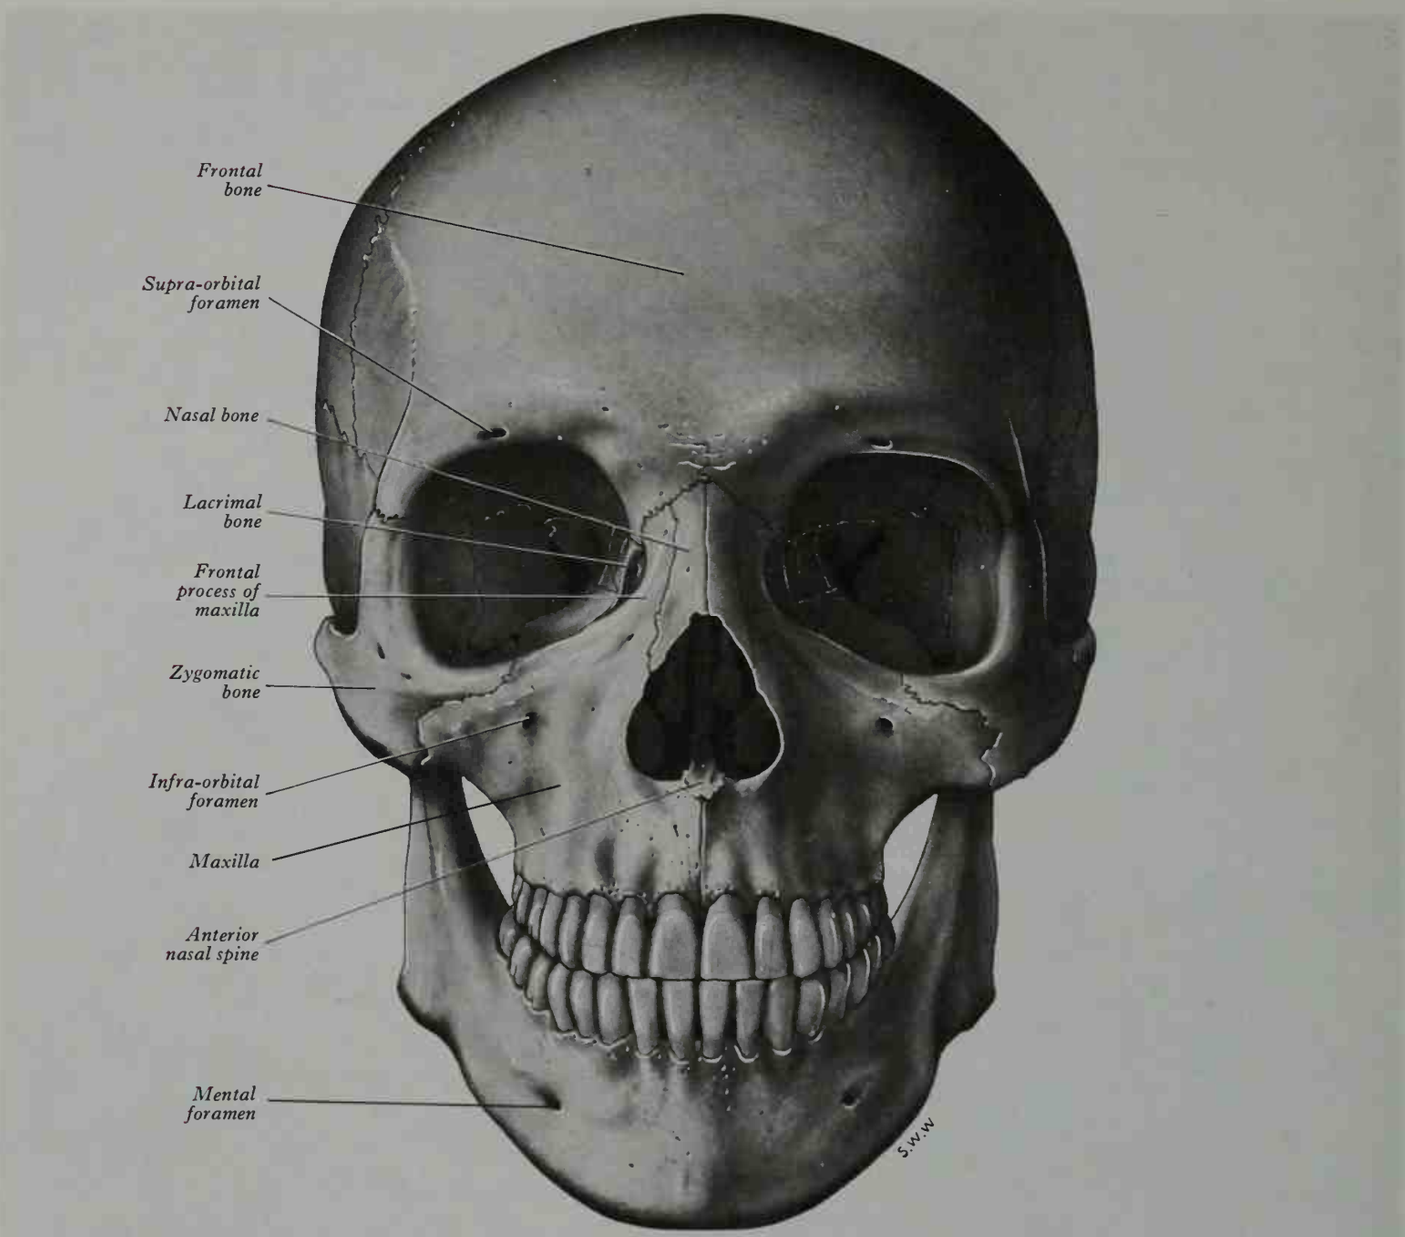
ventricular system and the existence of numerous connecting vessels between the intra- and the extra-cranial veins add to the complexity of the total situation. Nevertheless, it appears inescapable that the enclosure of the brain in an otherwise invariable space must be a considerable factor in the control of cerebral circulation. This peculiar, perhaps unique, location of the brain entails some penalties, however well adapted to ordinary circumstances. Lesions which occupy space can raise pressure within the cranium far more easily than elsewhere, and with far more devastating effects.



Even in the earlier vertebrates the *neurocranium*, developed from a series of cartilages ventral to the brain as in the human embryo (p. 141), has been joined by special cartilaginous supports for the external nares and olfactory receptors, the eyeballs, and the labyrinths. With the addition of jaw elements of branchial origin, and of dermal or 'membrane' bones, arising in the mesenchyme underlying the skin over the dome of the head, over the jaws and in the roof of the buccal cavity, the vertebrate skull becomes defined in all its complexity. It must be emphasized that all the cartilaginous elements usually become ossified, except in

minor groups, such as the sharks, where the persistence of cartilage is considered to be degenerate rather than primitive. Moreover, some of the dermal elements appear to be as ancient—judged by the fossil record—as 'cartilage' bones, and may even have preceded them in evolution. It may therefore be misleading to regard cartilage as the primeval substance in this respect. Bone may arise by two major routes; either by direct ossification in mesenchymal tissues, or indirectly in cartilages, themselves derived from such tissue. The roof and sides of the neurocranium, or 'brainbox', are developed in the former manner from sheets, or membranes, of mesenchyme in or subjacent to the dermis; hence the terms 'membrane' or 'dermal' bone, the latter being perhaps preferable as it is more informative. These dermal members of the cranial box are currently considered to be at least as primitive in origin as its chondrocranial base. In the case of the jaws the march of events appears more certain; the primary cartilaginous elements, derived from the branchial apparatus, have been replaced by overlying dermal bone.

The 'capsules', enclosing the special sense organs, which have become integral parts of the vertebrate skull, obviously afford a

3.63A The skull. Anterior aspect. (Norma frontalis.) Compare with the Key, **3**.63B.

measure of protection; but they also confer advantages which, though less obvious, may be of greater significance in terms of survival. The primitive nostrils of lower vertebrates are concerned in olfaction; and even when they lead backwards into nasal cavities with the development of a secondary palate in the majority of land vertebrates, the olfactory function persists side by side with the new respiratory arrangement. In both functions the maintenance of open airways, whatever sphincteric mechanisms are added, is a clear necessity. The skeletal elements surrounding the eyes have from the beginning provided sockets, more or less complete, containing not only the eyeballs but also their muscles. The latter, in their attachments to the walls of the optic 'capsule', have varied only in minor details of arrangement from their appearance in the earliest vertebrates, judging from their extant forms. With little exception their effects are rotatory, and it is difficult to envisage how this mode of action could be effective in the absence of a socket. The bony orbit not only aids the stationing of the eyeball during its rotations, but also ensures that the distance between the two eyes remains equal, a necessary prelude to binocular vision.

The deep situation of the labyrinths in cartilage or bone entails a fixed relationship between the three semicircular canals on each side. The fusion of the otic capsules into the base of the cranium determines a strict orientation of the six canals not only with respect to each other but also in relation to the head itself. Without such an arrangement no orderly correlation between these peripheral receptors and their central nervous connexions could be developed.

Axial muscles have extended from the vertebral column to the caudal aspects of the skull from the earliest differentiation of these regions, and they become further elaborated and more massive in land animals with the development of a neck and the increased problems of suspending the head in quadrupeds. In all but the jawless fishes (Agnatha), such as the lamprey, a numerically insignificant class of vertebrates, the primitive skull is invaded by the ligamentous and muscular apparatus of the jaws, the maxillae becoming integrated with the rest of the skull at a very early stage. In both cases the large muscle masses, whether axial or mandibular, create stresses transmitted to the skull which are at least considerable and sometimes very great, and which are associated with extensive cranial modifications to resist and absorb them. Even in human beings, whose masticatory and neck musculatures are of modest development, the whole body weight can be suspended from the bite of the teeth. In other mammals, especially amongst quadrupeds, the far greater development of jaws and greater weight of head accentuate these problems and lead to the development of large plates, bars and buttresses of bone which owe nothing in their origin to the protection which

they undoubtedly increase. A perfect example of this is to be seen in the high cranial dome of the elephant, which is associated with the production of a large area of attachment for the massive extensor neck muscles necessary to the suspension of so weighty a head. However, enough has perhaps now been said to emphasize the diversity of functions in which the skull is involved beyond the truism of its protectiveness.

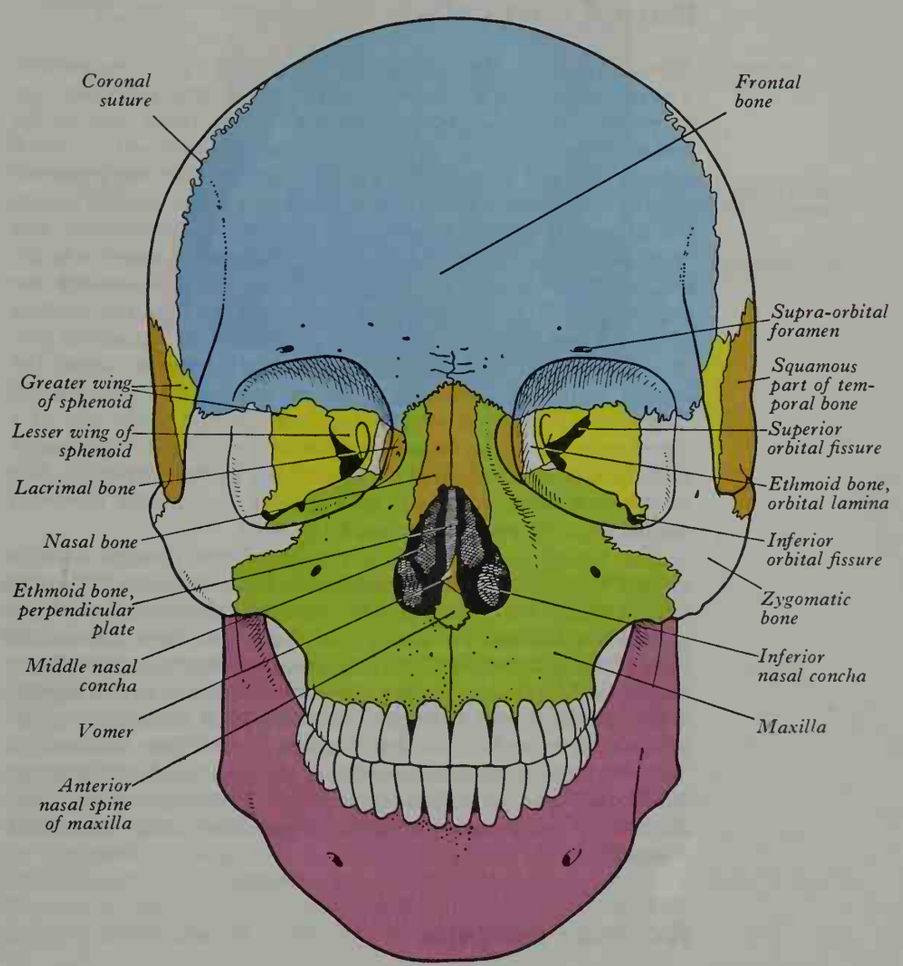
General Cranial Features

When the mandible is left out of account the remainder of the skull, strictly speaking, constitutes the *cranium*, but the term skull is widely used with the same significance. The upper part of the cranium forms a box to enclose and protect the brain, and is often termed the *calvaria*. The remainder of the skull forms the *facial skeleton*, of which the upper part is immovably fixed to the calvaria and the lower part is the freely movable mandible.

The skull, considered as a whole, is of greater practical importance than the individual bones of which it is made up. Nevertheless, the position of its individual constituents must be familiar before the student can follow more detailed description (**3**.61A, B; 62A, B).

The skull may be viewed from above (*norma verticalis*), from below (*norma basalis*), from behind (*norma occipitalis*), from in front (*norma frontalis*) and from the side (*norma lateralis*). The roof of the calvaria, or *calva* (skull cap), may be removed and the interior may be examined. In the erect attitude the lower margins of the orbital openings and the upper margins of the external acoustic meatuses lie on the same horizontal (the Frankfurt plane), and it is important that the student should bear this in mind when examining the various aspects of the skull.

The region of the forehead is formed by the *frontal bone* (**3**.61A, B), which passes backwards in the vault of the skull as far as the *coronal suture*, where it meets the anterior borders of the right and left *parietal bones*. These two bones together form the greater part of the cranial vault, and they articulate with each other at the serrated *sagittal suture*. Posteriorly they extend backwards to meet the *occipital bone*, which forms the back of the head. The suture between the two parietals and the occipital bone is called *lambdoid*, after the Greek letter lambda, Λ, which it resembles in shape. Each parietal bone curves downwards on the side of the vault until it meets the upper limit of the *greater wing* of the *sphenoid bone* in front, and the *squamous part* of the *temporal bone* behind. When the *calva*, or *skull cap* is removed, the section passes through the frontal bone and usually cuts across the lower part of the parietal bone, but it may involve the squamous part of the temporal bone. Posteriorly the section cuts the occipital bone. Consequently, the calva consists of (1) a large part of the frontal bone; (2) most of the two parietal bones; (3) possibly, small parts of the squamae of the temporal bones; and (4) a small part of the occipital bone.



When the calva is removed, the floor of the calvaria, the *base of the skull*, is exposed. It shows a natural subdivision into three regions, which are named the anterior, middle and posterior cranial fossae (**3**.75A, B).

The anterior cranial fossa forms less than the anterior third of the base and is limited behind by a sharp edge on each side of the median plane. It is important to observe that the floor of the anterior cranial fossa constitutes the roof of the orbit, on each side, and the roof of the nasal cavity, in the median area. On each side of the median plane an *orbital part* projects backwards from the *frontal bone* and constitutes most of the roof of the orbit. These two plates are separated by a relatively narrow interval, which is occupied by a perforated strip of bone. This is termed the *cribriform plate* of the *ethmoid bone*; it forms a large part of the roof of the nose, while the rest of the bone to which it belongs participates in the side walls and the septum of the nasal cavity. In the median plane the cribriform plate bears a crestlike elevation on its upper surface, the *crista galli*. The posterior part of the floor of the anterior cranial fossa is formed by the *sphenoid bone*. In the median area the front of the *body of the sphenoid* meets the cribriform plate of the ethmoid. On each side a narrow *lesser wing* projects laterally from the body and meets the posterior margin of the orbital part of the frontal bone. It is the sharp posterior border of the lesser wing of the sphenoid bone which forms the posterior limit of the floor of the anterior cranial fossa on each side of the midline. This border is related to the lateral cerebral fissure (p. 984).

The middle cranial fossa (**3**.75A, B), which lies immediately behind the anterior fossa, is of small extent in the median region but is expanded, in a backward and lateral direction, on each side. The narrow median portion of the floor is formed by the body of the sphenoid, the upper surface of which is hollowed out to contain the hypophysis cerebri (pituitary gland). The floor of the lateral part of the fossa is formed by the *greater wing* of the sphenoid in front, and by the *petrous part* of the *temporal bone* behind. The greater wing extends laterally from the side of the body of the sphenoid and curves upwards in the side of the skull to reach the antero-inferior part of the parietal bone. Behind it the floor of the fossa is formed by the anterior surface of the petrous part of the temporal bone, which is continuous laterally with its squamous region.

The posterior cranial fossa (**3**.75A, B) is almost circular in outline and occupies roughly two-fifths of the base of the skull. It is formed to a large extent by the *occipital bone*. The large opening in its floor, termed the *foramen magnum*, is entirely within the bone and through it the brain becomes continuous with the spinal cord. The anterior part of the fossa is formed by the *basilar part* of the occipital bone, which is fused in front with the posterior part of the sphenoid. On each side the lateral wall of the fossa is formed by the posterior surface of the petrous part of the temporal bone above, and by the *lateral* (*condylar*) *part* of the occipital bone, below. The *mastoid part* of the temporal bone, which lies immediately posterolateral to the petrous part, joins the *squamous part* of the occipital bone to complete the fossa.

When the skull is viewed from in front (*norma frontalis*, **3**.63)

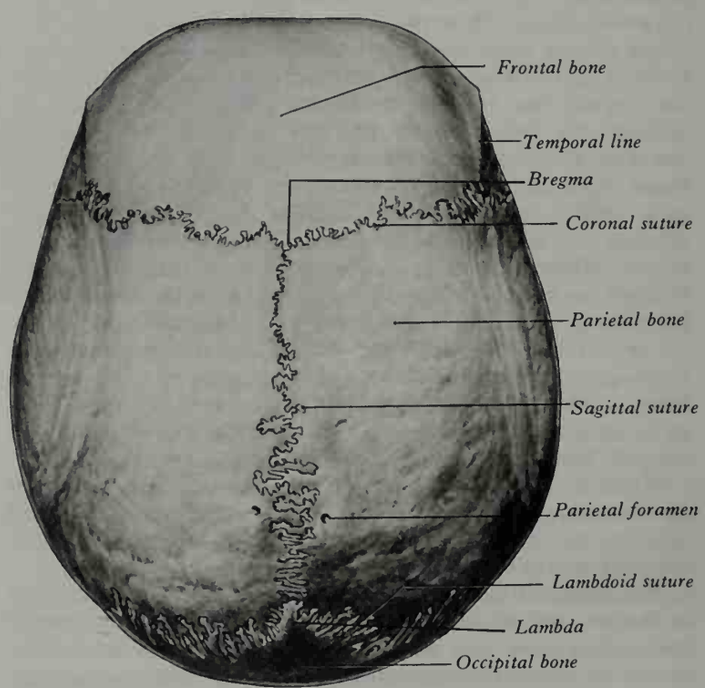
3.63B The skull. Anterior aspect. (Norma frontalis.) Key to **3**.63A. *Note.*—*Blue* = frontal bone; *yellow* = sphenoid bone; *green* = maxillae; *brown* = lacrimal, nasal, temporal bones and vomer; *magenta* = mandible; *uncoloured* = parietal, zygomatic and ethmoid bones.

the *orbits*, which contain the eyeballs, and the anterior aperture of the *nasal cavity*, are apparent. The part below the mouth is formed entirely by the *body* of the *mandible*; the part above the mouth is formed almost entirely by the *maxillae*, or upper jaws. The latter form the upper boundary of the mouth, and the lower and lateral boundaries of the anterior nasal aperture. In addition, on each side the maxilla forms the medial part of the lower margin of the orbit, which it helps the zygomatic bone to complete, while its frontal process ascends in the medial margin of the orbit to reach the *frontal*. The frontal processes of the two maxillae are separated from each other by the two *nasal bones*, which are the upper boundary of the anterior nasal aperture.

When the skull is viewed from the side (*norma lateralis*, **3**.61) the *ramus* of the *mandible*, which passes from the posterior end of the body of the bone upwards and slightly backwards to reach the cranium, is visible. The *head* of the mandible, which lies at the upper end of the posterior border of the ramus, is adapted to the *articular fossa* on the under surface of the squamous part of the temporal bone. The back of the mandibular head is separated from the ear passage, the *external acoustic meatus*, by the *tympanic part* of the temporal bone. Above and in front of the meatus the *zygomatic process* of the temporal bone passes forwards to meet the zygomatic or cheek bone, and the two form the *zygomatic arch*, or *zygoma*, which is separated widely from the rest of the side of the skull. The *zygomatic bone* is responsible for the prominence of the upper and anterior part of the cheek. It forms the lateral part of the lower margin of the orbital opening, as already stated, and ascends in the lateral margin to meet the frontal bone.

When the mandible is removed (**3**.70) a process of bone can be seen immediately behind the maxilla and above the level of the maxillary teeth. This is the *pterygoid process*, which projects downwards from the sphenoid along the line of union of its greater wing with its body. It consists of a large lateral plate with a smaller one medial to it.

The inferior aspect of the cranium (*norma basalis*, **3**.71 A, B) is the external aspect of the base of the skull. Posteriorly is the *occipital bone*, with the foramen magnum. Lateral to the foramen magnum the occipital bone articulates with the *mastoid part* of the temporal bone. Anterolaterally it articulates with the *petrous part*, which extends forwards almost to the root of the pterygoid process. In the anterior part of the inferior aspect of the cranium, the *bony palate*, which lies in the roof of the mouth, can be seen within the arch of the teeth of the maxilla. Four bones contribute to its formation, viz., the two maxillae and the two palatine bones. The anterior three-fourths of the bony palate are formed by the *palatine processes* of the maxillae, which meet each other in the median plane; the posterior fourth is formed by the *horizontal plates* of the *palatine bones*; their *perpendicular plates* are hidden as they ascend, on each side, from the lateral border of the horizontal plate to form the posterior part of the lateral wall of the nose.



The *lacrimal bone*, which lies in the anterior part of the medial wall of the orbit, the *vomer*, which forms a large part of the nasal septum (**3**.77), and the *inferior concha*, which lies in the lateral wall of the nasal cavity, can be seen only when the orbits and the nose are examined (pp. 300, and 313). With these exceptions all the bones of the skull have now been identified, and a more detailed study can be undertaken.

THE EXTERIOR OF THE SKULL

Norma Verticalis

The outline of the skull, as seen from above (**3**.64), varies greatly. The outline may be more or less oval or more nearly circular, but its greatest width is usually nearer to the occipital than to the frontal region. This aspect of the skull is traversed by three sutures. (1) The *coronal suture* is the joint between the posterior edge of the frontal and the anterior borders of the parietal bones. On each side of the median plane it passes downwards and forwards across the cranial vault. (2) The *sagittal suture* is in the median plane between the interlocking upper borders of the two parietal bones. (3) The *lambdoid suture* joins the posterior borders of the parietal bones to the superior border of the squamous part of the occipital. It runs downwards and forwards across the cranial vault. The meeting place of the coronal and sagittal sutures is the *bregma*, and in the fetal skull it is the site of a membrane-filled gap, the *anterior fontanelle* (p. 345). The *lambda* is situated at the junction of the sagittal and lambdoid sutures, and in the fetal skull is the site of a similar but smaller defect in ossification, the *posterior fontanelle* (*p*. 345).

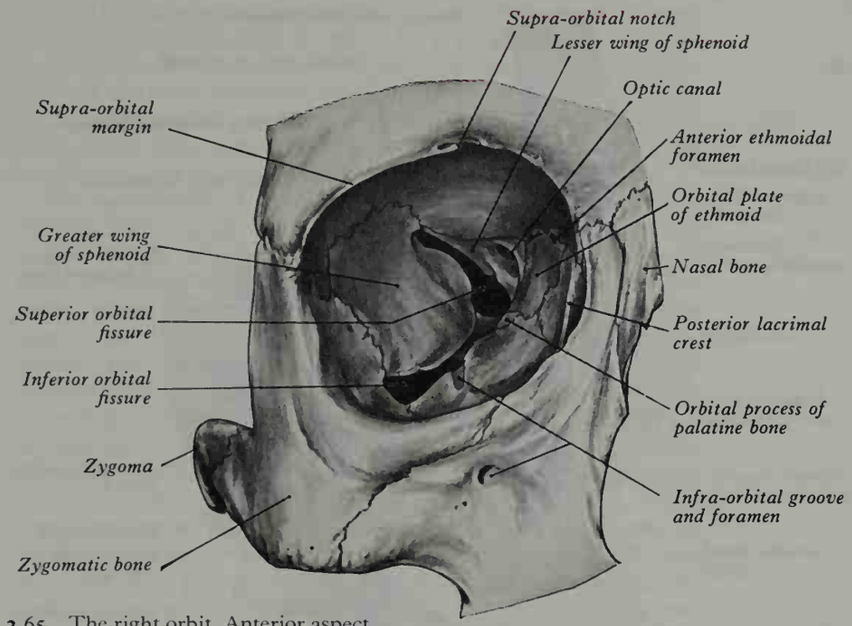
The region of maximum convexity of the parietal bone is termed the *parietal tuber* (*eminence*) and can be easily felt in the living subject. In this situation the norma verticalis passes into the norma lateralis and the norma occipitalis, but there are no real lines of demarcation. The *parietal foramen*, which is often absent on one or both sides, pierces the parietal bone near the sagittal suture about 3·5 cm in front of the lambda. It transmits a small emissary vein from the superior sagittal sinus within the skull (p. 740). A recent numerical assessment gives an incidence of about 40–60 per cent (in different races) for this foramen (p. 340). Anteriorly the norma verticalis slopes down into the norma frontalis.

3.64 The skull, superior aspect. (Norma verticalis.)

Norma Frontalis

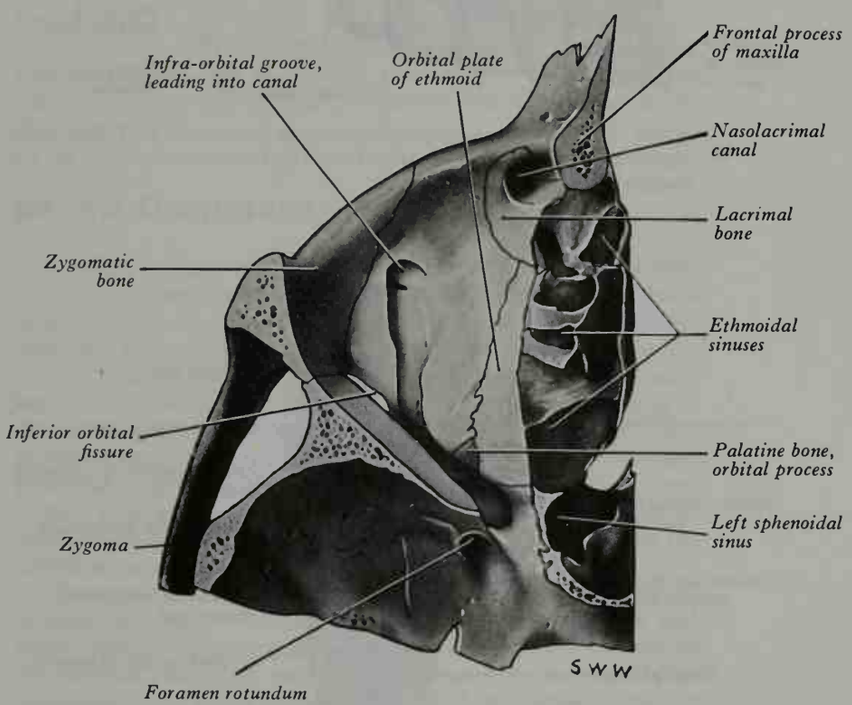
Viewed from the front (**3**.63), the skull exhibits a more or less oval outline, wider above than below. Its upper part is formed by the frontal bone and is smooth and convex. Its lower part, the face, is very irregular and is interrupted by the orbits and the anterior bony aperture of the nasal cavities. Immediately above the medial part of each orbit the *superciliary arch* forms a rounded elevation, better marked in the male than in the female skull, and these two arches are connected by a median elevation, the *glabella*. Below the glabella the skull recedes to the point where the nasal bones meet the frontal, forming the floor of a depression at the root of the nose. The point where the internasal and frontonasal sutures meet is named the *nasion*. Above the superciliary arch on each side there is a slight rounded elevation termed the *frontal tuber*, or tuberosity. These bony landmarks can be felt in the living subject,

and provide reference points for the surgeon and the anthropologist.



The orbital opening is more or less quadrangular in shape. Its *supra-orbital margin* is formed entirely by the frontal bone; at the junction of its sharp lateral two-thirds with its rounded and medial third, is the supra-orbital notch (or foramen, as the case may be), which transmits the supra-orbital vessels and nerve. The *lateral margin* is formed almost entirely by the frontal process of the zygomatic bone, but it is completed above by the zygomatic process of the frontal bone, and the suture which connects these two bones can be felt in the living subject as a slight depression. The zygomatic bone laterally and the maxilla medially share in the formation of the *infra-orbital margin*. Both these margins are sharp and can be felt easily through the skin. The *medial margin* is not so clear-cut; formed above by the frontal bone and below by the lacrimal crest of the frontal process of the maxilla, which is sharp and distinct in its lower half only.

The anterior nasal aperture is piriform (pear-shaped), wider below than above and bounded by the nasal bones and the maxillae. The two nasal bones articulate with each other in the median plane and both articulate with the frontal bone above. On each side the nasal bone articulates behind with the frontal process of the maxilla, but its lower border, to which the lateral nasal cartilage is attached, is free and forms the upper boundary of the piriform aperture (**3**.63).

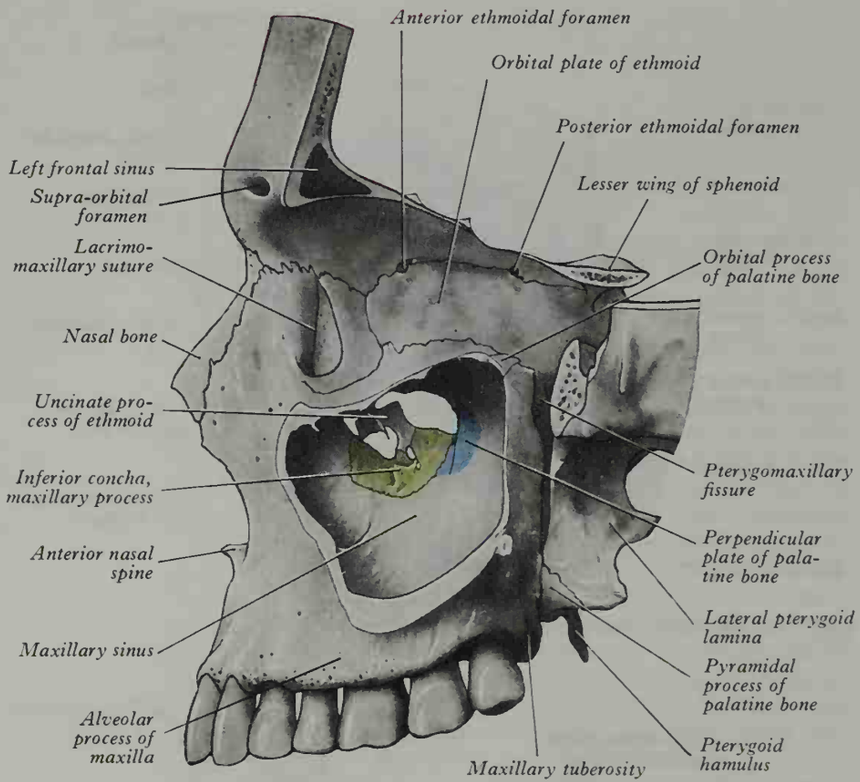


The maxillae predominate in the skeleton of the face, and it is their growth which is responsible for the elongation of the face between the ages of 6 and 12 years. Only the anterior surface of the maxilla is visible in the norma frontalis. Medially this surface presents the well-marked *nasal notch*, which forms the lower border and part of the lateral border of the piriform aperture. A prominent, sharp projection marks the meeting of the two maxillae in the lower boundary of the aperture and is termed the *anterior nasal spine*. It is palpable in the lower border of the free part of the nasal septum. About 1 cm below the infra-orbital margin the maxilla is perforated by the *infra-orbital foramen*, which transmits the infra-orbital vessels and nerve; it lies on, or just lateral to, a vertical line passing through the supra-orbital notch. The *alveolar process* of the maxilla, which contains the sockets for the maxillary teeth, can be examined most satisfactorily in the basal view (p. 304). The *zygomatic process* of the maxilla is a short but stout projection from the upper and lateral part of the anterior surface of the bone. Its upper surface is oblique and articulates with the zygomatic bone at the zygomaticomaxillary suture. Inferiorly it presents a free lower border, which meets the body of the bone above the first molar tooth, and can be palpated through the skin of the cheek or through the mucous membrane of the vestibule of the mouth. The *frontal process* of the maxilla ascends behind the nasal bone, forming the lower part of the medial margin of the orbital opening, and reaches the frontal bone. The *prominence of the cheek* below and lateral to the orbit is produced by the zygomatic bone. It is the convex lateral surface of the bone which can be examined both in the norma frontalis and in the norma lateralis. The mandible is described on p. 315.

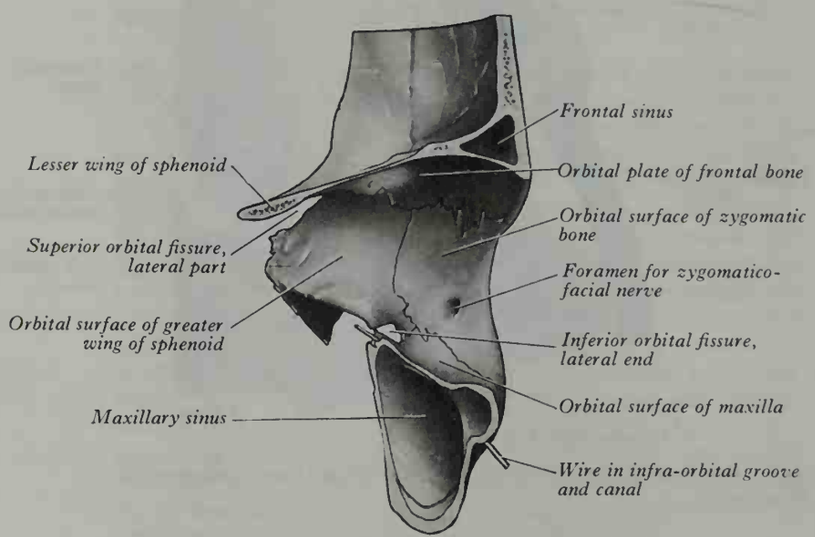
The *glabella* may show the remains of the frontal suture, which in about 9 per cent of skulls extends upwards to the coronal suture. It indicates that the adult frontal bone is formed by the fusion of right and left halves, which ossify independently of each other. The medial part of the *superciliary arch* gives origin to the corrugator supercilii. The nasal part of the frontal bone and the frontal process of the maxilla give origin to the orbital part of the orbicularis oculi. Between these two areas the medial palpebral ligament is attached to the frontal process of the maxilla (**3**.63A). The procerus arises from the nasal bone near the median plane. The lower margin of the nasal bone usually presents a small notch, converted into a foramen by the lateral cartilage of the nose. It transmits the external nasal nerve. In front of the orbicularis oculi the levator labii superioris alaeque nasi takes origin from the frontal process of the maxilla. More laterally, the levator labii superioris arises from the maxilla in the interval between the infra-orbital margin and the foramen of the same name.

The stout root of the canine tooth produces an elevation termed the *canine eminence*, which separates the *canine fossa* on its lateral side from the *incisive fossa* on its medial side. The levator anguli oris arises from the canine fossa. The surface bordering the nasal notch gives origins to the nasalis and depressor septi, below which is the origin of the incisive muscle.

3.65 The right orbit. Anterior aspect.



3.66 A horizontal section through the left orbit and nasal cavity viewed from above.



The zygomatic bone is marked opposite the junction of the infra-orbital and lateral margins of the orbit by the small *zygomaticofacial foramen* (**3**.63) which transmits the nerve of the same name and a minute artery. The foramen, which is sometimes duplicated, opens laterally and downwards. Below the foramen the zygomatic bone gives origin to the zygomaticus minor, and more laterally to the zygomaticus major. The zygomaticofacial foramen is often absent; it was missing in 12 to 30 per cent of different populations in a series of 580 crania (*see* p. 348).

The Orbital Cavity

The orbits (**3**.65, 66, 67) are two recesses which contain the eyeballs, their associated muscles, vessels, nerves, etc., and most of the lacrimal apparatus, together with a variable amount of soft

3.67A Oblique parasagittal section through the anterior part of the skull, showing the medial wall of the left orbit and the medial wall of the left maxillary sinus.

3.67B The lateral wall of the left orbit, viewed from the medial side. Compare with **3**.67A, which represents the opposite part of the same section of the skull.

fat. The orbital cavity is pyramidal; its base is the orbital opening, and its long axis is directed backwards and medially. Each orbit presents a roof, floor, medial and lateral walls, a base or orbital opening and an apex.

The superior wall or roof is a thin, gently concave plate which intervenes, throughout most of its extent, between the orbit and the brain in the anterior cranial fossa. Anteromedially it is separated into two laminae by the frontal sinus, an air space in the bone communicating with the nasal cavity. Anterolaterally is a deep hollow, the *lacrimal fossa*, in which is the orbital part of the lacrimal gland. At the posterior end of the junction of the roof with the medial wall the *optic canal or foramen* establishes communication between the orbit and the middle cranial fossa. It contains the optic nerve and the ophthalmic artery. Close to the superior, medial and lower margins of the opening of the canal into the orbit a common tendinous ring is attached to the orbital walls for the origin of certain muscles of the eyeball (**7**.269).

The medial wall (**3**.67A) is exceedingly thin, except at its most posterior part, and slopes gently downwards and laterally into the floor. Anteriorly is the *lacrimal groove*, for the lacrimal sac. The groove communicates below with the nasal cavity through the *nasolacrimal canal*, which is little more than 1 cm long and contains the nasolacrimal duct. The floor of the groove separates the orbital from the nasal cavity, but behind it air-containing ethmoidal sinuses intervene between them. Posteriorly, the medial wall is related to the anterior part of the sphenoidal sinus and forms its lateral wall.

The inferior wall or floor of the orbit (**3**.66) is relatively thin and in most of its extent forms the roof of the maxillary sinus (**3**.67A). It is not quite horizontal, but faces upwards and slightly laterally. In front it is continuous with the lateral wall, but posteriorly the two walls are separated by the *inferior orbital fissure*. This leads into the orbit from the pterygopalatine fossa posteriorly, and anteriorly from the infratemporal fossa. The maxillary nerve is the most important structure traversing the fissure. The medial lip of the fissure is notched by the *infra-orbital groove*, which passes forwards in the floor, sinking into it anteriorly and becoming the *infra-orbital canal* whose anterior opening is the *infra-orbital foramen*. The groove, canal and foramen transmit the infra-orbital nerve, the continuation of the maxillary nerve. Through the anterior part of the inferior orbital fissure a vein passes to connect the inferior ophthalmic with the pterygoid plexus in the infratemporal fossa. The infra-orbital foramen is sometimes double or even multiple (Harris 1933), the supernumerary foramina being usually smaller and hence named *accessory*. Such accessory infra-orbital foramina have been recorded at incidences of 2 to 18 per cent in various populations (*see* p. 348).

The lateral wall (**3**.67B) is the thickest, especially where it separates the orbit posteriorly from the middle cranial fossa. In front it is between the orbit and the temporal fossa. The lateral wall and the roof are continuous anteriorly, but they are separated posteriorly by the *superior orbital fissure*. This is noticeably widened at its medial end (**3**.65), and its long axis is directed medially, backwards and slightly downwards. It communicates with the middle cranial fossa and transmits the oculomotor, trochlear and abducent nerves and the terminal branches of the ophthalmic nerve, and the ophthalmic veins. Where the fissure begins to widen its lower border is marked by a bony projection, often sharp in character, which gives attachment to the lateral part of the common tendinous ring (**7**.269). Royle (1973) has drawn attention to an '*infra-orbital*' *sulcus*, present in 22 of 64 orbits, which extends from the superolateral end of the superior orbital fissure towards the floor of the orbit. It may be associated with an anastomotic vessel between the middle meningeal and infra-orbital arteries.

The boundaries of the *orbital opening* have already been described (p. 299). The *apex* of the orbit is at the medial end of the superior orbital fissure.

Further details of the orbital walls are given in the following paragraphs.

The roof of the orbit is formed almost entirely by the orbital plate of the frontal, but the under surface of the lesser wing of the sphenoid forms its posterior part. The suture between the two bones is almost horizontal. The *optic canal* lies between the two roots of the lesser wing and is bounded medially by the body of the sphenoid bone. Near the junction of the roof and the medial wall, and close to the orbital opening, the small *trochlear fossa* (occasionally replaced by a trochlear spine) marks attachment of the fibrous loop for the tendon of the superior oblique muscle of the eyeball.

The medial wall (**3**.67A) is limited in front by the anterior lacrimal crest of the frontal process of the maxilla, which gives attachment to the orbicularis oculi and to the lacrimal fascia. Behind this crest the maxilla and the lacrimal bone join to form the *lacrimal groove*, the suture between them being in its floor. The upper opening of the *nasolacrimal canal* lies at the lower end of the groove, and its lateral boundary is formed by the tiny *hamulus of the lacrimal bone*, which curves forwards and medially

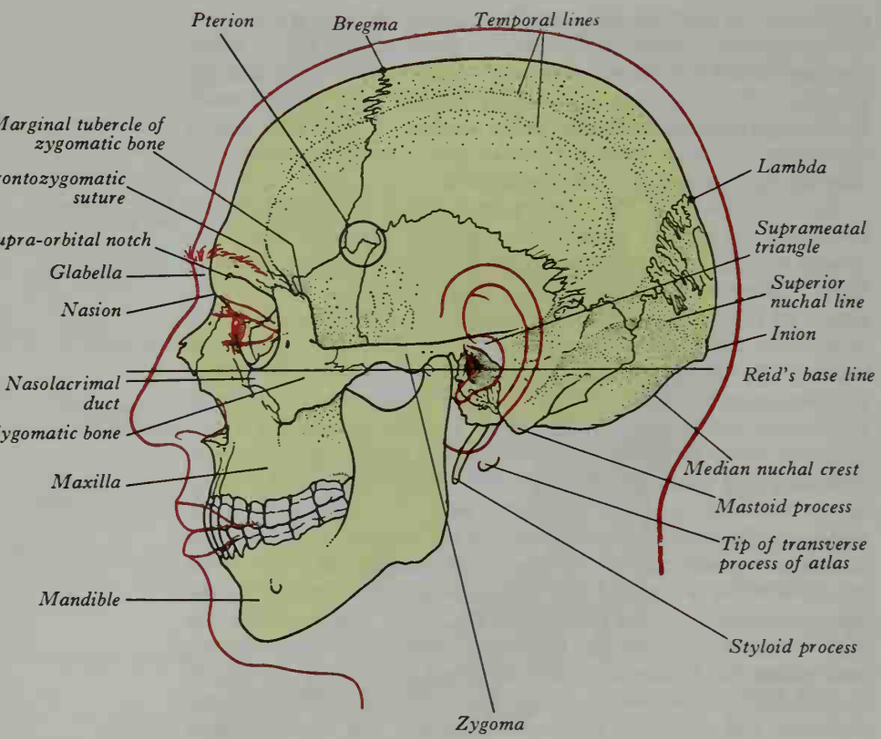
to meet the lower part of the anterior lacrimal crest. The posterior border of the groove is formed for the most part by the *crest of the lacrimal bone*, which gives origin to the lacrimal part of the orbicularis oculi (p. 531) and to the lacrimal fascia, which bridges over the groove. The posterior part of the orbital surface of the lacrimal bone is flattened, and articulates behind, by an almost vertical suture, with the orbital plate of the labyrinth of the ethmoid bone. The frontolacrimal and the lacrimomaxillary sutures indicate the other limits of the orbital aspect of the lacrimal bone. The *orbital plate of the ethmoid* makes the largest contribution to the medial wall. Almost rectangular, it consists of very thin bone, forming the lateral walls of the ethmoidal sinuses. Above, it articulates with the medial edge of the orbital plate of the frontal, and the line of this suture is interrupted by the *anterior* and *posterior ethmoidal foramina*, which lead into minute bony canals. These transmit vessels and nerves of the same names—the posterior ethmoidal nerve, however, is often absent—and lead into the anterior cranial fossa, where they open at the lateral edge of the cribriform plate. Below, the orbital plate articulates with the medial edge of the orbital surface of the maxilla and, at its most posterior part, with the orbital process of the palatine bone. Posteriorly, the orbital plate of the ethmoid articulates with the body of the sphenoid, which forms the most posterior part of the medial wall of the orbit, separated from the roof by the optic canal.

3.68 Radiograph of adult skull. Frontal view. 1. Maxillary sinus. 2. Frontal sinus. Both infra-orbital canals are shown. Compare with the radiographs in illustrations **3**.62A, B.

Racial and sexual variation in the position and incidence of the ethmoidal canals was analysed in a series of 580 crania from several populations (*see* p. 348). The anterior foramen was observed to lie outside the fronto-ethmoidal suture in about 10–20 per cent of several modern races, and in as much as 62 per cent of 53 Peruvian crania.

The inferior wall or floor of the orbit (**3**.66) is mostly formed by the orbital surface of the maxilla and, anterolaterally, by the zygomatic bone. At its posteromedial corner, where the floor meets the medial wall, a small triangular area is formed by the orbital process of the palatine bone. In addition to the maxillary nerve the *inferior orbital fissure* transmits the infra-orbital vessels, the zygomatic nerve, and a few minute twigs from the pterygopalatine ganglion. The fissure is bounded above by the greater wing of the sphenoid, below by the maxilla and the orbital process of the palatine bone, and laterally by the zygomatic bone or the zygomaticomaxillary suture. In 35 to 40 per cent of skulls the maxilla and the sphenoid bone articulate with each other at the anterior end of the fissure and exclude the zygomatic bone from it. In the anteromedial part of the floor, just lateral to the hamulus of the lacrimal bone, a small depression may mark the origin of the inferior oblique muscle from the maxilla.

The lateral wall of the orbit (**3**.67B) is formed by the orbital surface of the greater wing of the sphenoid behind, and by the orbital surface of the frontal process of the zygomatic bone in front. These two bones meet at the sphenozygomatic suture. This aspect of the zygomatic bone presents the openings of minute canals for the zygomaticofacial and the zygomaticotemporal nerves. The former lies near the junction of the floor of the orbit with its lateral wall, the latter at a slightly higher level, sometimes close to the sphenozygomatic suture. The *superior orbital fissure* is bounded above by the lesser and below by the greater wing of the sphenoid and medially by its body. The lacrimal and frontal nerves traverse the narrow, lateral part of the fissure, which transmits also the meningeal branch of the lacrimal artery and the occasional orbital branch of the middle meningeal artery. The trochlear nerve is situated more medially and lies just outside the common tendinous ring of the recti (p. 1178). The two divisions of the oculomotor nerve, the nasociliary and the abducent nerves, pass within the tendinous ring, and therefore traverse the wider, medial part of the fissure. They may be accompanied by the superior and inferior ophthalmic veins, but the superior ophthalmic vein may accompany the trochlear nerve whilst the inferior vein may pass through the medial end of the fissure below the ring (**7**.269).



Norma Occipitalis

The outline of the skull, viewed from behind, is like a broad arch, convex above and on each side, and flattened below. The *lambdoid suture* can now be seen through its entire length. Its serrations are deep and prominent above and behind, but become much less conspicuous as the suture is traced downwards and forwards. Inferiorly it meets the *occipitomastoid* and *parietomastoid sutures* at the postero-inferior angle of the parietal bone (**3**.61). The posterior portions of the parietal bones, parietal tuberosities and foramina, visible in the norma occipitalis, have already been viewed from above. Sutural bones are relatively common at the lambda (meeting of lambdoid and sagittal sutures) and along the lambdoid suture (*see* pp. 322 and 338).

The most outstanding feature of the norma occipitalis is the *external occipital protuberance* (**3**.61) and the ridges which lead away from it. The protuberance is in the lower part of the field in the median plane and may be overhanging. It can readily be identified in the living at the upper end of the median furrow at the back of the neck. The *superior nuchal lines* are the ridges, often sharp in character, which pass laterally from the protuberance. They are the boundary between the scalp and the neck, and the portions of the occipital bone below them, now seen foreshortened in perspective, will be better seen in the norma basalis. The *highest nuchal lines*, when present, are curved ridges, about 1 cm above the superior nuchal lines. Commencing at the upper part of the protuberance, they are more arched than the superior nuchal lines. In various ethnic groups the incidence of this feature varied from 3·6 to 40 per cent (*see* p. 348).

The mastoid process and the mastoid part of the temporal bone are inferolateral in this aspect of the skull, and can be examined more satisfactorily in the norma lateralis.

The *inion* is the most salient point on the external occipital protuberance in the median plane. To the lower part of the protuberance are attached the upper end of the ligamentum nuchae and, to its upper part, fibres of trapezius, which arises also from the adjoining part of the *superior nuchal line*. The lateral part of the line (**3**.86) gives attachment to the posterior fibres of sternocleidomastoid and, under cover of that muscle, to fibres of splenius capitis. The *highest nuchal line* has attached medially the galea aponeurotica and laterally the occipital belly of the occipitofrontalis.

3.69 Left lateral aspect of the head, showing the surface relations of the bones.

Norma Lateralis

Much of the side of the skull (3.61) has already been seen and described when it was examined from other aspects, but in its central area many features have not yet been considered. This region is limited above by the *temporal line*, which arches upwards and backwards from the zygomatic process of the frontal across the coronal suture to the parietal bone. Salient at first, and felt easily through the skin, it arches across the parietal bone and becomes much less distinct and is usually represented by *two curved ridges*, which enclose between them a smooth and often polished strip of bone. Posteriorly the upper of these two lines fades away, but the lower becomes more prominent again as it curves downwards and forwards across the squamous part of the temporal bone, just above the base of the mastoid process. This part of the line, which is often termed the *supramastoid crest*, becomes continuous with the posterior root of the zygomatic process. Throughout its extent the temporal line marks the periphery of the temporalis and its covering fascia. On the parietal bone the muscle arises from the lower ridge, while the fascia is attached to the upper ridge and to the bone immediately below.

The temporal fossa is the region bounded by the zygomatic arch, the temporal line and the frontal process of the zygomatic bone, and to its floor is attached the temporalis. An irregularly H-shaped arrangement of sutures can be seen in the anterior part of the fossa, the horizontal limb of the H being formed by the suture between the antero-inferior angle of the parietal and the upper border of the greater wing of the sphenoid bone. In this situation the frontal, the sphenoid, the parietal and the squamous part of the temporal bone closely adjoin one another (3.69), and a small circular area can be outlined so as to include portions of all four. This area is termed the **pterion**, and its centre—an important landmark for the surgeon—lies 4·0 cm above the zygomatic arch and 3·5 cm behind the frontozygomatic suture (3.61). (The anterior branch of the middle meningeal artery is marked by the pterion. It also gives an approximate indication of the position of the more deeply lying lesser wing of the sphenoid which, in life, is in the stem of the Sylvian (lateral) cerebral fissure. Hence, centrally, the pterion is also sometimes termed the *Sylvian point*.) The anterior wall of the fossa is formed by the temporal surface of the zygomatic bone, the adjoining part of the greater wing of the sphenoid and a small portion of the frontal bone. It is between the fossa and the orbit. Inferiorly the fossa communicates freely with the infratemporal fossa through the gap which separates the zygomatic arch from the side of the skull. In this situation the tendon and some fleshy fibres of the temporalis descend to reach their insertion into the mandible (p. 316).

The zygomatic arch, formed by the temporal process of the zygomatic bone and the zygomatic process of the temporal bone, is easily palpable where the cheek and temple meet each other. Its sharp, upper border is obscured by the attachment of the temporal fascia, and its lower border by the origin of masseter, which arises also from its deep surface. The arch stands away from the rest of the skull, separated from it by a gap which is deeper in front than behind. Anteriorly, the arch is crossed obliquely downwards and backwards by the zygomaticotemporal suture.

The *zygomatic process of the temporal bone* widens posteriorly as it approaches the squamous part, and divides into anterior and posterior roots. The *anterior root* passes medially in front of the *mandibular fossa* into the smooth *articular tubercle*, the anterior boundary of the fossa. The *posterior root* passes backwards, lateral to the fossa, and its upper border becomes continuous with the supramastoid crest of the temporal bone.

The external acoustic meatus opens immediately below the posterior part of the posterior root of the zygoma. Its margins are roughened, especially below and in front, for the attachment of the cartilaginous segment of the meatus. The upper margin and the upper part of the posterior margin are formed by the squamous part of the temporal bone; the rest is formed by the *tympanic part* of the temporal bone. The squamotympanic suture is antero-superior to the opening, but the suture on the posterior wall is usually obliterated in the adult. Below the meatus the tympanic plate is drawn downwards, forming a somewhat triangular roughened area. Immediately above and behind the meatus there is frequently a small depression with a bony spicule (*suprameatal spine*) in its anterior margin. This lies within the area of the *suprameatal triangle*, which is bounded above by the supramastoid crest, in front by the posterosuperior margin of the orifice of the meatus and behind a vertical line, drawn as a tangent to the curve of the posterior margin of the meatal orifice. This triangle forms the lateral wall of the mastoid (tympanic) antrum (3.69 and p. 329), which is an air space of importance to the surgeon and is contained in the petrous part of the temporal bone.

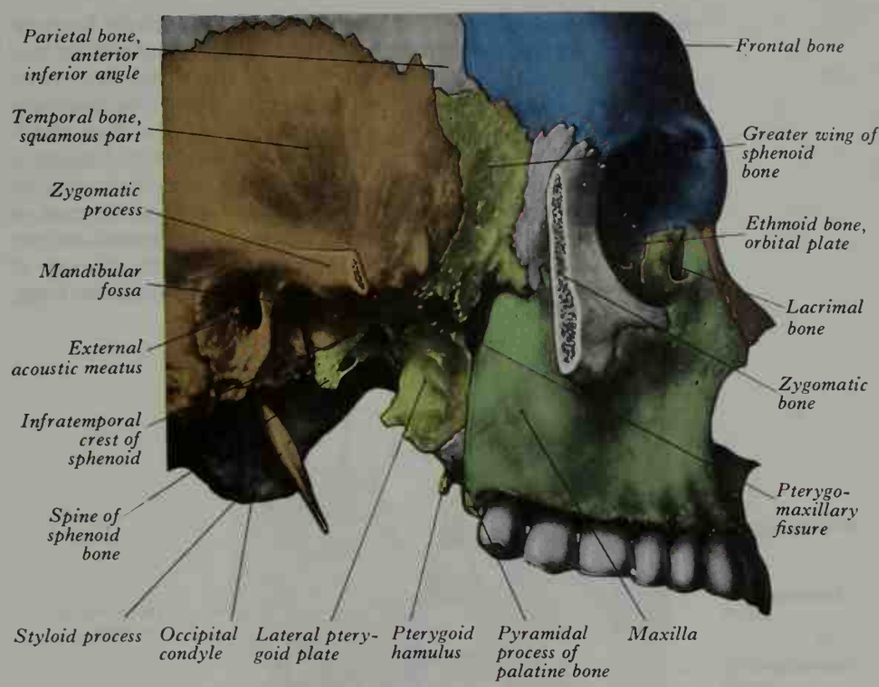
The mastoid part of the temporal bone appears in the norma lateralis behind the meatus. Above, it is continuous with the squamous portion in front, but, behind, it possesses a free upper border, which articulates with the postero-inferior part of the parietal bone at the horizontal *parietomastoid suture*. Its posterior border is free and articulates with the squamous part of the occipital bone at the *occipitomastoid suture*. These two sutures meet each other at the lateral extremity of the lambdoid suture. The meeting point of the three sutures is the *asterion*. The *mastoid process* (3.61) is a strong, nipple-shaped projection from the lower part of the mastoid portion of the temporal bone. It lies immediately behind and below the external acoustic meatus and can be felt through the skin under cover of the lobule of the auricle. The *mastoid foramen* pierces the bone above the base of the mastoid process and near, or on, the occipitomastoid suture; it transmits an emissary vein from the sigmoid sinus. A sutural ossicle may occur in the parietomastoid suture, usually at the asterion, in the position of the posterolateral fontanelle (Le Double 1903), but sometimes elsewhere along the suture.

The styloid process (3.61) is a slender, elongated projection which, although attached to the base of the skull, is better seen in the norma lateralis. It lies a short distance in front of the mastoid process but on a deeper plane, its base being partly ensheathed by the lower margin of the tympanic plate. Directed downwards, forwards and slightly medially, its tip is usually hidden by the posterior margin of the ramus of the mandible, when that bone is in place. From its extremity the stylohyoid ligament passes downwards and forwards to the lesser cornu of the hyoid bone (p. 319), which is therefore suspended from the skull.

The infratemporal fossa (3.70) is an irregular space behind the maxilla. It communicates with the temporal fossa through the gap between the zygomatic arch and the side of the skull. Medial

to this gap, the roof is formed by the infratemporal surface of the greater wing of the sphenoid, and a small part of the squamous temporal. In this situation the greater wing is pierced by the foramen ovale and the foramen spinosum. Medially is the lateral pterygoid plate. These walls are considered in detail in the norma basalis (p. 305). Behind, below and on the lateral side the fossa is freely open. The anterior and medial walls meet below but they are separated above by the *pterygomaxillary fissure*, through which the infratemporal fossa communicates with the pterygopalatine fossa. The upper end of the pterygomaxillary fissure is continuous with the posterior end of the *inferior orbital fissure*, which the infratemporal fossa communicates with the pterygopalatine fossa. The upper end of the pterygomaxillary fissure is connects the infratemporal fossa with the orbit (p. 300).

The pterygopalatine fossa is a small pyramidal space situated below the apex of the orbit. It communicates with the infratemporal fossa through the pterygomaxillary fissure, with the nasal cavity through the sphenopalatine foramen, and with the orbit through the medial end of the inferior orbital fissure. The foramen rotundum opens on its posterior wall, and the maxillary nerve, which runs forwards and laterally from the foramen across the upper part of the fossa, is the most important of its contents.



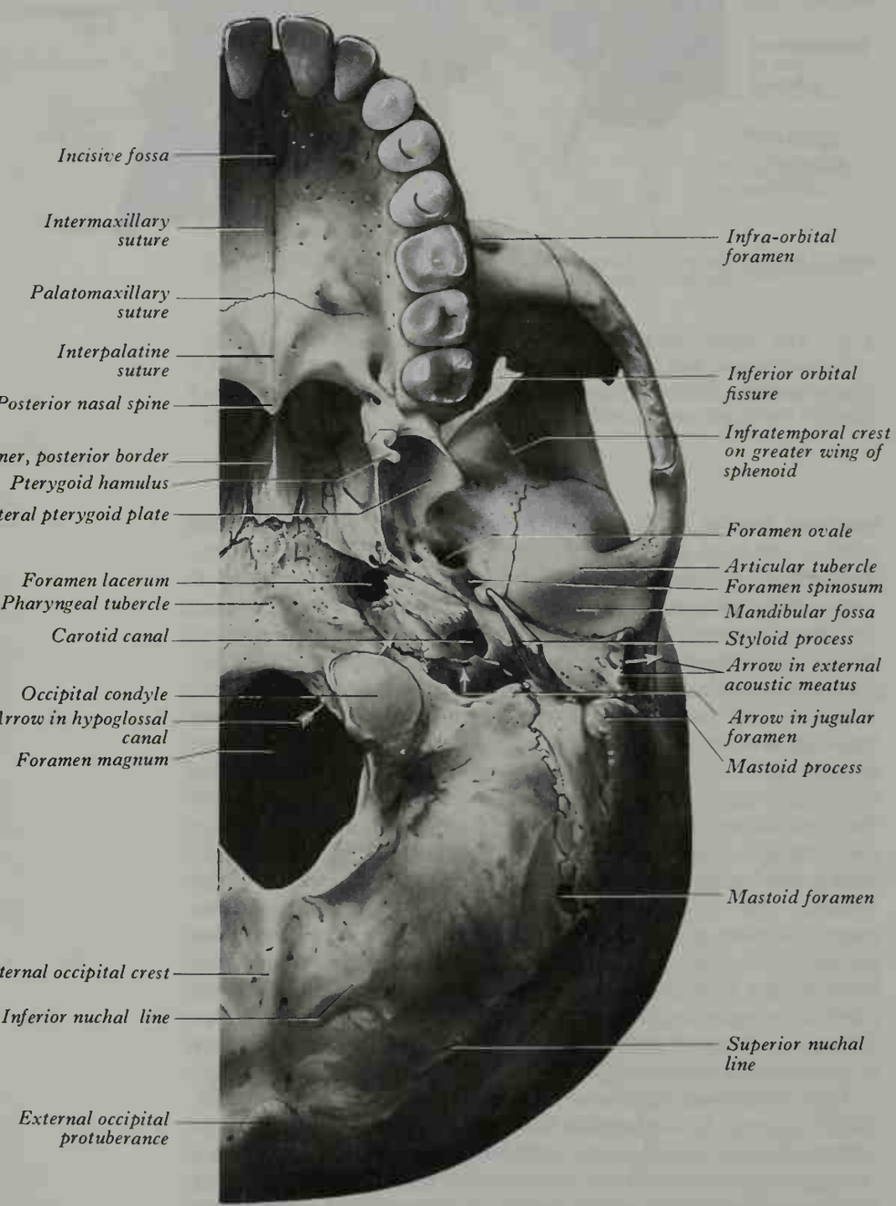
The floor of the *temporal fossa* is marked by a few small vascular furrows, of which the most constant are above the external acoustic meatus; they are produced by the middle temporal vessels. In the anterior wall of the fossa the *zygomaticotemporal foramen* pierces the posterior, temporal surface of the zygomatic bone in an upward and backward direction. It transmits the zygomaticotemporal nerve and a minute artery. In addition to the tendon of the temporalis, the deep temporal vessels and nerves traverse the gap between the zygomatic arch and the side of the skull and ascend into the temporal fossa.

As the anterior root springs from the zygomatic process, it is marked by a small tubercle often termed the *tubercle of the root of the zygoma*, to which are attached fibres of the lateral ligament (**4**.18) of the temporomandibular joint. It is palpable immediately in front of the head of the mandible. Behind the mandibular fossa a small downward projection from the posterior root of the zygoma, *the postglenoid tubercle*, meets the tympanic plate at the anterosuperior part of the orifice of the external acoustic meatus (**3**.93), and its anterior aspect takes a small part in the formation of the mandibular fossa.

The posterior part of the lateral surface of the *mastoid process* and its rounded apex are roughened by the insertions of the sternocleidomastoid, splenius capitis and longissimus capitis, from before backwards. In front of and parallel to this roughened area, the partially obliterated remains of the squamomastoid suture may be visible. From this position of the suture it will be obvious that the floor of the suprameatal triangle, and therefore the lateral wall of the mastoid antrum, is formed by the squamous part of the temporal bone. The tympanomastoid fissure is placed on the anterior aspect of the base of the process. The outer opening of the mastoid canaliculus (**3**.96), which transmits the auricular branch of the vagus nerve, is between the lips of the fissure.

The *styloid process* is covered on its lateral aspect by the parotid gland and intervenes between it and the internal jugular vein. It gives origin to three muscles. The stylohyoid arises by a slender tendon from its posterior aspect, nearer to the base than the tip, the styloglossus from the tip and the adjacent part of the anterior aspect, and the stylopharyngeus from the medial aspect of the base. The stylomandibular ligament is attached to the lateral aspect of the process near to the stylohyoid ligament at its tip. Behind the base of the process the facial nerve emerges from the stylomastoid foramen and passes forwards lateral to the process in the substance of the parotid gland.

The *infratemporal fossa* (**3**.70) contains the lower part of the temporalis as it passes to the coronoid process. The maxillary artery and its branches and the pterygoid plexus of veins are medial to the temporalis and usually on the lateral surface of the lower head of the lateral pterygoid muscle. The deepest part of the fossa is occupied by the medial pterygoid, the mandibular nerve and the chorda tympani. The mandibular nerve enters the fossa through the foramen ovale in its roof and breaks up into terminal



3.70 The right infratemporal fossa. *Note.*—*Blue*=frontal bone; *yellow*=sphenoid and lacrimal bones; *brown*=temporal and nasal bones; *green*=maxilla. The parts shown of the parietal, zygomatic, ethmoid and palatine bones are uncoloured.

branches medial to the lateral pterygoid muscle. Its branches traverse the fossa and most of them leave it to gain other regions. The chorda tympani enters the fossa on the medial side of the spine of the sphenoid and runs downwards and forwards to join the lingual nerve. The maxillary nerve appears at the upper part of the fossa as it passes between the upper end of the pterygopalatine fossa and the inferior orbital fissure. The anterior wall of the fossa is pierced by two or three small foramina for the posterior superior alveolar vessels and nerves. It is limited below by the alveolar part of the maxilla in the region of the molar teeth, and in this situation a horizontal strip of the bone is closely covered with the mucous membrane of the gum. Immediately above this strip are attached the upper fibres of buccinator, which extends backwards behind the last molar tooth on to the tuberosity of the maxilla. The medial wall of the fossa, formed by the lateral pterygoid plate, is completed below and in front by the pyramidal process (tubercle) of the palatine bone which is wedged in between the tuberosity of the maxilla and the lateral pterygoid plate. The superficial head of the medial pterygoid muscle arises from this surface of the pyramidal process and the adjoining part of the maxillary tuberosity.

The *pterygomaxillary fissure* is a triangular interval formed by the divergence of the maxilla from the pterygoid process of the sphenoid bone. It admits the terminal part of the maxillary artery to the pterygopalatine fossa, and its uppermost part gives passage to the maxillary nerve, which appears for a brief part of its course in the upper part of the infratemporal fossa before it enters the inferior orbital fissure to gain the orbit (p. 300).

The *pterygopalatine fossa* (**3**.70) communicates *above* with the orbit through the medial—or posterior—part of the inferior orbital fissure, and it is closed *inferiorly* where the lower part of the lateral surface of the perpendicular plate of the palatine bone meets the postero-inferior part of the medial surface of the maxilla. It is bounded *behind* by the root of the pterygoid process and the adjoining part of the anterior surface of the greater wing of the sphenoid, *medially*, by the upper part of the perpendicular plate of the palatine bone with its orbital and sphenoidal processes, *in front*, by the medial portion of the upper part of the posterior surface of the maxilla. *Laterally* it communicates with the infratemporal fossa through the pterygomaxillary fissure. The most important contents of the fossa are the maxillary nerve, the pterygopalatine ganglion and the terminal part of the maxillary

artery. The maxillary nerve enters the fossa through the foramen rotundum and passes forwards and laterally to the posterior end of the infra-orbital groove in the floor of the orbit. Below and medial to the foramen rotundum the pterygoid canal transmits the nerve (and artery) of the same name from the lower part of the anterior wall of the foramen lacerum to the pterygopalatine ganglion, and inferomedially the palatovaginal canal transmits the pharyngeal nerve (and artery) from the ganglion to the roof of the pharynx. A fourth foramen, on the medial wall, is the *sphenopalatine foramen* (**3**.78). It is bounded above by the body of the sphenoid, in front by the orbital process of the palatine bone,

3.71 A The inferior surface of the left half of the base of the skull. (Norma basalis.) Compare with Key, **3**.71 B.

behind by the sphenoidal process and below by the upper border of the perpendicular plate. It carries into the nasal cavity the nasopalatine nerve and accompanying vessels. The fifth foramen is placed inferiorly at the junction of the anterior and posterior walls, and leads into the *greater palatine canal*. Bounded anterolaterally by the maxilla and posteromedially by the perpendicular plate of the palatine bone, this canal transmits the anterior, middle and posterior palatine nerves and the greater and lesser palatine vessels, which emerge through foramina on the bony palate (*vide infra*).

Norma Basalis

The inferior surface of the base of the skull is very irregular (**3**.71, 72, 73). It extends from the incisor teeth of the maxillae, back to the superior nuchal lines of the occipital bone. Laterally are the other teeth, the zygomatic arch and its posterior root, and the mastoid process. It is useful to divide the area into anterior, middle and posterior parts. The anterior part, formed by the hard palate and the alveolar arches, is on a lower level than the rest, which is divided, in an arbitrary manner, into middle and posterior parts by a transverse line through the anterior margin of the foramen magnum.

The Anterior Part of the Norma Basalis

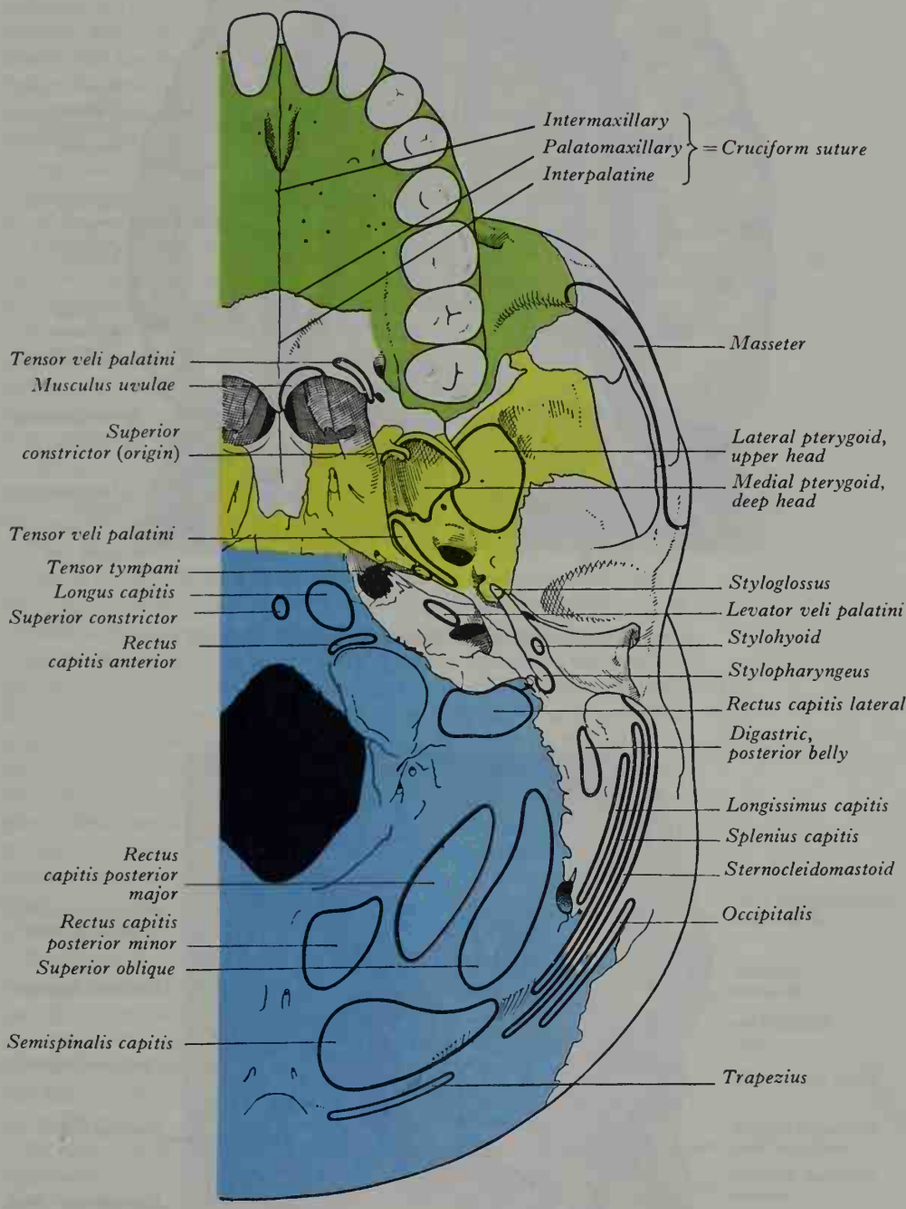
The *bony palate* (**3**.72) lies within the upper dental arch, and is formed by the palatine processes of the maxillae and the horizontal plates of the palatine bones, separated by a *cruciform suture*, made up of the intermaxillary, interpalatine and palatomaxillary sutures. Owing partly to the downward projection of the alveolar arches, the palate is arched both from before backwards and from side to side. The depth and the breadth of the palatine vault are subject to considerable variation but are always greatest in the region of the molar teeth. The *incisive fossa* lies anteriorly in the median plane. The *lateral incisive foramina*, which lead into the incisive canals and so to the floor of the nasal cavity (p. 315), are situated in its lateral walls; the *median incisive foramina*, which are present in some skulls, open on its anterior and posterior walls. The *greater palatine foramen*, which is the lower orifice of the canal of the same name, opens close to the lateral border of the palate immediately behind the palatomaxillary suture (**3**.72). A vascular groove, deep behind and becoming shallower in front, leads forwards from the foramen. The *lesser palatine foramina*, usually two on each side, are situated behind the greater foramina. They pierce the *pyramidal process of the palatine bone*, which projects backwards and laterally from the posterolateral corner of the bony palate and becomes wedged into the notch between the lower ends of the two pterygoid plates. (When more than one lesser palatine foramen is present, the supernumerary foramina are sometimes described as *accessory*. The incidence of such accessary foramina is high and shows some racial and sexual variation from 30 to 70 per cent—*see* p. 348.) The vault of the bony palate is pierced by numerous small foramina and marked by depressions for the palatine glands. Near the posterior border it presents a slightly curved ridge of variable prominence, termed the *palatine crest*, which commences behind the greater palatine foramen and runs medially. The free posterior border of the bony palate projects backwards in the median plane as the *posterior nasal spine*.

The *alveolar arch* provides sixteen sockets, or alveoli, for the teeth. These vary in size and depth and are single or subdivided by septa according to the roots of the teeth which they contain.

The lateral incisive foramen transmits the terminal branches of the greater palatine vessels and the nasopalatine nerve. When median incisive foramina are present the left nasopalatine nerve passes through the anterior and the right through the posterior foramen. The lateral foramina are sometimes held to be in the line of fusion of the os incisivum (premaxilla) with the maxilla proper, and represent a primitive communication between the mouth and the nose. In young skulls what is possibly a suture line between the os incisivum and the maxilla may be visible, extending from the posterior part of the incisive fossa to the septum between the sockets of the lateral incisor and canine teeth (but *see* p. 340).

The greater palatine foramen transmits the greater palatine nerve and vessels, and the vessels groove the lateral part of the palate as they run forwards to the incisive fossa. The lesser palatine foramina, usually two, sometimes one and occasionally three in number, perforate the inferior and medial aspects of the pyramidal process of the palatine bone; they contain the lesser palatine nerves and vessels. The palatine crest, which commences on the tubercle and extends on to the horizontal plate of the palatine bone, gives attachment to part of the tendon of the tensor veli palatini muscle. To the free posterior border of the palate is attached the palatine aponeurosis and to the posterior nasal spine the musculus uvulae. These collagenous elements are continuous.

The margins of the median palatal intermaxillary suture are sometimes raised forming a longitudinal midline ridge, the *palatine torus*, the surface of which may be variously smooth, pitted or irregularly roughened. Similarly a longitudinal ridge, the *maxillary torus* is occasionally present on the alveolar process spanning the palatal aspect of the subcervical roots of the upper molar teeth.



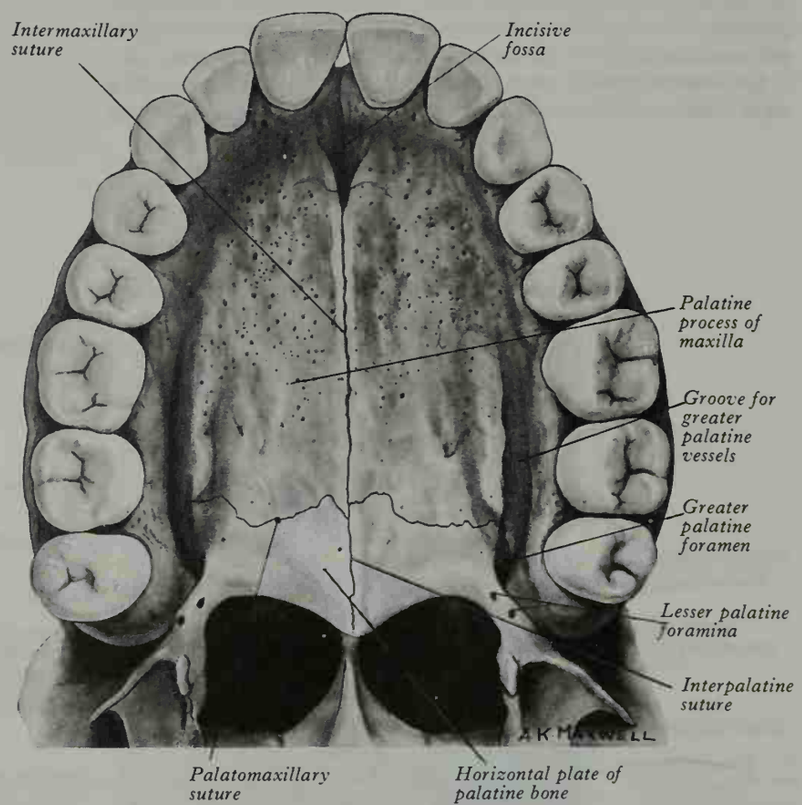
The Middle Part of the Norma Basalis

The middle part of the external surface of the base of the skull (**3**.71, 73) extends from the posterior border of the bony palate to an arbitrary line drawn transversely through the anterior margin of the foramen magnum. In the median plane anteriorly the *posterior border of the vomer* separates the two *posterior nasal apertures*. Immediately behind the vomer the posterior part of the inferior surface of the body of the sphenoid is directly continuous with the inferior surface of the *basilar part of the occipital bone*, which forms a broad bar of bone extending backwards and downwards to the foramen magnum. It is convex from side to side and wider behind than in front. A short distance in front of the foramen magnum is a small midline elevation, the *pharyngeal tubercle* the attachment of the highest fibres of the superior constrictor muscle of the pharynx.

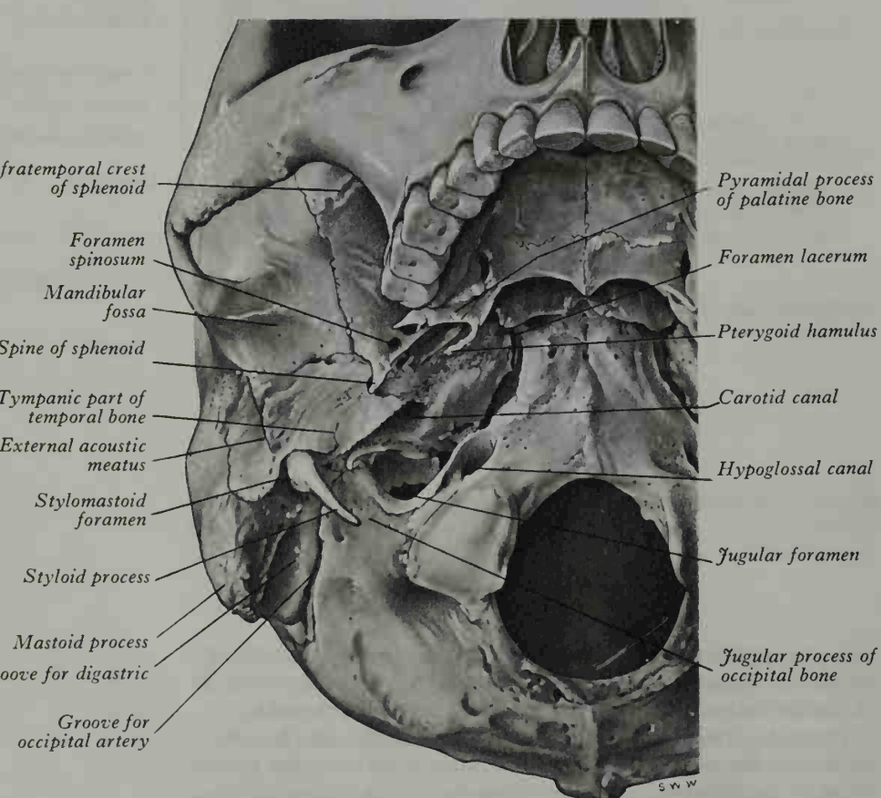
The pterygoid process descends behind the third molar tooth from the junction of the greater wing and body of the sphenoid. It has two laminae, the medial and lateral pterygoid plates, separated from each other by a cuneiform interval, directed backwards and somewhat laterally and named the *pterygoid fossa*. Anteriorly the pterygoid plates are fused except inferiorly, where they are separated by a narrow gap occupied by the *pyramidal process* of the palatine bone; the suture lines can usually be identified. Medially they articulate with the posterior border of the perpendicular plate of the palatine bone in front, and form with it the flattened area of bone which lies in the lateral wall of the posterior nasal aperture and nasopharynx. On the lateral side the fused laminae are separated from the posterior surface of the maxilla in front by the pterygomaxillary fissure (**3**.70). The *medial pterygoid plate* is the narrower and projects directly backwards. Its medial surface is covered in life with mucous membrane and forms the lateral boundary of the posterior nasal aperture and part of the lateral wall of the nasopharynx. The posterior border of the medial pterygoid plate is sharp, and presents a small projection about its midpoint. Above this projection the border is curved and is attached to the pharyngeal end of the auditory tube. At its upper end the border divides to enclose the shallow, *scaphoid fossa* (**3**.73); below, it projects beyond the rest of the plate as the slender *pterygoid hamulus*. This process curves downwards and laterally and is grooved anteriorly at its root by the tendon of the tensor veli palatini. The *lateral pterygoid plate* projects backwards and laterally and its lateral surface forms the medial wall of the infratemporal fossa. Superiorly it is continuous with the *infratemporal surface of the greater wing of the sphenoid*, which forms the anterior part of the roof of the infratemporal fossa. This surface of the greater wing is directed downwards and, sometimes, slightly to the lateral side. It is roughly pentagonal; its anterior margin is the posterolateral border of the inferior orbital fissure; anterolaterally it is limited by the infratemporal crest. Laterally it articulates with the squama of the temporal bone; medially it is continuous with the root of the pterygoid process and the side of the body of the sphenoid; posteromedially it articulates with the petrous part of the temporal bone.

The foramina ovale et spinosum are important openings on the infratemporal surface of the greater wing of the sphenoid. The *foramen ovale*, irregularly oval, lies close to the upper end of the posterior margin of the lateral pterygoid plate. It transmits the mandibular division of the trigeminal nerve. Posterior and slightly lateral to the foramen ovale the *foramen spinosum* pierces the greater wing and transmits the middle meningeal artery to the middle cranial fossa. It is much smaller than the foramen ovale and is circular. Immediately posterolateral to the foramen spinosum this surface of the greater wing has an irregular downward projection, the *spine of the sphenoid*. The medial surface of the spine is flattened, and together with the adjoining part of the posterior border of the greater wing forms the anterolateral border of a groove which is completed posteromedially by the petrous part of the temporal bone. This groove contains the cartilaginous part of the *auditory tube*, and leads backwards into the canal for the tube in the petrous part of the temporal bone and forwards to the upper part of the posterior border of the medial pterygoid plate. In the roof of the groove the posterior border of the greater wing and the anterior border of the petrous temporal are apposed at the petrosphenoidal suture.

Occasionally the foramen ovale is deficient posteriorly, being then confluent with the foramen spinosum, the frequency varying



3.71B Outline drawing of norma basalis showing the attachments of muscles. Key to **3**.71A. *Blue*=occipital bone; *yellow*=sphenoid bone; *green*=maxilla.



from 0·7 to 10·4 per cent in modern populations. Similarly, the posterior circumference of the foramen spinosum may be defective with an incidence of 2 to 17 per cent (*see* p. 348).

Behind and medial to the groove for the tube the *inferior surface of the petrous temporal* occupies the interval between the greater wing of the sphenoid and the basilar part of the occipital bone. The anterior part of this surface is rough and uneven, and its apex is separated from the posterolateral part of the body of the sphenoid by an irregular bony canal, termed the *foramen lacerum*. Behind this rough area a large and approximately circular

foramen leads upwards into the bone, the inferior opening of the *carotid canal*, occupied by the internal carotid artery. The canal turns forwards and medially and opens on the posterior wall of the foramen lacerum. Emerging from the canal the artery turns upwards to gain the cranial cavity. The lower part of the foramen lacerum is occupied by fibrocartilage, and no large structure enters or leaves the skull through this structure.

3.72 The bony palate and the alveolar arch. Inferior aspect.

3.73 The right and part of the left side of the norma basalis of the skull. To show some features to better advantage, the anterior end of the skull has been elevated so that the Frankfurt plane is tilted to an angle of about 45° to the horizontal.

From the base of the spine of the sphenoid the *squamotympanic fissure* runs laterally and slightly backwards between the upper part of the tympanic plate and the floor of the mandibular fossa. The fissure can usually be traced to the upper part of the anterior margin of the orifice of the external acoustic meatus, but it is sometimes obliterated near its lateral end. The *mandibular fossa* is deeply concave from before backwards and gently concave from side to side, and is wider at its lateral end. It contains the head of the mandible when the mouth is closed. Anteriorly the articular surface passes on to a transverse rounded elevation, the *articular tubercle*, continuous laterally with the anterior root of the zygoma. In front is the part of the squamous temporal which lies in the roof of the infratemporal fossa. Behind the squamotympanic fissure the *tympanic part of the temporal bone* separates the mandibular fossa from the external acoustic meatus. This part of the temporal bone is roughly triangular, the apex being at the medial end of the squamotympanic fissure close to the root of the spine of the sphenoid. Its lower border is free and skirts the anterolateral margin of the lower opening of the carotid canal, extending backwards and laterally to reach the root of the styloid process. There it forms the *sheath of the styloid process*, which is longer and more apparent on the lateral than on the medial side. At its lateral margin the tympanic part is fused with the rest of the temporal bone below and behind and is free above, where it forms the anterior border of the orifice of the external acoustic meatus.

The upper border of the *vomer*, which is applied to the inferior surface of the body of the sphenoid, is expanded into an *ala* on each side (3.113), and the groove between the alae fits the *rostrum of the sphenoid*. The lateral border of each ala reaches to a thin lamella which projects medially from the root of the medial pterygoid plate, and is termed the *vaginal process*. The two may come merely into contact or the edge of the ala may extend into the narrow interval between the body of the sphenoid above and the vaginal process below. The inferior surface of the vaginal process is marked by an anteroposterior groove, which is converted into a canal anteriorly by the upper surface of the sphenoidal process of the palatine bone. This is the *palatovaginal canal*, opening anteriorly through the posterior wall of the pterygopalatine fossa. It transmits the pharyngeal branch of the pterygopalatine ganglion and a minute pharyngeal branch from the third part of the maxillary artery. A second canal may be present in this situation on the medial side of the palatovaginal canal. It lies between the ala of the vomer and the upper surface of the vaginal process and is termed the *vomerovaginal canal*. When present it leads forwards into the anterior end of the palatovaginal canal.

In front of the pharyngeal tubercle the inferior surface of the basilar part of the occipital bone is intimately related to the roof of the nasal pharynx and the pharyngeal tonsil. Lateral to the tubercle is attached the longus capitis, and the area extends forwards on each side beyond the tubercle. Behind the longus capitis the rectus capitis anterior is inserted, in front of the occipital condyle and medial to the hypoglossal canal.

At the upper part of the posterior border of **the medial pterygoid plate** the *scaphoid fossa* gives origin to the anterior fibres of the tensor veli palatini, which descends along the lateral surface and posterior border of the plate to reach the *hamulus*. The tendon of the muscle twists medially round the lateral and anterior aspects of the process to gain the soft palate. The posterior border of the medial pterygoid plate, notched above by the auditory tube (p. 325), gives attachment to the pharyngobasilar fascia. Its lower part and the posterior aspect of the hamulus give origin to the highest fibres of the superior constrictor muscle of the pharynx, which curve upwards and medially to be inserted into the pharyngeal tubercle. The tip of the hamulus gives attachment to the pterygomandibular raphe. At its upper end the posterior border of the medial pterygoid plate is marked by a small tubercle, which lies on the medial side of the scaphoid fossa. This tubercle projects backwards below the posterior opening of the *pterygoid canal*, which leads forwards to open on the posterior wall of the pterygopalatine fossa. It transmits the nerve and vessels of the pterygoid canal and lies in the line of fusion of the pterygoid process and greater wing with the sphenoidal body.

The *pterygoid fossa*, between the opposed surfaces of the two pterygoid plates, is completed below and in front by the pyramidal process of the palatine bone.

The lateral pterygoid plate (3.70) is a wider lamina than the medial plate, and its irregular posterior border may present a backward projection, termed the *pterygospinous process*, which is connected by a ligament (sometimes ossified) to the spine of the sphenoid. The lateral surface, which is the rougher of the two, gives origin to the lower head of the lateral pterygoid muscle; the medial surface gives origin to the greater part of the medial pterygoid. The lateral aspect of the *pyramidal process of the palatine bone*, which appears between the tuberosity of the maxilla and the lower part of the lateral pterygoid plate, gives origin to some fibres of the superficial slip of the medial pterygoid.

The infratemporal surface of the greater wing of the sphenoid affords origin to the upper head of the lateral pterygoid muscle, and is crossed by the deep temporal and masseteric nerves, which run between the muscle and bone. The *foramen ovale*, in addition to the mandibular nerve, contains the accessory meningeal artery. Its sharp posterior border provides attachment for the fibres of the tensor veli palatini, which intervenes between the mandibular nerve and auditory tube. **The foramen spinosum** transmits the small meningeal branch of the mandibular nerve in addition to the middle meningeal artery. In the interval between the foramen ovale and the scaphoid fossa the bone sometimes presents a small foramen, the *sphenoidal emissary foramen*, which transmits an emissary vein from the cavernous sinus. The *spine of the sphenoid*, which varies greatly in size, and may be sharply pointed or blunt, has attached to it the sphenomandibular ligament. It is related laterally to the auriculotemporal nerve and medially to the chorda tympani, by which its medial aspect is sometimes grooved, and to the auditory tube. Anteriorly the most posterior fibres of the tensor veli palatini are attached to it. The groove for the tube varies in width and depth and its roof is occasionally completed by fibrous tissue. The lateral or sphenoidal wall of the groove gives origin posteriorly to fibres of the tensor tympani.

To the lateral part of the rough inferior surface of the petrous part of the temporal bone the levator veli palatini is attached. The **foramen lacerum** is bounded in front by the posterolateral part of the body of the sphenoid and the adjoining roots of the pterygoid process and greater wing, behind and laterally by the apex of the petrous part of the temporal, and medially by the basilar part of the occipital. It is a canal nearly 1 cm long, but no large structure passes completely through it. The anterior orifice of the carotid canal opens on its posterior wall, and the vessel with its venous and sympathetic plexuses, ascends through the upper end of the foramen. In the foramen the deep petrosal nerve from the carotid sympathetic plexus is joined by the greater petrosal nerve to form the nerve of the pterygoid canal, which opens on the lower part of the anterior wall. Meningeal branches of the ascending pharyngeal artery and emissary veins from the cavernous sinus pass right through the foramen. The cartilage which fills its lower part is a remnant of the primitive chondrocranium.

The floor of the *mandibular fossa* is very thin and corresponds to the most lateral part of the floor of the middle cranial fossa. It is covered in the recent state by white fibrocartilage (p. 440). The *tubercle of the root of the zygoma* gives attachment to the lateral ligament of the temporomandibular joint. A thin edge of bone may be visible in the depths of the medial end of the *squamotympanic fissure*. It is the lower border of the downturned lateral portion of the tegmen tympani and therefore a part of the petrous temporal. It divides the upper part of the squamotympanic fissure into *petrotympanic* and *petrosquamous* fissures. Through the petrotympanic fissure the chorda tympani travels in its anterior canaliculus, as it passes downwards and forwards from the tympanic cavity. The anterior tympanic branch of the maxillary artery also traverses the petrotympanic fissure.

The tympanic part of the temporal bone (3.73) is separated from the capsule of the temporomandibular joint by a portion of the parotid gland, which usually contains the auriculotemporal nerve. It is thinnest near the centre of this surface and is occasionally deficient (p. 327). Its grooved upper aspect forms the anterior wall, the floor and the lower part of the posterior wall of the external acoustic meatus. Except where it ensheathes the styloid process its posterior surface is fused with the petromastoid part of the bone.

The Posterior Part of the Norma Basalis

The median region of the posterior part of the cranial base (3.71) features anteriorly **the foramen magnum**, which leads into the posterior cranial fossa. The foramen is oval, wider behind than in front, and its anteroposterior measurement exceeds its transverse. It transmits a number of structures, of which the most important is the lower end of the medulla oblongata. Anteriorly the margin of the foramen magnum is overlapped slightly on each side by an *occipital condyle*, which projects downwards to articulate with the superior articular facet on the lateral mass of the atlas. Oval in outline, the condyle is placed obliquely so that its anterior end is nearer the median plane. It shows a pronounced convexity from before backwards and is less convex from side to side. The medial aspect is roughened for ligamentous attachments. Above the anterior part of the condyle the occipital bone is pierced by the *hypoglossal (anterior condylar) canal*, which runs laterally and slightly forwards from the posterior cranial fossa and contains the hypoglossal nerve.

A depression of variable depth occurs behind the condyle. It is the *condylar fossa*, and may be pierced by a *condylar canal* which, when present, transmits an emissary vein from the sigmoid sinus. (The incidence of condylar canals shows racial variation—from 13·3 per cent in modern Palestinians to 70 per cent in Peruvian crania. It also illustrates sexual variation, being present, for example, in 58 per cent of male Burmese, but only 31 per cent of females, *see* p. 348.) Lateral to the condyle the *jugular process of the occipital bone* articulates with the petrous temporal. The anterior border of the process is free and forms the posterior boundary of the *jugular foramen*.

The jugular foramen is a large irregular hiatus between the occipital bone and the jugular fossa of the petrous temporal, and is set at the posterior end of the petro-occipital suture. In front it is separated from the lower orifice of the carotid canal by a raised ridge of bone, and on its lateral side it is related to the medial aspect of the sheath of the styloid process. Medially it is separated from the hypoglossal canal by a thin bar of bone. The foramen is usually larger on the right side of the skull, and its long axis is directed forwards and medially. The anterior part of the foramen transmits the inferior petrosal sinus; its intermediate part, the glossopharyngeal, vagus and accessory nerves; its posterior part the internal jugular vein. When the superior bulb of the internal jugular vein is well developed the jugular fossa of the temporal bone is recessed out in an upward and lateral direction in company.

Posterior to the root of the styloid process the *stylomastoid foramen* transmits the facial nerve. Posterolateral to the foramen the tip of the *mastoid process* projects downwards and forwards, and forms the lateral wall of the *mastoid notch*, from which the posterior belly of the digastric takes origin. Medial to the notch this part of the temporal bone may be grooved by the occipital artery (3.73).

In the median plane behind the foramen magnum the squamous part of the occipital bone presents the *external occipital crest*, to which is attached the upper end of the ligamentum nuchae. It terminates behind at the external occipital protuberance. Near its midpoint the *inferior nuchal line* begins and curves backwards and laterally. It is nearly parallel to the *superior nuchal line*, which extends in the same direction from the external occipital protuberance and may be raised into a distinct crest in its medial part.

The foramen magnum provides a wide communication between the posterior cranial fossa and the vertebral canal. Anteriorly the apical ligament of the dens and the membrana tectoria pass through it, both being attached to the upper surface of the basilar part of the occipital bone. Its wider, posterior part transmits the lower end of the medulla oblongata and the meninges. In the subarachnoid space the spinal roots of the accessory nerves, and the vertebral arteries, with their sympathetic plexuses, ascend into the cranium, and the posterior spinal arteries descend, one on each posterolateral aspect of the

brainstem, as does the anterior spinal artery on the front of the brainstem in the median plane. In addition, the lower part of the tonsils of the cerebellum may project into the foramen on each side of the medulla oblongata. The *anterior margin* of the foramen gives attachment to the anterior atlanto-occipital membrane, which is continuous on each side with the capsular ligament of the atlanto-occipital joint. To the *posterior margin* is attached the posterior atlanto-occipital membrane, and to the roughened medial aspect of the condyle, the alar ligament.

In addition to the hypoglossal nerve the *hypoglossal canal* contains a meningeal branch of the ascending pharyngeal artery and a small emissary vein from the basilar plexus. Not uncommonly the canal is divided into two by a spicule of bone (p. 322). The inferior surface of the jugular process of the occipital bone provides attachment for the rectus capitis lateralis.

The jugular foramen (3.71) is directed upwards, medially and backwards, and on the external surface of the skull its apparent size is increased owing to the presence of the jugular fossa of the temporal bone on its lateral side. The floor of the fossa separates the superior bulb of the internal jugular vein from the tympanic cavity, and its lateral wall is pierced by a minute canal, the *mastoid canaliculus*, which transmits the auricular branch of the vagus nerve. Passing laterally through the bone, this nerve is very near to the facial canal, and finally emerges in the tympanomastoid suture. It is extracranial at birth but becomes surrounded by bone as the tympanic plate and the mastoid process develop. On or near the ridge between the jugular fossa and the orifice of the carotid canal, the *canaliculus for the tympanic nerve* pierces the bone to transmit to the middle ear the tympanic branch from the glossopharyngeal nerve. On the upper boundary of the jugular foramen, near its medial end, there is a small notch—more easily identified on the internal surface—which contains the inferior ganglion of the glossopharyngeal nerve. The orifice of the *cochlear canaliculus* (p. 329) lies at the apex of the notch, the projecting edges of which may reach the occipital bone and divide the foramen into three parts.

The stylomastoid foramen lies behind the root of the styloid process and at the anterior end of the mastoid notch. As the facial nerve emerges from the foramen it is close to the posterior belly of the digastric, which it supplies before entering the parotid gland. In addition to the facial nerve the foramen carries the stylomastoid branch of the posterior auricular artery. A vascular groove crosses the inferior aspect of the posterior part of the temporal bone medial to the mastoid notch. It is occupied by the occipital artery, and its absence indicates that the vessel lies at a lower level than usual and between the splenius and longissimus capitis instead of deep to both.

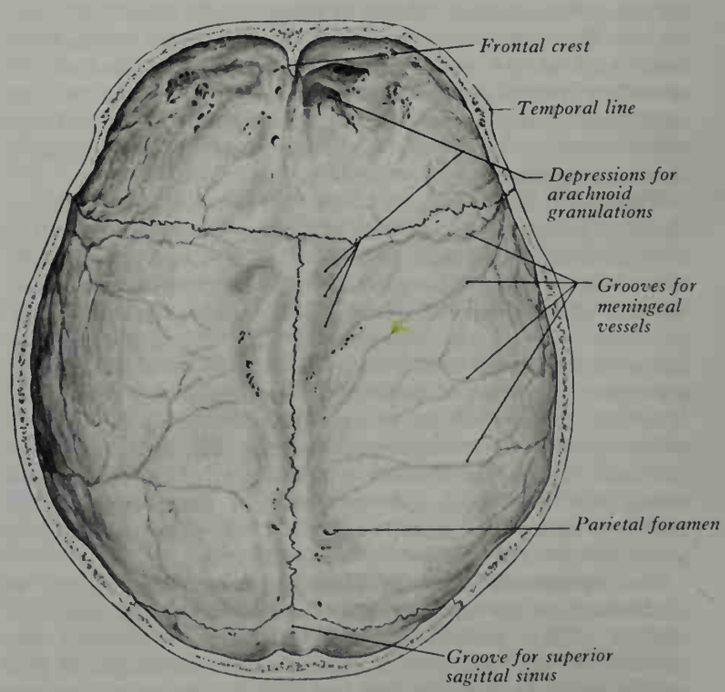
The area below the *inferior nuchal line* gives insertion medially to the rectus capitis posterior minor and laterally to the rectus capitis posterior major (3.71 B). The interval between the inferior and the superior nuchal lines provides insertion medially for the semispinalis capitis and laterally for the obliquus superior. In its medial part the *superior nuchal line* gives origin to the highest fibres of the trapezius; laterally, fibres of the sternocleidomastoid and, more anteriorly, splenius capitis are attached to it.

THE INTERIOR OF THE CRANIUM

The cranial cavity contains the brain and its meninges, and their blood vessels. Its walls are formed by the frontal, parietal, sphenoid, temporal and occipital bones and, to a small extent by the ethmoid bone. They are lined with a fibrous membrane, the *endocranium*, which is the outer zone of the dura mater. It passes through the various foramina which lead to the exterior, and becomes continuous with the periosteum on the outer surface of the skull, the *pericranium*. Both these fibrous membranes are continuous with the sutural ligaments, or cartilages, which occupy the narrow interosseous intervals at the sutures.

The walls of the cranial cavity vary in thickness in different skulls and in different parts of the same skull; but they tend to be thinner in situations where they are well covered with muscles externally, e.g. the temporal and posterior cranial fossae. Most of the cranial bones display *outer* and *inner tables*, formed of compact bone and separated from each other by the *diploë*, cancellous bone containing red bone marrow in its interstices. The inner table is thinner and more brittle than the outer table, which is generally very resilient. Many of the bones are so thin that the two tables are continuous, e.g. the vomer, pterygoid plates.

The skull is thicker in some races and some individuals, but no relationship exists between thicknesses of skull and cranial capacity, and in all races, the bones of the skull are thinner in women and children than in men.



The interior of the skull is described in two parts: the internal surface of the skull cap, the calva, and the internal surface of the base of the skull.

The Internal Surface of the Cranial Vault

The *calva* or *skull cap* (3.74) includes most of the frontal and parietal bones and the upper part of the squama of the occipital bone. It is marked, therefore, by the coronal, sagittal and lambdoid sutures, which may or may not be visible because the cranial sutures tend to become obliterated in old age and the process commences on the cerebral surface. The cranial vault is deeply concave in all directions and presents numerous vascular furrows and other markings.

Anteriorly, in the median plane, the *frontal crest* projects backwards. It gives attachment to the falx cerebri and is grooved by the commencement of the *sagittal sulcus*. This accommodates the superior sagittal sinus, and widens progressively as it runs backwards in the median plane below the sagittal suture. On each side of the sagittal sulcus the bone presents a number of irregular depressions, the *granular foveolae*. They become more numerous and obvious as skulls age and are adapted to the arachnoid granulations.

The frontal branch of the middle meningeal vein, and sometimes its accompanying artery, groove the bone deeply about 1 cm behind the coronal suture, corresponding more or less to the precentral sulcus of the cerebrum. The rami of these vessels and

3.74 The internal (endocranial) surface of the skull cap or calva.

those of their parietal branches course upwards and backwards in grooves on the inner surface of the parietal bone. Smaller grooves produced by meningeal vessels may be present on the inner surfaces of the frontal and occipital bones. When present, the *parietal foramina* open on this surface near the sagittal groove about 3·5 cm in front of the lambdoid suture. Each transmits an emissary vein from the superior sagittal sinus.

The *impressions for the cerebral gyri* are less distinct on the vault than on the base of the skull and are seen best towards the latter.

The Internal Surface of the Cranial Base

The internal surface of the base of the skull (**3**.75) shows a natural division into anterior, middle and posterior cranial fossae. It is very irregular owing, partly, to the impressions for the cerebral gyri, which are especially conspicuous in the anterior and middle fossae, where they reflect accurately the pattern of the surface of the corresponding parts of the cerebrum. The dura mater is firmly adherent to the whole area, and through the numerous foramina and fissures its outer layer, the endocranium, is continuous with the periosteum on the exterior of the skull.

The Anterior Cranial Fossa

The anterior cranial fossa (**3**.75) is limited in front and on each side by the frontal bone. Its floor is formed by the orbital parts of the frontal bone, the cribriform plate of the ethmoid and the lesser wings and anterior part of the body of the sphenoid.

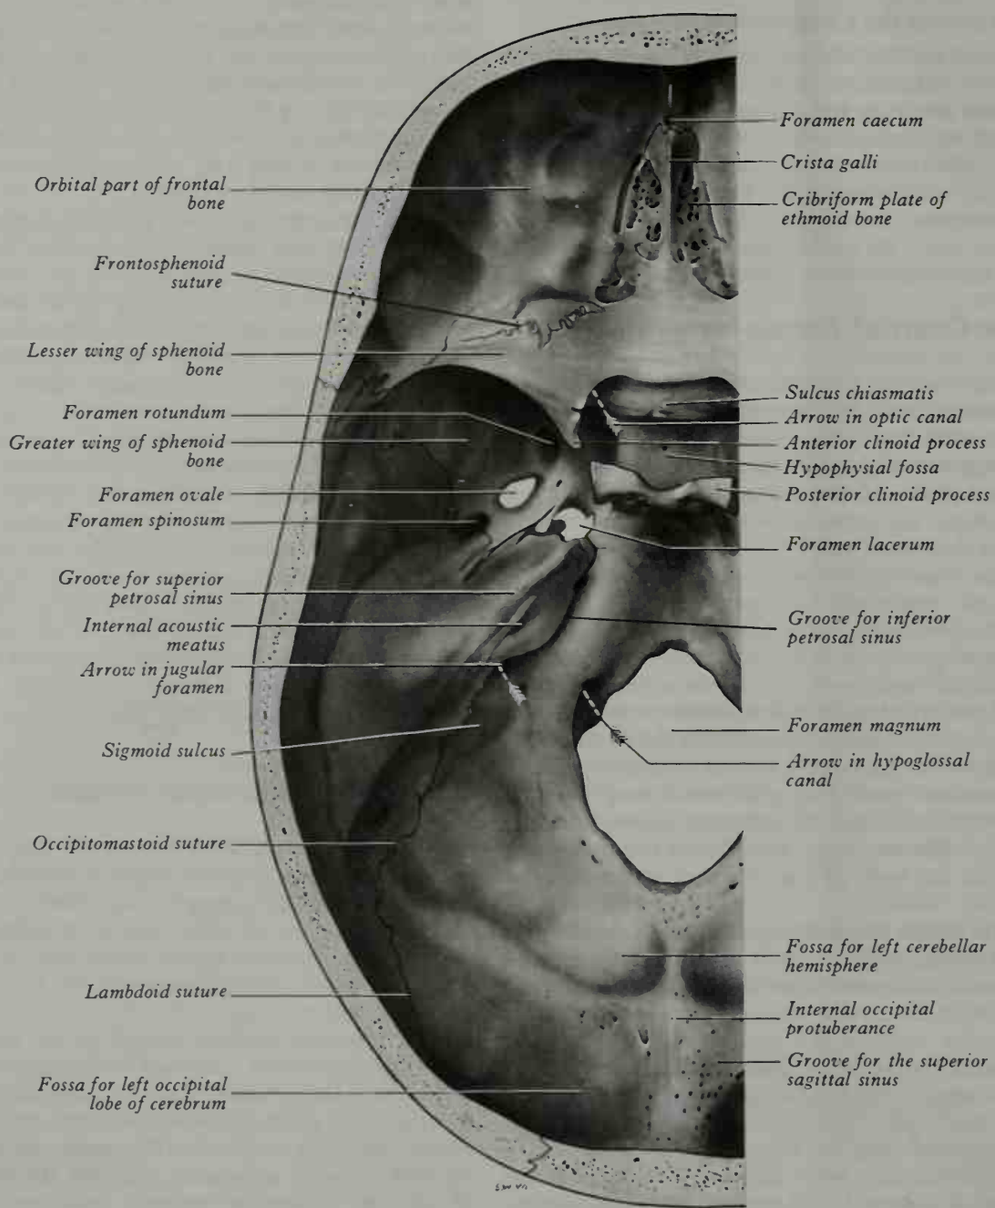
The cribriform plate of the ethmoid, which stretches across the median plane, lies between the two orbital parts of the frontal bone, and is depressed below the level of the rest of the floor. It separates the fossa from the nasal cavity, the roof of which it helps to form (**3**.78). Anteriorly it presents a median crest-like elevation, termed the *crista galli*, which projects upwards between the two cerebral hemispheres. A depression intervenes between the front of the crista galli and the *crest of the frontal bone*, the floor of which is crossed by the fronto-ethmoidal suture and marked by the presence of the *foramen caecum*. On each side the crista galli is separated from the orbital part of the frontal bone by a narrow interval. The numerous small foramina which perforate the cribriform plate transmit the minute olfactory nerves from the nasal mucosa to the olfactory bulb. Posteriorly the cribriform plate articulates with the body of the sphenoid at the spheno-ethmoidal suture.

The orbital part of the frontal bone forms the greater part of the floor of the fossa on each side of the median plane and separates the orbit and its contents from the inferior surface of the frontal lobe of the brain. Its cranial surface is convex and marked by impressions for the cerebral gyri and by one or two small grooves for meningeal vessels. In its anteromedial part it is split into two laminae to contain part of an air space, termed the *frontal sinus*. The medial part of the orbital plate covers the ethmoidal labyrinth and shuts it out from the floor of the anterior cranial fossa. Posteriorly it articulates with the anterior border of the *lesser wing of the sphenoid bone*. In the median plane the cerebral surface of the frontal bone is marked by the *frontal crest*, which projects backwards between the cerebral hemispheres and extends upwards on the interior of the skull cap.

The sphenoid bone completes the posterior region of the floor of the fossa. Centrally is the anterior part of the upper surface of its body, termed the *jugum sphenoidale*; this separates the fossa from bilateral air spaces in the body of the sphenoid and named the *sphenoidal sinuses* (**3**.77). Anteriorly the jugum articulates with the posterior margin of the cribriform plate; posteriorly it is limited by the anterior border of a groove, termed the *sulcus chiasmatis*, which crosses the body of the sphenoid in the forepart of the middle cranial fossa and leads from one optic canal to the other. Lateral to the jugum the floor of the anterior fossa is formed by the *lesser wing of the sphenoid*. The posterior margin of the lesser wing, which curves medially and backwards, is free and overhangs the middle cranial fossa. Laterally the lesser wing tapers to a point and meets the suture between the frontal bone and the greater wing at or near the lateral end of the superior orbital fissure. The medial extremity of its posterior border forms a projection termed the *anterior clinoid process*. Medially the lesser wing is connected to the body of the sphenoid by two roots, separated from each other by the *optic canal*. The anterior root, broad and flat, is continuous with the jugum sphenoidale; the posterior root, smaller and thicker, is connected to the body of the sphenoid opposite the posterior border of the chiasmal sulcus.

The crista galli and the frontal crest afford attachment to the falx cerebri. The foramen caecum between them usually ends blindly, but on rare occasions it is patent and accomodates a vein from the nasal mucosa to the superior sagittal sinus. The narrow groove on the lateral side of the crista galli is related to the gyrus rectus, and the olfactory bulb lies on the medial edge of the orbital part of the frontal bone. The *anterior ethmoidal canal* opens on the line of the suture between the orbital part of the frontal bone and cribriform plate (**3**.67, 104). It is placed behind the crista galli and is difficult to identify, for it is directed medially and is overlapped above by the medial edge of the orbital plate. It transmits the anterior ethmoidal nerve and vessels, which run forward under the dura mater and gain the nasal cavity by passing downwards through a slit-like foramen at the side of the crista galli. The *posterior ethmoidal canal* opens at the posterolateral corner of the cribriform plate and is overhung by the anterior border of the sphenoid. It transmits the posterior ethmoidal vessels.

The posterior border of the lesser wing of the sphenoid, fits into the stem of the lateral cerebral sulcus and may be grooved by the sphenoparietal sinus. Above, the lesser wing is related to the posterior part of the inferior surface of the frontal lobe and medially to the anterior perforated substance. Inferiorly it forms the upper boundary of the superior orbital fissure and helps to complete the roof of the orbit. The anterior clinoid process has attached to it the free border of the tentorium cerebelli and is grooved on its medial aspect by the internal carotid artery as it pierces the roof of the cavernous sinus. Not infrequently the anterior clinoid process is connected to the middle clinoid process by a thin bar of bone, which completes a caroticoclinoid foramen around the internal carotid artery. The jugum sphenoidale underlies posterior ends of the gyri recti and olfactory tracts.



The Middle Cranial Fossa

The middle cranial fossa (**3**.75A and B), is deeper than the anterior; it is more extensive on each side than in the midline. In front it is bounded by the posterior borders of the lesser wings of the sphenoid, the anterior clinoid processes and the anterior margin of the sulcus chiasmatis, behind by the superior borders of the petrous parts of the temporal bones and the dorsum sellae of the sphenoid bone, laterally by the temporal squamae, the frontal angles of the parietal bones and the greater wings of the sphenoid.

Centrally the floor is formed by the body of the sphenoid. In front, the chiasmal sulcus leads on each side into the optic canal. The sulcus is rarely in contact with the optic chiasma, which is usually above and behind it. The **optic canal** is between the two roots of the lesser wing with, medially, the body of the sphenoid. It extends forwards, laterally and somewhat downwards, containing the optic nerve, ophthalmic artery and meninges. Immediately behind the sulcus the upper surface of the body of the sphenoid is shaped like a Turkish saddle and is hence termed the *sella turcica*. Its anterior slope bears a median elevation, the *tuberculum sellae*, and behind that the surface is hollowed out as the *hypophysial fossa* (**3**.75), which contains the hypophysis cerebri. The floor of the hypophysial fossa forms part of the roof of the sphenoidal sinuses (**3**.62A). Posterior to the fossa a plate of bone projects upwards and forwards to form the *dorsum sellae* (**3**.62A). Each superolateral angle of the dorsum sellae is expanded into a *posterior clinoid process*. Lateral to the sella turcica the body of the sphenoid presents a shallow *groove for the internal carotid artery*, as it runs forwards from the foramen lacerum. A small elevation marks the anterior part of the medial edge of the carotid groove and is termed the *middle clinoid process*; it may be joined to the anterior clinoid process by a thin bar of bone to make a foramen around the internal carotid artery. Posteriorly the lateral edge of the carotid groove may be deepened by a small projection termed the *lingula*.

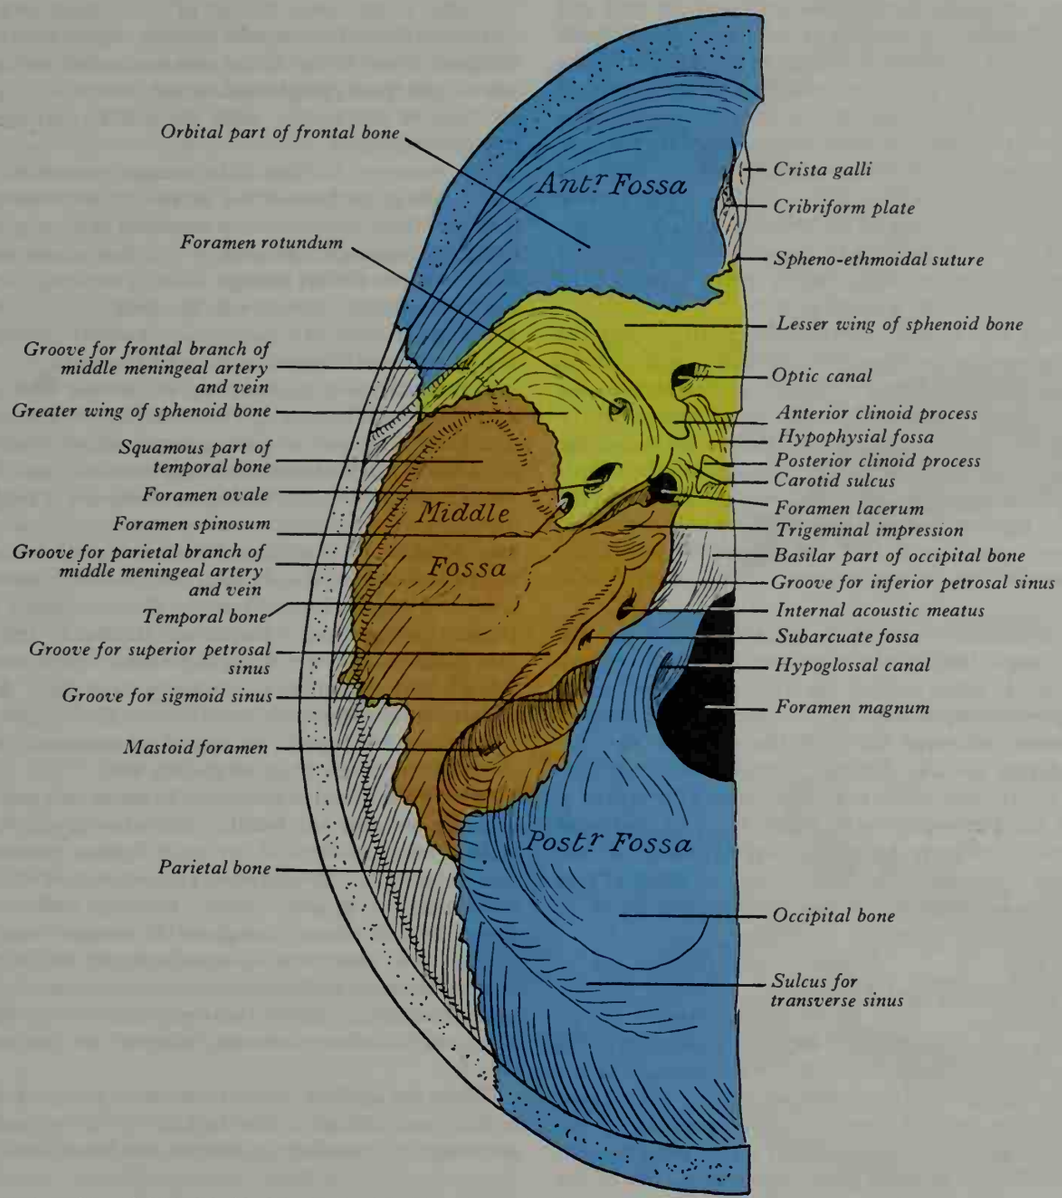
Laterally the middle cranial fossa is deep and supports the

temporal lobe of the cerebrum. It is formed in front by the cerebral surface of the greater wing of the sphenoid, behind by the anterior surface of the petrous part of the temporal bone, and laterally the cerebral surface of the temporal squama occupies the interval between these two bones. It is related in front to the apical region of the orbit, laterally to the temporal fossa, below to the infratemporal fossa. Anteriorly it communicates with the orbit through **the superior orbital fissure**, which is bounded above by the lesser wing, below by the greater wing, and medially by the side of the body of the sphenoid. The fissure is wider medially and its long axis is directed upwards, laterally and forwards. It transmits the terminal branches of the ophthalmic nerve, the ophthalmic veins, the oculomotor, trochlear and abducent nerves, and some smaller vessels. (*Vide infra.*)

3.75A The internal (endocranial) surface of the left half of the base of the skull. Compare with Key, **3**.75B

The foramen rotundum pierces the greater wing of the sphenoid immediately below and a little behind the medial end of the superior orbital fissure. It leads forwards into the pterygopalatine fossa, to which it conducts the maxillary nerve. (*Vide infra.*)

The foramen ovale passes through the greater wing of the sphenoid posterior to the foramen rotundum and lateral to the lingula and the posterior end of the carotid groove. It leads downwards into the infratemporal fossa and transmits the mandibular nerve to that region.



The foramen spinosum is near the posterolateral margin of the foramen ovale, and transmits the middle meningeal artery. The artery, with its accompanying veins, runs laterally to gain the temporal squama, on which it runs upwards, forwards and laterally. Crossing the sphenosquamosal suture for a second time it ascends on the greater wing and divides into frontal and parietal branches. The frontal branch proceeds upwards across the cerebral surface of the pterion (p. 302) and gains the anterior part of the parietal bone. In the region of the pterion the artery is often enclosed in a bony canal. The parietal branch runs backwards and upwards on to the upper part of the temporal squama and crosses the squamosal suture to gain the posterior part of the parietal bone. These arteries and (laterally) their accompanying veins lie in conspicuous grooves in the floor and lateral wall of the middle cranial fossa. (*Vide infra.*)

At the posterior end of the carotid groove and posteromedial to the foramen ovale is **the foramen lacerum**. It is bounded behind by the apex of the petrous temporal and in front by the body of the sphenoid and the posterior border of its greater wing. This end of the foramen lacerum contains the internal carotid artery and its accompanying sympathetic and venous plexuses. (*Vide infra.*)

Behind the foramen lacerum the anterior surface of the petrous temporal presents a shallow depression adjoining the apex of the bone, occupied by the trigeminal ganglion, the *trigeminal*

impression. Posterolateral to this the surface presents a shallow depression, limited posteriorly by a transversely rounded elevation, the *arcuate eminence*. This elevation is produced by the anterior semicircular canal, which is closely related here to the floor of the middle cranial fossa.

Lateral to the trigeminal impression the anterior surface of the petrous temporal displays a narrow groove passing backwards and laterally into the *hiatus for the greater petrosal nerve*. Lateral to this

3.75B The internal surface of the left half of the base of the skull. (Basis cranii interna.) Key to **3**.75A. *Blue*=frontal and occipital bones; *yellow*=sphenoid bone; *brown*=temporal bone.

is the *hiatus for the lesser petrosal nerve*. Anterolateral to the arcuate eminence the anterior surface of the petrous temporal is formed by the *tegmen tympani*, a thin osseous lamella which forms the roof of the tympanic cavity, and extends forwards and medially above the auditory tube. Lateral to the arcuate eminence the posterior part of the tegmen tympani forms the roof of the mastoid antrum, an air space in the bone continuous in front with the tympanic cavity.

The superior border of the petrous temporal separates the middle cranial fossa from the posterior cranial fossa. Behind the trigeminal impression it is grooved by the superior petrosal sinus, which connects the posterior end of the cavernous sinus to the upper end of the sigmoid sinus.

On each side of the body of the sphenoid the cavernous sinus extends from the medial end of the superior orbital fissure to the apex of the petrous part of the temporal bone. In addition to the internal carotid artery and its plexus of sympathetic nerves, the sinus contains the oculomotor, trochlear, abducent and ophthalmic nerves, but these structures are not in contact with bone. An anterior intercavernous sinus, which crosses the tuberculum sellae, and a posterior intercavernous sinus, which crosses the front of the dorsum sellae, connect the two cavernous sinuses to each other. The diaphragma sellae, which surrounds the infundibulum, is connected to the tuberculum in front and to the dorsum sellae behind. The posterior clinoid process gives attachment to the anterior extremity of the attached margin of the tentorium cerebelli and to the petrosphenoidal ligament (p. 1069).

The superior orbital fissure (**3**.65) opens into the orbit between its roof and its lateral wall. Its lower border is marked by a small projection which gives attachment to the lateral part of the common tendinous ring. At the lateral extremity of the fissure the greater wing articulates with the orbital part of the frontal bone (See also p. 300.)

The foramen rotundum, like the medial end of the superior orbital fissure, is intimately related to the lateral wall of the sphenoidal sinus. Originally a part of the fissure, it becomes separated secondarily. A small foramen may be present at the root of the greater wing medial to the foramen ovale; it transmits an emissary vein from the cavernous sinus and is often termed the *emissary sphenoidal foramen*. In addition to the mandibular nerve

the foramen ovale transmits the accessory meningeal artery, and, sometimes, the lesser petrosal nerve. Together with the middle meningeal artery **the foramen spinosum** transmits the meningeal branch of the mandibular nerve. Both these foramina are represented at first by notches on the margin of the greater wing, which subsequently become converted into foramina.

The foramen lacerum, as described above, is a short bony canal, traversed in its whole extent only by minute meningeal branches from the ascending pharyngeal artery and a few small veins. The internal carotid artery pierces its posterior wall and ascends through its upper opening. The greater petrosal nerve emerges from its hiatus and runs forwards in the groove which marks the anterior surface of the petrous part of the temporal bone. It turns downwards through the foramen lacerum on the lateral side of the internal carotid artery and is joined by the deep petrosal nerve to form the nerve of the pterygoid canal. This nerve leaves the foramen lacerum above its lower opening by traversing the *pterygoid canal*, which opens on its anterior wall. The lesser petrosal nerve lies to the lateral side of the greater as it emerges from its hiatus on the anterior surface of the petrous part of the temporal bone and may occupy a small groove.

In a young skull the suture between the petrous and the squamous parts of the temporal bone may be visible at the lateral limit of the *tegmen tympani*, but it is usually obliterated in the adult skull. In this situation anteriorly, the lateral margin of the tegmen tympani turns downwards, forming the lateral wall of the bony part of the auditory tube, and its lower border may be visible in the floor of the squamotympanic fissure (p. 306). Lateral to the anterior part of the tegmen tympani the temporal squama is thin and translucent over a small area. This corresponds to the deepest part of the mandibular fossa on the external surface of the base of the skull.

In front of the commencement of the groove for the superior petrosal sinus the upper border of the petrous temporal shows a shallow, smooth notch, often termed the *trigeminal notch*, which leads into the *trigeminal impression*. In this situation the roots of the trigeminal nerve intervene between the superior petrosal sinus and bone. A tiny spicule, directed forwards and medially, marks the anterior extremity of the notch and gives attachment to the lower end of the petrosphenoidal ligament. The abducent nerve bends forwards sharply across the upper border of the petrous part of the temporal bone immediately in front of this bony spicule, and so lies between the petrosphenoidal ligament and the side of the dorsum sellae.

The Posterior Cranial Fossa

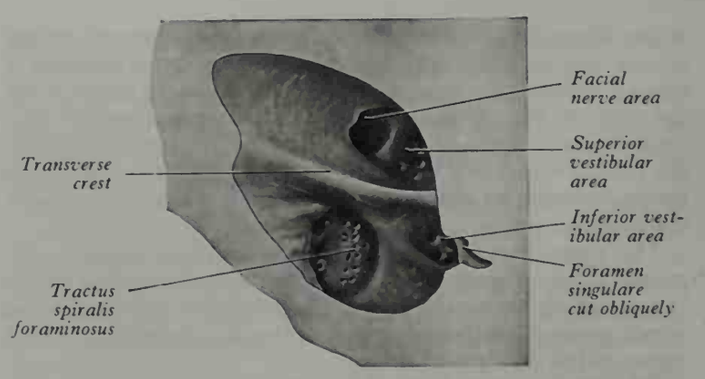
The posterior fossa (**3**.75 A and B) is the largest and deepest of the three cranial fossae. It is bounded in front by the dorsum sellae, the posterior part of the body of the sphenoid and the basilar part of the occipital bone; behind, by the lower portion of the squamous part of the occipital bone; on each side, by the petrous and mastoid parts of the temporal bone, the lateral part of the occipital and, above and behind, by a small part of the mastoid angle of the parietal bone. It contains the cerebellum behind and the pons and medulla oblongata in front.

The foramen magnum (p. 307) is in the floor of the fossa and surrounded by the parts of the occipital bone; by the basilar part in front, the lateral part on each side, and a small portion of the squama behind. Just in front of its transverse diameter it is encroached on by the medial aspects of the occipital condyles, so that it is somewhat ovoid in shape and wider behind. Its narrower, anterior part lies above the dens of the axis vertebra; its wider, posterior part communicates below with the vertebral canal, and through it the medulla oblongata becomes continuous with the spinal cord.

In front of the foramen magnum the basilar part of the occipital bone, the posterior part of the sphenoidal body and the dorsum sellae form a sloping surface, the *clivus*, gently concave from side to side, antero-inferior to the pons and medulla oblongata. On each side this area is separated from the petrous part of the temporal bone by the petro-occipital fissure, occupied in life by a thin plate of cartilage. The fissure is limited behind by the jugular foramen, and its margins are grooved by the inferior petrosal sinus.

The jugular foramen (p. 307) lies at the posterior end of the petro-occipital fissure, and leads forwards, downwards and laterally to the exterior. Its upper border is sharp and irregular and presents a *notch for the glossopharyngeal nerve*. Its lower border is smooth and regular. The posterior part of the foramen contains the sigmoid sinus, continuous below with the internal jugular vein. In front of the vein the accessory, vagus and glossopharyngeal nerves, in that order from behind forwards, traverse the foramen.

Medial to the lower border of the jugular foramen a rounded elevation, termed the *jugular tubercle*, marks the lateral part of the occipital bone. It lies above and somewhat in front of the inner opening of **the hypoglossal canal**, which pierces the bone at the junction of the basilar with the lateral part and contains the hypoglossal nerve.



The posterior surface of the petrous part of the temporal bone forms a large portion of the lateral (or anterolateral) wall of the posterior fossa. Above the anterior part of the jugular foramen **the internal acoustic meatus** (**3**.75) runs transversely in a lateral direction. It is a short passage, about 1 cm long, closed laterally by a perforated plate of bone which separates it from the internal ear. Through it pass the facial and vestibulocochlear nerves, the nervus intermedius and labyrinthine vessels.

Behind the petrous temporal the lateral wall of the posterior cranial fossa is formed by the mastoid part of the temporal bone. Anteriorly it bears a wide groove, which runs forwards and downwards, then downwards and medially, and finally forwards to the posterior limit of the jugular foramen. This groove contains the sigmoid sinus and is termed the *sigmoid sulcus* (**3**.75). At its upper end, where it touches the mastoid angle of the parietal bone, the groove is continuous with that for the transverse sinus and crosses the parietomastoid suture. As it descends, it lies *behind the mastoid antrum*, a most important relation of that cavity. In this part of its course the *mastoid foramen* opens near its posterior margin and transmits an emissary vein from the sinus. In its lowest part the sigmoid sulcus crosses the occipitomastoid suture and grooves the jugular process of the occipital bone. It is usually deeper on the right than on the left side.

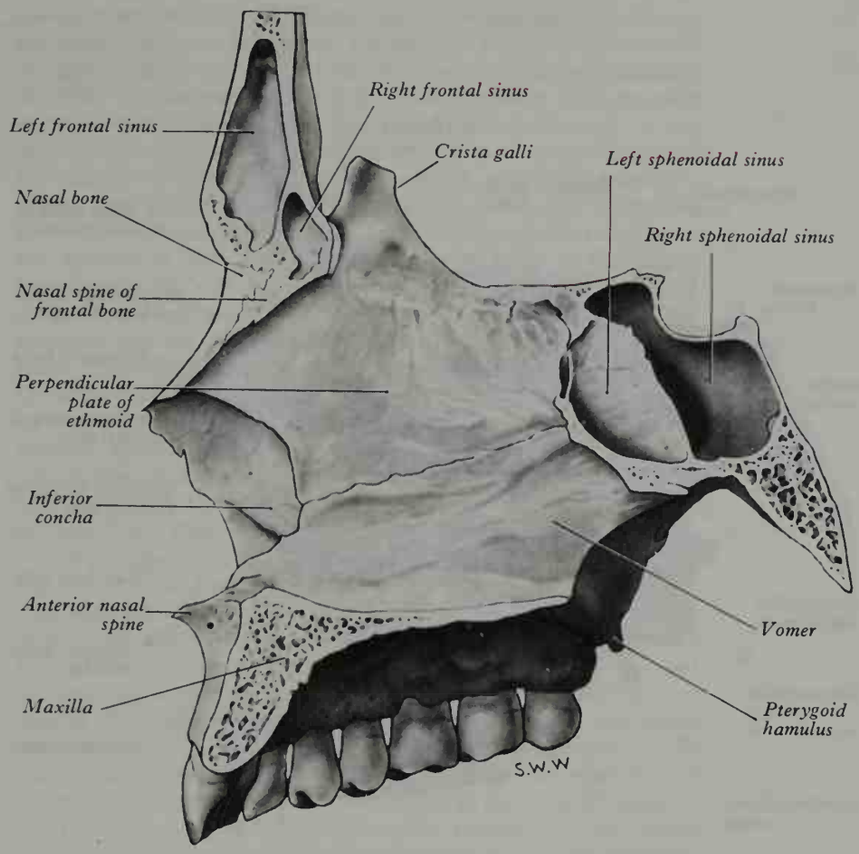
Behind the foramen magnum the squamous part of the occipital bone shows near the midline the *internal occipital crest*, which ends above and behind in an irregular elevation named the *internal occipital protuberance*. On each side of the protuberance a wide shallow groove curves laterally with a light upward convexity to the mastoid angle of the parietal bone. It is produced by the transverse sinus, is usually deeper on the right, and at its lateral extremity is continuous with the sigmoid sulcus. Below the transverse sulcus the internal occipital crest divides the bone into two gently hollowed fossae, adapted to the cerebellar hemispheres.

When the *condylar canal* is present (**3**.86), its inner orifice lies behind and lateral to the orifice of the hypoglossal canal. It transmits an emissary vein from the lower end of the sigmoid sinus.

The anterior wall of the posterior fossa (the clivus) is related to the plexus of basilar sinuses which connects the two inferior petrosal sinuses and communicates below with the internal

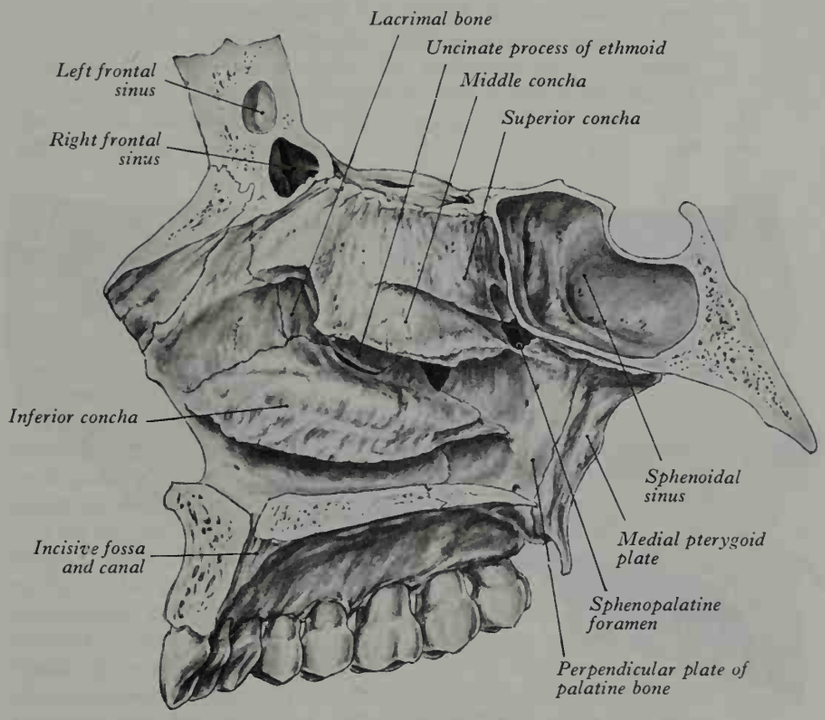
3.76 The fundus of the right internal acoustic meatus, exposed by a section through the petrous part of the right temporal bone nearly parallel to the line of its superior border.

vertebral venous plexus. A little in front of the foramen magnum the membrana tectoria is attached to the basilar part of the occipital bone (**4**.29), covering the attachment of the apical ligament of the dens. The jugular tubercle is often grooved by the glossopharyngeal, vagus and accessory nerves, as they pass to the jugular foramen. In addition to the hypoglossal nerve **the hypoglossal canal**, which is often subdivided (p. 322), transmits a meningeal branch of the ascending pharyngeal artery. To the roughened medial aspect of the occipital condyle (**3**.86) the alar ligament is attached.



The lower and posterior borders of **the jugular foramen** (pp. 307 and 329) are smooth and regular, but its upper border is sharp and interrupted by a notch, the ends of which may divide the foramen into two or sometimes three compartments. At its deepest part the notch is pierced by the *cochlear canaliculus*, which contains the perilymphatic 'duct' (*see* p. 1262).

The internal acoustic meatus is separated at its lateral end or *fundus* from the internal ear by a vertical plate which is divided into two unequal portions by a *transverse crest* (**3**.76). Above the crest anteriorly the bone is pierced by **the facial canal**, which conducts the facial nerve through the petrous temporal to the stylomastoid foramen. Behind the opening of the facial canal there is a small depression, termed the *superior vestibular area*, which presents a number of openings for the passage of the nerves to the utricle and the anterior and lateral semicircular ducts. Below the transverse crest anteriorly lies the *cochlear area*, in which a number of small, spirally arranged openings encircle the central canal of the cochlea and constitute the *tractus spiralis foraminosus*. Behind the cochlear area the *inferior vestibular area* presents several openings for the nerves to the saccule. Below and behind the inferior vestibular area the *foramen singulare* gives passage to the nerve to the posterior semicircular duct.

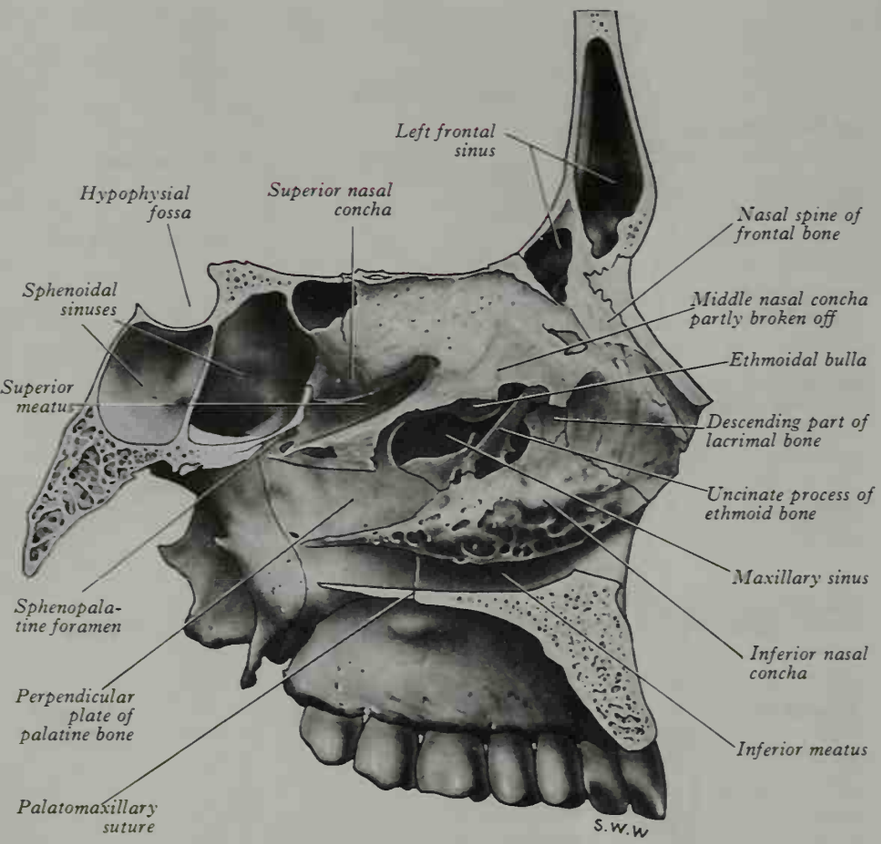


Behind the orifice of the internal acoustic meatus a thin plate of bone with an irregularly curved margin projects backwards, and the slit which it bounds contains the external opening of the *aqueduct of the vestibule* (**3**.94). Within the aqueduct the saccus and ductus endolymphaticus (p. 1203) are situated together with a small artery and vein. In the area between the internal acoustic meatus and the external opening of the aqueduct of the vestibule there is a small depressed area, termed the *subarcuate fossa* (**3**.75B), which lodges a small process of the dura mater. It lies nearer to the upper border of the bone (**3**.94) and is pierced by a small vein. In the infant the fossa is relatively large and extends as a short blind tunnel under the anterior semicircular canal; it corresponds to the floccular fossa in some animals.

In addition to an emissary vein, the *mastoid foramen* transmits a meningeal branch of the occipital artery, which is sometimes large enough to produce a groove on the squamous part of the occipital bone.

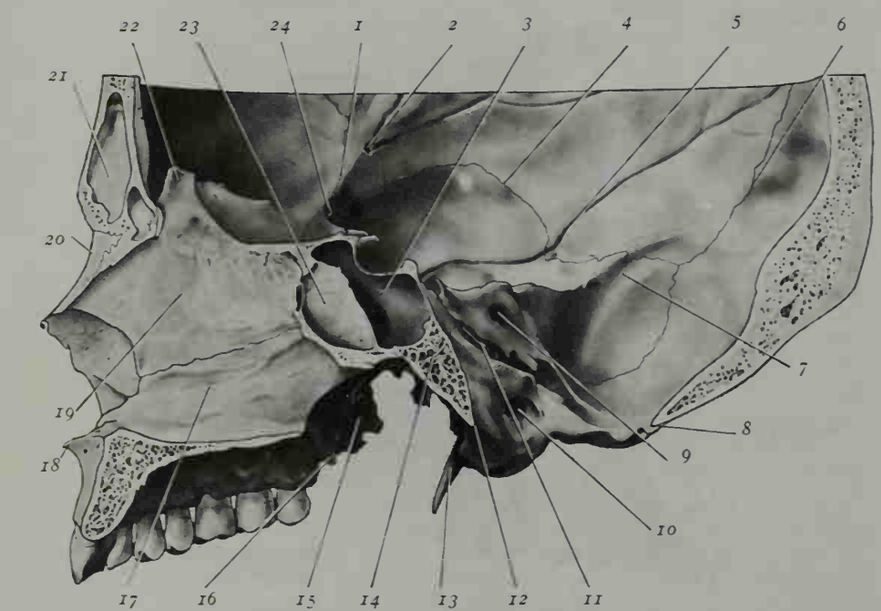
The internal occipital crest, to which the falx cerebelli is attached, may be grooved by the occipital sinus. Its lower end is related to the inferior vermis of the cerebellum. The internal occipital protuberance is related to the confluence of sinuses and is grooved on each side by the commencement of the transverse sinus. The margins of the groove for the transverse sinus give attachment to the two layers of the tentorium cerebelli. On each side of the internal occipital crest the bone is thin and translucent, in marked contrast to the regions of the crest and of the internal occipital protuberance.

3.77 The bony nasal septum. Left side. An enlarged part of **3**.80.



3.78 The roof, floor and right lateral wall of the right nasal cavity.

The Nasal Cavity



The nasal cavity, the first of the respiratory passages, is an irregularly shaped space which extends from the roof of the mouth upwards to the base of the skull. It is divided into right and left halves by a *septum* (**3**.77), which is approximately median. In the dried skull the septum is deficient anteriorly, and as a result a single *anterior nasal aperture* presents in the norma frontalis. The septum, however, reaches the posterior limit of the cavity, which communicates with the nasal part of the pharynx through a pair of *posterior nasal apertures*, immediately above the posterior border of the bony palate. The cavity is wider below than above and is widest and vertically deepest in its central region. It communicates with the frontal, ethmoidal, maxillary and sphenoidal sinuses.

Each half of the cavity has a roof, a floor, lateral and medial walls, the medial wall being formed by the nasal septum.

The roof (**3**.77, 78) is horizontal in its middle part but slopes downwards in front and behind. The anterior sloping part is formed by the nasal spine of the frontal and the nasal bones and contributes to the formation of the external nose. The horizontal part is formed by the cribriform plate of the ethmoid bone and

separates the nasal cavity from the medial part of the floor of the anterior cranial fossa. It presents numerous small openings for the passage of the olfactory nerves. The posterior sloping part is formed by the body of the sphenoid and is interrupted, on each side, by the rounded orifice of a sphenoidal sinus.

The floor is smooth, gently concave from side to side, and slopes upwards a little as it passes backwards from the anterior aperture to the posterior aperture. It is formed by the upper surface of the bony palate and therefore intervenes between the nasal and oral cavities. Anteriorly the palatine processes of the two maxillae meet in the median plane, and behind them the horizontal plates of the palatine bones articulate with each other in the midline and with the palatine processes of the maxillae in front. In its anterior part the floor close to the septum presents a small funnel-shaped opening which leads into the *incisive canals* (p. 341).

The medial wall is formed by the bony *nasal septum* (**3**.77), which extends between the roof and the floor. It is a thin sheet of bone and presents a wide deficiency in front, occupied in the recent state by the septal cartilage. It is formed almost entirely by the vomer and the perpendicular plate of the ethmoid. The *vomer* extends from the inferior surface of the sphenoid body to the bony palate and forms the lower and posterior part of the septum, including its posterior border. It is marked by small furrows for vessels and nerves. The *perpendicular plate of the ethmoid* forms the upper and anterior part of the septum (**3**.77) and is continuous above with the cribriform plate (p. 334). The septum is often deflected to one side and the deviation occurs most commonly in the line of the vomero-ethmoidal suture.

The lateral wall (**3**.78, 79) is very irregular, owing to the presence of three bony projections termed the inferior, middle and superior nasal *conchae*. It is formed, for the most part, by the nasal surface of the maxilla below and in front, by the perpendicular plate of the palatine bone posteriorly, and above by the nasal surface of the ethmoidal labyrinth, which intervenes between the nasal cavity and the orbit. The three conchae project downwards and slightly medially, and each forms the roof of a groove which communicates freely with the nasal cavity. These grooves are termed the meatuses of the nose.

The *inferior concha* is a thin curved lamina and is an independent bone. It articulates with the nasal surface of the maxilla and the perpendicular plate of the palatine bone, and possesses a free lower border, which is gently curved. The *inferior meatus* is under the inferior concha and extends downwards to the floor of the nasal cavity. It is the largest of the three meatuses and extends almost the entire length of the lateral wall of the nose. The inferior meatus is deepest at the junction of its anterior and middle thirds, and at this point is the lower orifice of the nasolacrimal canal.

The *middle* and *superior conchae* are projections from the medial surface of the ethmoidal labyrinth. The *middle concha* is much the larger and extends backwards to articulate with the perpendicular plate of the palatine bone. The *middle meatus* is between the middle and inferior conchae. Its lateral wall displays several important features which can be examined only after the removal of the middle concha (**3**.79). Its upper part is occupied by a rounded elevation, the *ethmoidal bulla*, which contains the middle ethmoidal air cells. Below and in front of the bulla a thin, curved lamina of bone, named the *uncinate process of the ethmoid*, passes downwards and backwards, crossing the large bony orifice of the maxillary sinus. The curved gap (**3**.79) which intervenes between this process and the ethmoidal bulla is the *hiatus semilunaris*. At its upper end it becomes continuous with the *ethmoidal infundibulum*, a short, curved canal which receives the openings of the anterior ethmoidal air cells and then leads upwards through the labyrinth into the frontal sinus. In about 50 per cent of skulls, however, the infundibulum ends blindly and the frontal sinus then opens directly into the upper and anterior part of the middle meatus. The middle ethmoidal air cells open above, or near, the bulla.

The *superior concha* is a small curved lamina which lies above and behind the middle concha. It roofs in the *superior meatus*, which is much the shortest and shallowest of the three meatuses; it receives the opening of the posterior ethmoidal air cells. Immediately behind the superior meatus the sphenopalatine

foramen, which opens into the pterygopalatine fossa, pierces the lateral wall of the nasal cavity. A narrow interval, the *sphenoethmoidal recess*, separates the superior concha from the anterior surface of the body of the sphenoid, through which the sphenoidal sinus opens into the nasal cavity.

The posterior nasal apertures, or *choanae*, are separated from each other by the posterior border of the vomer. They are bounded below, on each side, by the posterior border of the horizontal plate of the palatine bone, above by the sphenoid bone, and laterally, on each side, by its medial pterygoid plate.

The anterior nasal aperture has been described on p. 299. In addition to the numerous small foramina for the transmission of the olfactory nerves, the horizontal part of the roof presents a separate foramen, situated anteriorly, for passage of the anterior ethmoidal nerve and vessels. The posterior sloping part of the roof is formed above by the anterior aspect of the body of the sphenoid, with which the sphenoidal concha (p. 323) is fused, and below by the ala of the vomer and the sphenoidal process of the palatine bone.

The floor (**3**.78) is crossed at the junction of its middle and posterior thirds by the palatomaxillary suture. Close to the median plane anteriorly it is pierced by the incisive canal (p. 341). Both incisive canals open into the incisive fossa on the bony palate and they possibly traverse the line of union of the os incisivum (premaxilla) with the maxilla; they represent a primitive communication between the mouth and the nose (but *see* p. 341).

At the upper and lower borders of **the medial wall** (**3**.77) other bones, in addition to the vomer and the perpendicular plate of the ethmoid, make minor contributions to the septum. Above and in front, the nasal bones and the nasal spine of the frontal bone, above and behind, the rostrum and crest of the sphenoid, and below, the nasal crests of the maxillae and palatine bones all take small parts in its formation. The vomer is grooved by the nasopalatine nerves, as they run downwards and forwards to reach the incisive canal.

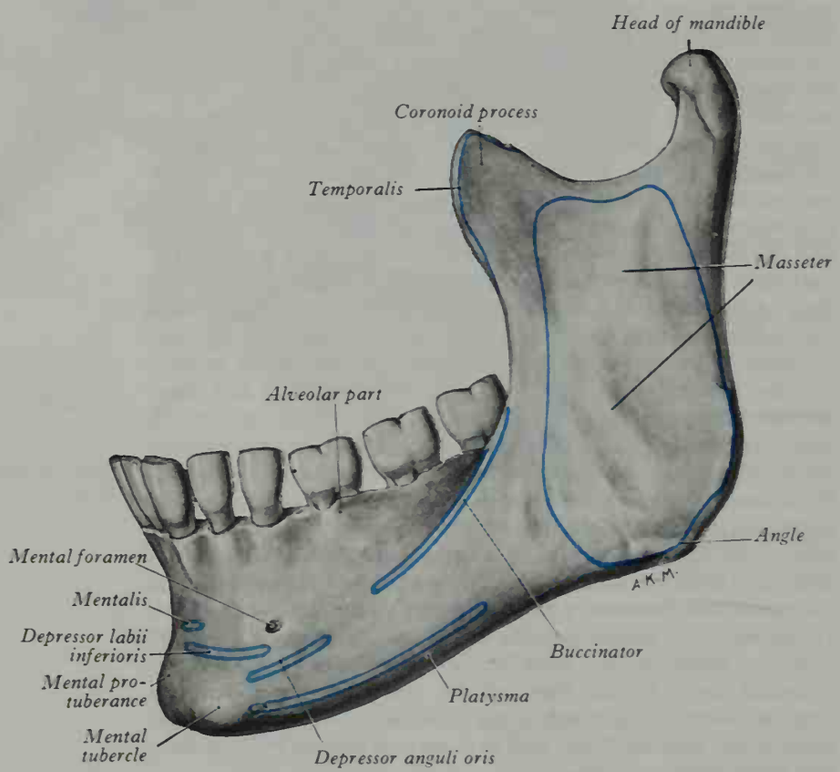
The lateral wall (**3**.78, 79) is formed anteriorly and above by the nasal bone and the frontal process of the maxilla. Behind the frontal process of the maxilla, and articulating with its posterior border, the lacrimal bone lies in the lateral wall of the middle meatus and articulates below with the lacrimal process of the inferior concha. These two bones form the medial wall of the nasolacrimal canal (**3**.79), which conveys the nasolacrimal duct to the inferior meatus. Posteriorly the lacrimal bone articulates with the ethmoidal labyrinth and helps to close some of the ethmoidal air cells. The *uncinate process of the ethmoid* springs from this part of the labyrinth and curves downwards and backwards in the lateral wall of the middle meatus. It is a very thin and fragile process, about 3 mm wide, which curves across the maxillary hiatus and articulates near its extremity with the ethmoidal process of the inferior concha. The concave, posterior border of the process is free and forms the medial edge of the hiatus semilunaris; the convex anterior border is free in its upper part only. Owing to its position relative to the maxillary hiatus the uncinate process helps to form the medial wall of the maxillary sinus. The *maxillary hiatus*, which forms such a wide opening on the nasal surface of the maxilla (**3**.116), is greatly reduced in size by the neighbouring bones. Its lower part is covered by the inferior concha and its maxillary process; above the inferior concha the uncinate process of the ethmoid, as already stated, encroaches on the gap. Posteriorly the anterior part of the perpendicular plate of the palatine bone closes it in still further, and above and in front small portions of the ethmoidal labyrinth and the lacrimal bone overlap its margins (**3**.79). As a result, the maxillary hiatus is reduced sometimes to a single orifice in the floor of the posterior part of the hiatus semilunaris, although as a rule additional openings exist behind the uncinate process, and between its lower border and the upper border of the inferior concha. The *ethmoidal bulla* is very variable in its size and shape and may be fused with the upper part of the uncinate process. In that event the duct of the frontal sinus opens into the upper part of the middle meatus medial to the blind end of the infundibulum. A third concha (*concha suprema*) is often present on the medial surface of the ethmoidal labyrinth above and behind the posterior end of the superior concha; it is little more than a slight ridge, separated from the superior concha by a shallow depression. The *sphenopalatine foramen* (**3**.78) is posterior to the superior meatus. It transmits the sphenopalatine artery and the nasopalatine and superior nasal nerves from the pterygopalatine fossa. It is bounded above by the body of the sphenoid and sphenoidal concha, below by the notched upper border of the perpendicular plate of the palatine bone, and in front and behind by its orbital and sphenoidal processes.

THE INDIVIDUAL CRANIAL BONES

The Mandible

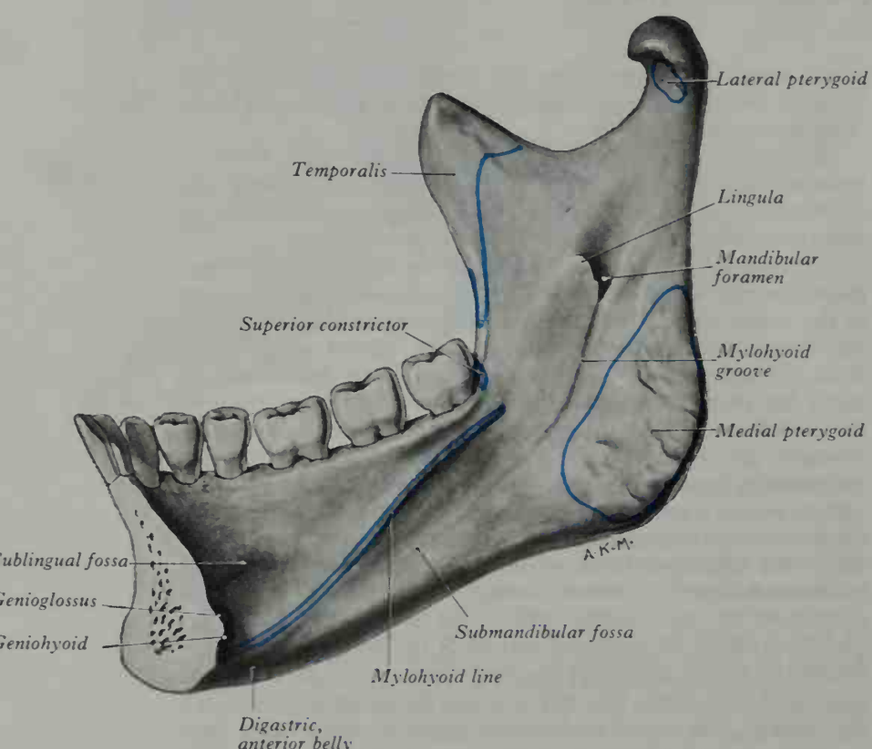
The mandible (**3**.81), which is the largest and strongest bone of the face, has a curved, horizontal *body*, which is convex forwards, and two broad *rami*, which project upwards from the posterior ends of the body.

The body of the mandible is curved like a horseshoe, and possess external and internal surfaces, separated by upper and lower borders. The *external surface* is marked in the upper part of the median plane by a faint ridge, often indistinguishable, which indicates the line of fusion of the two halves of the fetal bone (*symphysis menti*). Inferiorly the ridge divides to enclose a triangular raised area, termed the *mental protuberance*, the base of which is depressed in the centre but raised on each side to form the *mental tubercle*. Below the interval between the two premolar teeth, or below the second premolar, the *mental foramen*, from which emerge the mental nerve and vessels, opens on the surface. The posterior border of the foramen is smoothed out by the direction of the emerging mental nerve, largely backwards but also somewhat upwards (Warwick 1950). A faint ridge, termed the *oblique line*, runs upwards and backwards from the mental tubercle, to become pronounced behind, where it is continuous with the anterior border of the ramus.



The lower border of the body is termed the *base of the mandible*. It extends backwards and laterally from the mental symphysis, and becomes continuous with the lower border of the ramus behind the third molar tooth. Near the median plane it presents a small, roughened depression, the *digastric fossa*. Behind the digastric fossa the base is thick and rounded and presents a slight downwards convexity.

The upper border of the body is the *alveolar part*, which is hollowed by sixteen *sockets* for the roots of the teeth. These sockets vary in size and depth, and are single or subdivided by septa according to the teeth which they contain.



The *internal surface* is divided into two areas by an oblique ridge, termed the *mylohyoid line*. Sharp and distinct in the region of the molar teeth, it becomes almost indiscernible in front. It commences behind the third molar tooth, almost a centimetre from the upper border, and runs forwards and downwards to reach the mental symphysis in the interval between the two digastric fossae. Below the mylohyoid line the surface is slightly concave, the hollow being the *submandibular fossa* for the submandibular salivary gland. The area above the mylohyoid line widens as it is traced forwards and presents in front a triangular depression, the *sublingual fossa*, for the sublingual salivary gland. Above the sublingual fossa and extending backwards to the third molar tooth a strip of the bone is closely covered with the mucous membrane of the mouth. Above the anterior ends of the mylohyoid lines the posterior surface of the symphysis menti is marked by a small irregular elevation, which may be divisible into upper and lower parts, termed the *mental spines* (genial tubercles). Posteriorly, the *mylohyoid groove* extends downwards and forwards on to the body from the ramus and passes below the posterior end of the mylohyoid line. Immediately superior to the

mental spines, the majority of mandibles present a midline pit which continues into a bony canal (Ingram—personal communication). As yet its development and contents are uncertain, but clinically it has proved a useful radiological landmark (*see* p. 349): the name *genial foramen* has been proposed. (See also *accessory mandibular foramina*, below.)

Above the mylohyoid line, the bone medial to the roots of the molar teeth is sometimes developed into a rounded ridge or *torus mandibularis*. For the incidence of this feature consult Mayhall *et al.* (1970) and Berry (1975).

3.81A The left half of the mandible. Lateral (external) aspect.

3.81B The right half of the mandible. Medial (internal) aspect.

The ramus of the mandible (3.81) is quadrilateral and has two surfaces, four borders and two prominent processes. The *lateral surface* is flat and marked by oblique ridges in its lower part. The *medial surface* presents, a little above its centre, an irregular opening, the *mandibular foramen*. This opening leads into the *mandibular canal*, which curves downwards and forwards into the body of the bone to open on the external surface at the mental foramen. In front and on the medial side the foramen is obscured by a thin triangular process termed the *lingula*. The *mylohyoid groove* commences behind the lingula and runs downwards and forwards to reach the internal surface of the body. The part of the medial surface which lies behind the groove is marked by a number of short ridges. The *inferior border* of the ramus is continuous in front with the base of the mandible; behind, it meets the posterior border at the *angle of the mandible*. Eversion of the angle is characteristic of the male mandible; in the female it is frequently incurved. The *upper border* is thin and bounds a wide notch, the *mandibular incisure*. It is surmounted in front by a triangular, flattened projection, termed the coronoid process, and behind by a strong, articular process named the condylar process. The *posterior border*, thick and rounded, extends from the back of the condylar process to the angle of the mandible. It is gently curved, being convex backwards above and concave below, and is intimately related to the parotid salivary gland. The *anterior border* is thin above, where it is continuous with the anterior border of the coronoid process, and thicker below, where it is continuous with the oblique line.

The coronoid process is a flattened triangular projection, directed upwards and slightly forwards in the living subject. Its posterior border bounds the mandibular incisure; its anterior border is continuous with the anterior border of the ramus. Its margins and medial surface provide insertion for most of the fibres of the temporalis.

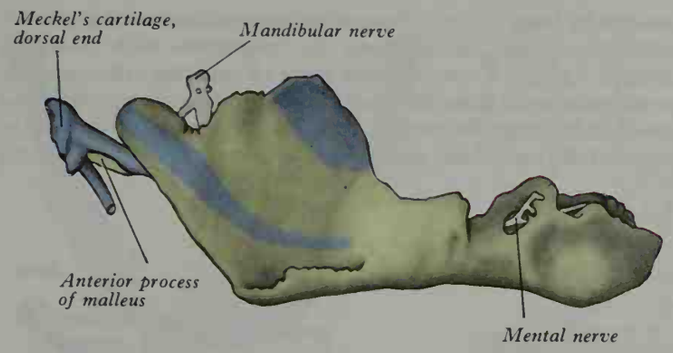
The condylar process is expanded above to form the *head* of the mandible, which is covered with fibrocartilage. It articulates with the mandibular fossa of the temporal bone—an articular disc intervening. It is knuckle-shaped, being convex in all directions, and its transverse measurement is greater than its anteroposterior. The lateral aspect of the head has a blunt point which projects beyond the lateral surface of the rest of the ramus and can be felt in the living just in front of the tragus of the auricle. When the mouth is opened the head passed downwards and forwards, and the examining finger sinks into a small depression. The constricted portion below the head is termed the *neck of the mandible*. It is slightly flattened from before backwards, and its anterior aspect is limited on the lateral side by the backward continuation of the margin of the mandibular incisure. Medial to this ridge the anterior surface of the neck presents a rough muscular depression, the *pterygoid fovea*.

The mandibular canal runs from the mandibular foramen obliquely downwards and forwards in the ramus, and then horizontally forwards in the body below the sockets of the teeth, with which it communicates by small canals. It contains the inferior alveolar nerve and vessels, from which branches enter the roots of the teeth. Between the roots of the first and second premolars, or below the root of the second premolar tooth, the mandibular canal divides into *mental* and *incisive canals*; the mental canal swerves upwards, backwards and laterally to reach the mental foramen; the incisive canal is continued below the incisor teeth. (But *see* p. 1287 for canal variations.)

More detailed inspection of **the body of the mandible** shows a small shallow fossa, sometimes termed the incisive fossa, below the incisor teeth and providing attachment for mentalis and a part of orbicularis oris. The anterior end of the oblique lines gives origin to the depressor labii inferioris and the depressor anguli oris. Platysma is inserted into the bone below these muscles and extends backwards beyond them. The lower margin of the *mental foramen* is sharp and the mental nerve is directed upwards and backwards as it emerges from the bone. Adjoining the alveolar border, the bone is closely covered with the mucous membrane of the mouth. Immediately below this area, in the region of the molar teeth, the buccinator has a linear attachment which extends medially behind the last molar tooth to the pterygomandibular raphe.

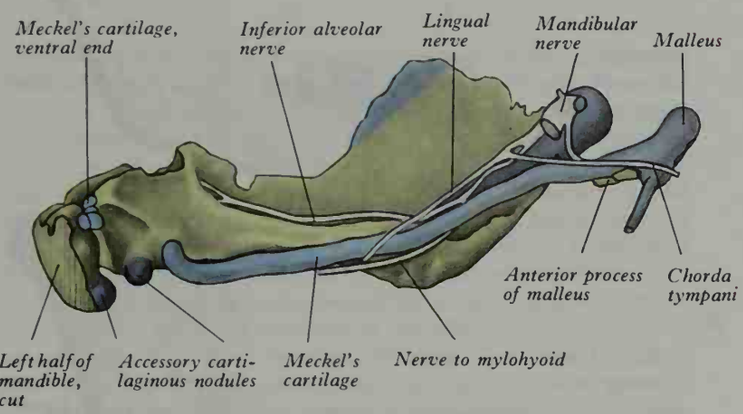
The mylohyoid line gives origin to the mylohyoid muscle. Above its posterior end the bone gives origin to fibres of the superior constrictor muscle of the pharynx, and the *pterygomandibular raphe* is attached immediately behind the third molar tooth. The lingual nerve gains the tongue by passing above the posterior end of the mylohyoid line and here is closely related to the inner surface of the mandible (*see* p. 1067). The upper mental spine gives origin to the genioglossus and the lower to the geniohyoid. The *submandibular fossa* lodges some of the submandibular lymph nodes in addition to the submandibular salivary gland, and the facial artery may come into contact with this region as it descends to curl round the base of the mandible, where it sometimes produces a shallow groove. The *digastric fossa* gives attachment to the anterior belly of the digastric and lies below the anterior end of the mylohyoid line.

The ramus and its processes provide insertion for all the principal muscles of mastication. Its *lateral surface* gives insertion to the masseter, except at its upper and posterior part, where it is covered by the parotid gland.



The *medial surface* gives insertion to the medial pterygoid at the roughened area which lies behind and below the mylohyoid groove. To the *lingula*, the medial border of the mandibular foramen, the sphenomandibular ligament is attached. Posterior to the lingula the mylohyoid nerve and vessels enter the *mylohyoid groove*, which reaches the body of the mandible below the posterior end of the mylohyoid line, and the nerve and vessels then pass on to the superficial aspect of the mylohyoid. In front of the mylohyoid groove and below the lingula the medial surface of the ramus is related to the medial pterygoid, but the lingual nerve intervenes between the muscle and the bone. The lowest fibres of insertion of the temporalis descend beyond the coronoid process and are attached to the anterior border of the ramus and the adjoining part of the medial surface. The area above and behind the mandibular foramen is related to the maxillary artery and its inferior alveolar branch, and next to the part adjoining the mandibular incisure is the lateral pterygoid. The *mandibular notch* transmits the masseteric nerve and vessels from the infratemporal fossa.

The coronoid process is covered on its lateral aspect by the anterior fibres of the masseter as they pass downwards and backwards to be inserted into the ramus. If the finger is pressed into the yielding part of the cheek below the zygomatic bone, the anterior border of the coronoid process can be identified in the living when the mouth is opened.



The condylar process is expanded and projects beyond the surfaces of the ramus, but more so on the medial than on the lateral side. The *articular surface* of the mandible extends only for a short distance down the anterior surface of the process, but it covers the whole of its superior aspect and descends for 5 mm or more on its posterior aspect. Its superior aspect slopes medially and slightly downwards and backwards. Its projecting lateral part is separated from the cartilaginous part of the external acoustic meatus by a portion of the parotid gland. The smooth lateral aspect of the *neck of the mandible* gives attachment to the lateral ligament of the temporomandibular joint (**4**.18) and is covered by the parotid gland. The pterygoid fovea on the front of the neck receives the insertion of the lateral pterygoid muscle. The medial surface of the neck is related to the auriculotemporal nerve above and to the maxillary artery below.

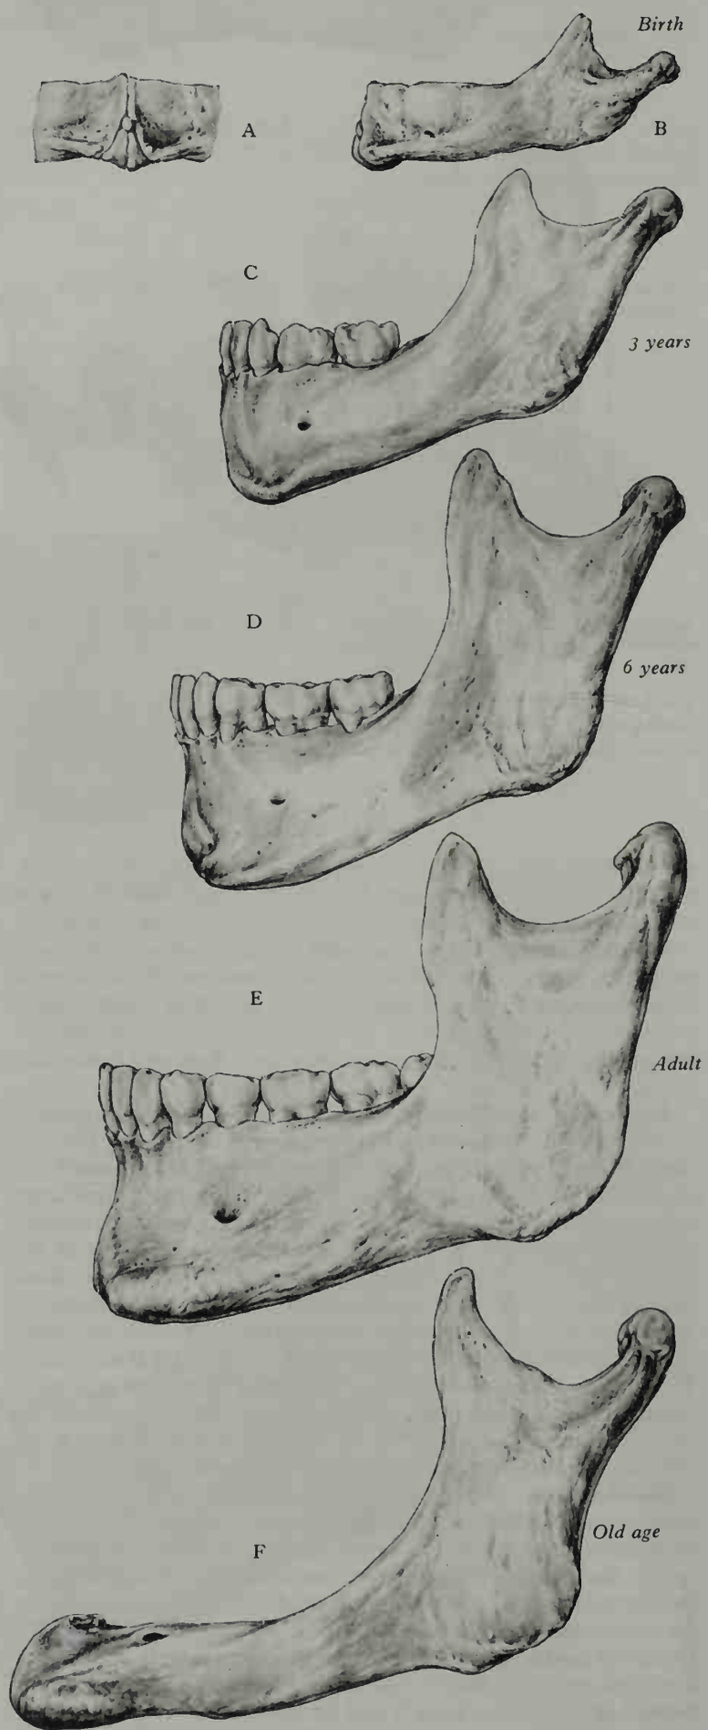
The relation of the *parotid gland* to the mandible requires special mention. It occupies the interval below the external acoustic meatus, bounded in front by the posterior border of the ramus, behind by the mastoid process and medially by the styloid process; but it extends forwards beyond this area and covers the lateral aspect of the temporomandibular joint and the part of the lateral surface of the ramus behind the masseter. In addition it curls round the posterior border and comes into contact with the medial aspect of the ramus just above the insertion of the medial pterygoid.

Accessory foramina of the mandible, as in the case of other bones, are commonly present, usually unnamed, and infrequently described. Yet a recent study of 300 mandibles yielded a count of 2,449 accessory foramina (Sutton 1974). Since there is evidence that many of these transmit auxiliary nerve supplies to the teeth

3.82A The right half of the mandible of a human embryo. 95 mm long. Lateral aspect. (Reconstruction model by Prof. A. Low.) *Note.*—*Blue* = cartilage; *yellow* = bone.

3.82B The right half of the mandible of a human embryo. 95 mm long. Medial aspect. The developing bone is shown in yellow, and the cartilage in blue. (Reconstruction by Prof. A. Low.)

and their sockets (from such nerves as the facial, mylohyoid, buccal, transverse cervical cutaneous, and others), their occurrence is of importance in dental nerve block techniques.



Further mandibular variants include *lingual depressions* molar or canine in position; *variable position* of the mental foramen; *multiple mental foramina* either double or triple; *lingual fenestrations* of molar sockets; *retromolar foramina*; and *condylar defects*. For incidences in 125 mandibles *see* Azaz and Lustmann (1973).

Aspects of mandibular structure. In addition to variations in the form and course of the mandibular canal (e.g. Fawcett 1895; Barros 1959; Carter and Keen 1971) and extensions from accessory mandibular foramina (Sutton 1974), there have been numerous attempts to analyse the fine architecture of the surface tables and buttresses of compact bone and the geometry of the internal trabeculae, and to relate these to the habitual functional stresses imposed on the bone. These are too numerous to review in detail here, but as an introduction to the literature the reader should consult Beltrami (1945); Seipel (1948); Dal Pont (1960); Weiss (1965); Scott and Symons (1970); and Mercier *et al.* (1970). An interesting preliminary report of the use of holographic interferometry in the study of surface strains induced by orthodontic forces has recently appeared (Hewitt 1976, *et seq.*).

Ossification. The mandible is ossified in dense fibromembranous tissue which lies lateral to the inferior alveolar nerve and its incisive branch and the lower portion of Meckel's cartilage (**3**.82). Each half is ossified from one centre which appears near the mental foramen about the sixth week of fetal life, i.e. just after the appearance of the primary centre for the clavicle (p. 358). From this centre ossification spreads to form the body and ramus; it extends medially, first below, then around the inferior alveolar nerve and its incisive branch and upwards to form a trough and later crypts for the developing teeth. By the tenth week the part of Meckel's cartilage below the incisor teeth is surrounded and

invaded by bone (p. 150). Somewhat later secondary or accessory cartilages appear, which have no connexion with Meckel's cartilage (**3**.82). A cone-shaped mass of cartilage, the *condylar cartilage*, extends from the head of the mandible downwards and forwards through the ramus; this contributes to the growth in height of the ramus and though it is largely invaded and replaced by bone by the middle of fetal life, its upper end persists as a zone of proliferating cartilage beneath the fibrous articular surface of the head until the third decade. Another secondary cartilage, into which ossification soon extends, occurs along the anterior border of the coronoid process; it has disappeared before birth. One or two cartilaginous nodules also appear on each side at the symphysis menti. About the seventh month of fetal life these may ossify to form a variable number of small ossicles, the *mental ossicles*, in the fibrous tissue of the symphysis. These ossicles unite with the remainder of the bone before the end of the first year of life (*see* Lebourg and Champagne 1951; Sicker 1962; Scott and Symons 1970; and consult **3**.83A).

It may be mentioned here that ^{3}H-thymidine labelling in the *rat* showed no interstitial growth in the condylar cartilage; it expanded by surface accretion only (Kvinnsland and Kvinnsland 1975).

318 **3**.83A–F The mandible at different periods of life.

Age Changes in the Mandible

At birth (**3**.83A and B) the mandible is in two separate halves, united in the median plane by fibrous tissue. This union is usually termed the *symphysis menti*. The anterior extremities of both mandibular rudiments are covered by cartilages, which are separated only by the fibrous tissue of the symphysis. Until fusion occurs across the midline new cells are added to each cartilage from the fibrous tissue on its symphysial aspect, while ossification proceeds in its mandibular side towards the midline. When the latter process overtakes the former, and extends into the median zone of fibrous tissue, fusion of the two halves of the mandible occurs. This description accords with recent observations, but many uncertainties still remain. The body of the bone is a mere shell, enclosing the sockets of the deciduous teeth, imperfectly partitioned off from one another. The mandibular canal runs near the lower border of the bone, and the mental foramen opens below the socket of the first deciduous molar tooth, and its direction is forwards (Warwick 1950). The coronoid process is relatively large and projects above the level of the condyle.

After birth (**3**.83C), in the first year, the two halves of the bone become joined at the symphysis from below upwards; but a trace of separation near the alveolar margin may still be visible at the beginning of the second year. The body elongates, more especially behind the mental foramen, to provide space for the three additional teeth developed in this part (*see* pp. 1300–1301). During the first and second years, as the prominence of the chin develops, the mental foramen alters in direction from forwards to upwards and backwards, and then almost horizontally backwards, as in the adult (Warwick 1950). This change accompanies the altering direction of the emerging mental nerve. The persisting upper end of the condylar cartilage fulfils the role of the epiphysial plate of a long bone. Its proliferation contributes to the vertical height of the ramus and to the downward and forward growth of the mandible as a whole. It also increases the distance between the condyles as the base of the skull widens. At this stage the cartilage is covered on its articular aspect by a self-perpetuating fibrous layer, deep to which is the proliferating intermediate zone which is responsible for the growth of the ramus. Beneath this is a layer of hypertrophic cartilage cells and then bone (Blackwood 1959). The depth of the body increases; growth of the alveolar part of the bone affords room for the roots of the teeth, and the subalveolar portion becomes thicker and deeper. After the second dentition the mandibular canal is situated a little above the level of the mylohyoid line, and the mental foramen occupies the position usual to it in the adult. As the mandible increases in size, bone is laid down along the posterior borders of the ramus and the coronoid process, while at the same time absorption of bone is occurring along their anterior borders. This process of remodelling goes on continuously until the bone has reached its adult size, and it enables the alveolar part to lengthen sufficiently to provide the necessary space for the permanent molar teeth (Enlow and Harris 1964). Organ culture of the condylar cartilage in rats showed no growth potential, but *in vivo* all the mandibular growth cartilages respond to mechanical forces (Petrovic 1972).

In the adult (**3**.83E) the alveolar and subalveolar portions of the body are of about equal depth. The mental foramen opens midway between the upper and lower borders of the bone, and the

mandibular canal runs nearly parallel with the mylohyoid line. The *angle* subtended by the lower border of the body of the mandible to a plane surface which touches the posterior surface of the condyle above and the posterior border of the ramus below, necessarily diminishes as the height of the ramus increases with age, but X-ray photographs of the same child at different ages (Brodie 1941) show that the *contour* of the angle of the mandible remains unaltered.

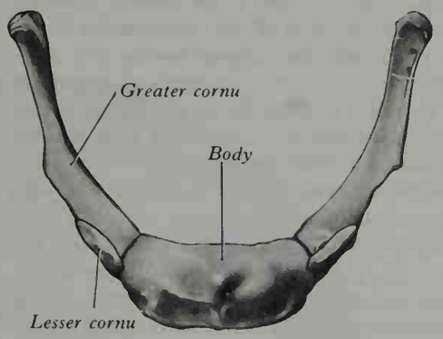
In old age (**3**.83F) the bone is reduced in size, as the teeth are lost. Following the loss of teeth the alveolar part is absorbed, and consequently the mandibular canal and the mental foramen are close to the alveolar border. The foramen and part of the canal may even disappear, thus exposing part of the inferior alveolar nerve (Gabriel 1958). The ramus is oblique in direction, the angle measures about 140°, and the neck of the mandible is more or less bent backwards (Fawcett *et al.* 1924). The process of absorption affects chiefly the thinner of the two alveolar walls and, after its completion, a linear *alveolar ridge* is found on the alveolar border of the bone. In the mandible the labial wall is the thinner in the incisor and canine regions, but it is the lingual wall which is the weaker in the molar region. The alveolar ridge lies therefore within the line of the teeth in the incisor region but lies outside that line in the molar region, forming a curve which is wider than the curve of the line of the teeth and intersects it on each side in the premolar region. In the maxilla, however, the labial wall is everywhere the thinner and after absorption, the alveolar ridge lies wholly within the curve of the line of the teeth.

The Hyoid Bone

The hyoid bone (**3**.84) is U-shaped and is suspended from the tips of the styloid processes of the temporal bones by the stylohyoid ligaments. It has a body, two greater and two lesser cornua.

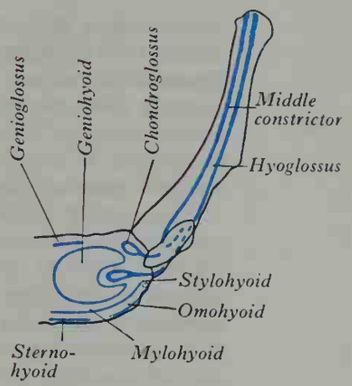
The body of the hyoid bone is an irregular, elongated quadrilateral in form. Its *anterior surface* is convex and directed forwards and upwards. Its upper part is crossed by a well-marked ridge, which has a slight downward convexity, and in many cases a vertical median ridge divides the body into lateral halves. The portion of the vertical ridge above the transverse line is present in the majority of specimens, but that below the transverse line is rarely seen. The *posterior surface* is smooth, concave, directed backwards and downwards, and separated from the epiglottis by the thyrohyoid membrane and a quantity of loose areolar tissue; a bursa intervenes between the bone and the membrane. In early life the lateral extremities of the body are connected to the greater cornua by cartilage, but after middle life they are usually united by bone.

The greater cornua of the hyoid bone project backwards from the lateral limits of its body; they are flattened from above downwards and diminish in size from before backwards. Each cornu ends posteriorly in a tubercle. When the throat is gripped between finger and thumb just above the thyroid cartilage, the greater cornua can be felt in the living subject and the bone can be moved from side to side.



The lesser cornua of the hyoid bone are two small, conical eminences attached by their bases at the angle of junction of the body and greater cornua. They are connected to the body of the bone by fibrous tissue and occasionally to the greater cornua by synovial joints, which usually persist throughout life, but occasionally become ankylosed (*vide infra*).

Attached to the *anterior surface of the body* is the geniohyoid in the greater part of its extent both above and below the transverse ridge; a portion of the origin of the hyoglossus invades the lateral margin of the geniohyoid area (**3**.84B). The lower part of this surface gives insertion to the mylohyoid, and below that to the sternohyoid medially and the omohyoid laterally. The *superior border* of the body is rounded and gives attachment to the lowest fibres of the genioglossi, to the hyo-epiglottic ligament and to the thyrohyoid membrane. The *inferior border* gives insertion to the sternohyoid medially and the omohyoid laterally, and sometimes to the medial fibres of the thyrohyoid. It gives attachment also to the levator glandulae thyroideae, when present.



The *upper surface of the greater cornu* gives origin to the middle constrictor of the pharynx and, more laterally, to the hyoglossus, both of which extend throughout its whole length. Near the junction of cornu with body the stylohyoid is inserted lateral to the hyoglossus, and a little posterior to this insertion the fibrous loop through which the tendon of the digastric runs is attached to the bone. The *medial border* gives attachment to the thyrohyoid membrane, the *lateral border* receives, anteriorly, the insertion of the thyrohyoid. The *inferior surface*, which is oblique, is separated from the thyrohyoid membrane by some fibro-areolar tissue.

The *posterior* and *lateral aspects of the lesser cornu* give origin to fibres of the middle constrictor of the pharynx. To its apex is attached the stylohyoid ligament, which is often in part ossified. The medial aspect of its base gives origin to the chondroglossus.

Ossification. The hyoid bone is developed from the cartilages of the second and third visceral arches—the lesser cornua from the second, the greater cornua from the third, and the body from the fused ventral ends of both (p. 150). Chondrification begins in the fifth week in these elements, and is completed in the third and fourth months. It is ossified from six centres; a pair for the body, and one for each cornu. Ossification commences in the greater cornu towards the end of intrauterine life, in the body before or shortly after birth, and in the lesser cornua around puberty. The centre in the body may be paired; those for the lesser cornua are very variable. The apices of the greater cornua remain cartilaginous until the third decade, and epiphyses may occur here. They fuse with the body. The synovial joints between the lesser cornua and the rest of the bone may be obliterated by ossification in the later decades.

3.84B A drawing of the left half of the hyoid bone to show the muscular attachments. Superior aspect.

The Occipital Bone

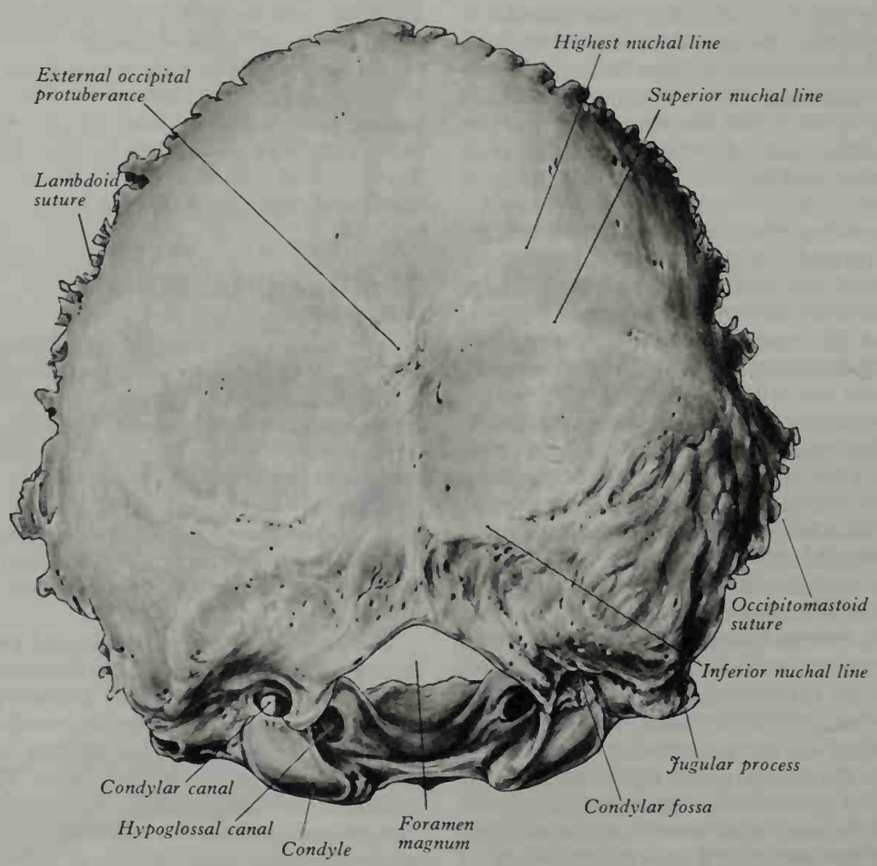
The occipital bone (**3**.85, 86, 87), forming much of the back and base of the cranium, is trapezoid in shape and, naturally, internally concave. It encloses basally a large oval opening, termed the *foramen magnum*, through which the cranial cavity communicates with the vertebral canal. The expanded plate above and behind this foramen is named the *squamous part*; the thick, somewhat quadrilateral piece in front of it is the *basilar part*; on each side of the foramen is a *lateral part*.

The squamous part of the occipital bone, above and behind the foramen magnum, is curved from above downwards and from side to side.

The *external surface* is convex and presents, midway between the summit of the bone and the foramen magnum, a prominence termed the *external occipital protuberance*. On each side two curved lines, one above the other, extend laterally from this bony prominence. The upper line, faintly marked and often almost imperceptible, is the *highest nuchal line*, and to it the galea aponeurotica is attached. The lower line is the *superior nuchal line*. The external surface above the highest nuchal lines is smooth, and covered with the occipital belly of the occipitofrontalis. The part below the highest nuchal lines is rough and irregular for the attachment of several muscles. From the external occipital

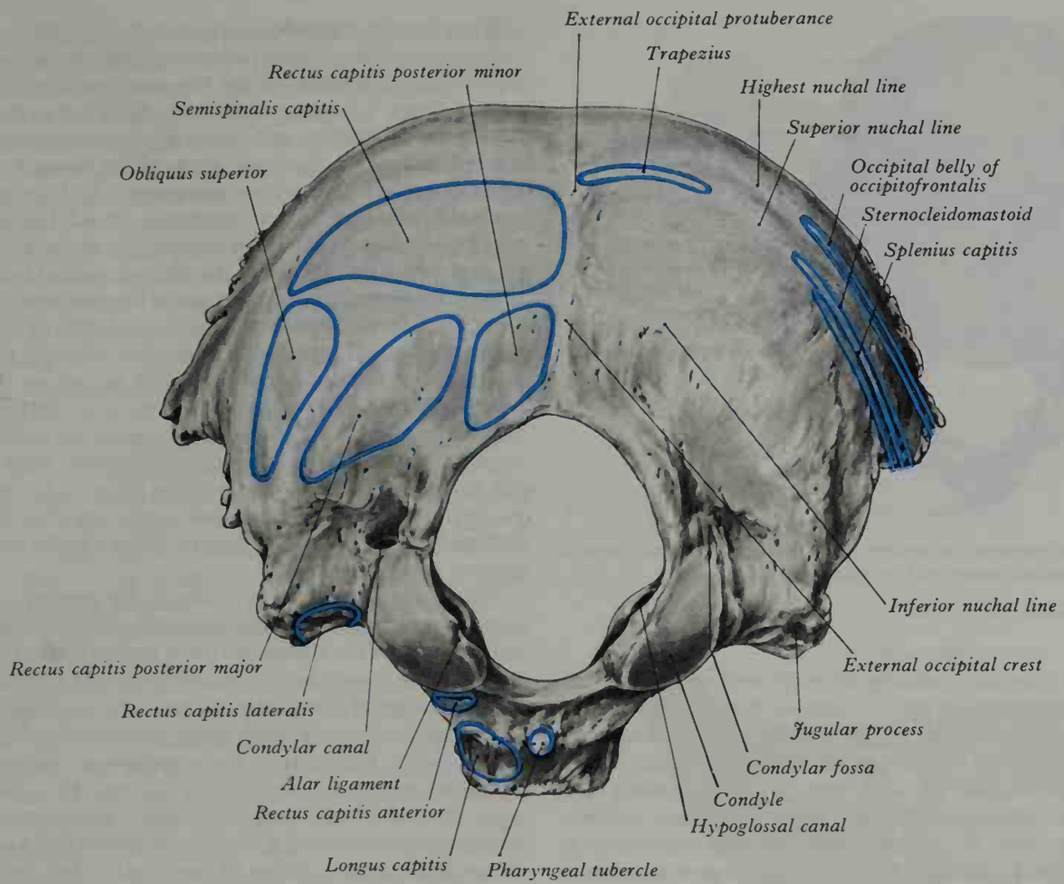
protuberance the *external occipital crest*, often faintly marked, descends to the foramen magnum, and affords attachment to the ligamentum nuchae; on each side the *inferior nuchal line* runs laterally from the midpoint of the crest. The areas of muscular attachments are shown in **3**.86. The posterior atlanto-occipital membrane is attached around the posterolateral part of the foramen magnum immediately outside the margin.

The *internal surface* of the squamous part is deeply hollowed out, and divided into four fossae by an irregular elevation, the *internal occipital protuberance*. The upper two fossae are triangular, and adapted to the poles of the occipital lobes of the cerebrum; the lower two are quadrilateral and shaped to the hemispheres of the cerebellum. A wide groove, with raised edges, extends upwards from the protuberance to the superior angle of the bone; this is the *sulcus of the superior sagittal sinus*. The posterior part of the falx cerebri is attached to its margins. A prominent ridge, the *internal occipital crest*, runs downwards and forwards from the protuberance; it gives attachment to the falx cerebelli, and bifurcates near the foramen magnum; the occipital sinus, which is sometimes duplicated, lies in the attached margin of the falx. At the lower part of the internal occipital crest a small depression is sometimes distinguishable; it is often termed the *vermian fossa*, since it is occupied by part of the inferior vermis of the cerebellum. On each side a wide *sulcus of the transverse sinus* extends laterally from the internal occipital protuberance; to the margins of these sulci the tentorium cerebelli is attached. The right sulcus is usually larger and continuous with the sulcus of the superior sagittal sinus; but the left may be larger than the right, or the two may be almost equal in size. The position of the *confluence of the sinuses* is indicated by a depression on one or other side of the protuberance.



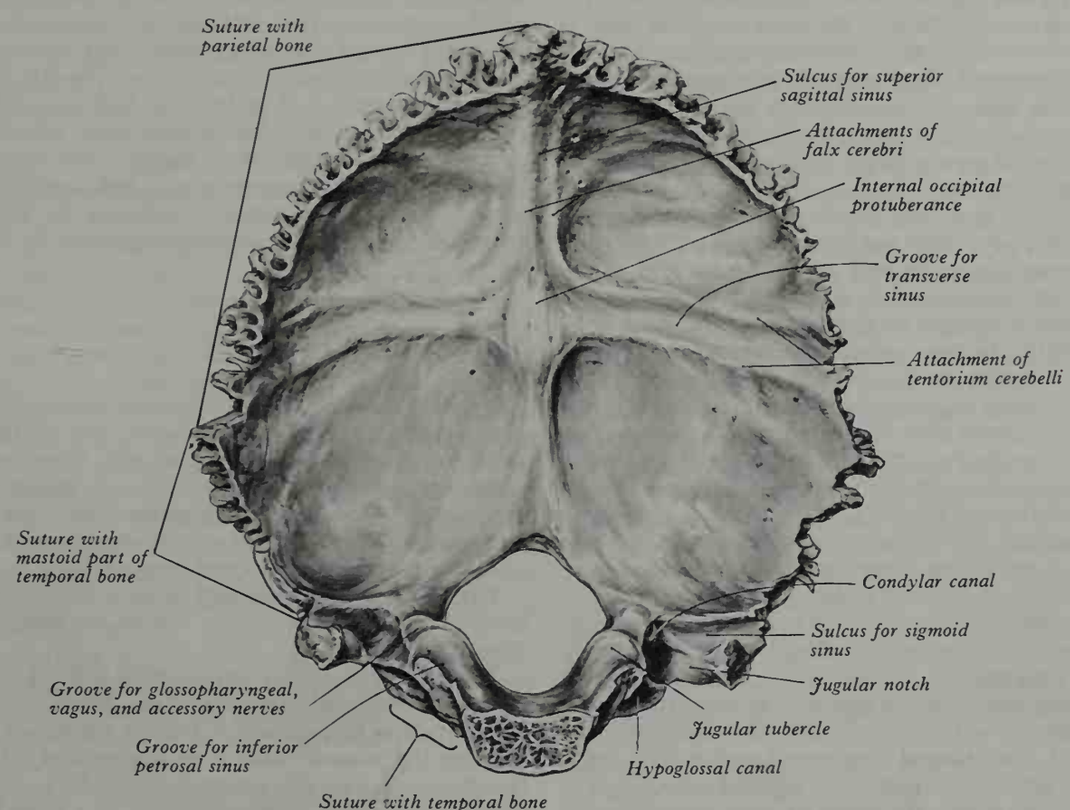
The *superior angle* of the squamous part articulates with the occipital angles of the parietal bones, and corresponds in position with the *posterior fontanelle* of the fetal skull. The *lateral angles* are at the ends of the sulci of the transverse sinus; each projects into the interval between the parietal bone and the mastoid part of the temporal bone. The *lambdoid borders* extend from the superior to the lateral angles; they are serrated for articulation with the occipital borders of the parietal bones to form the lambdoid suture. The *mastoid borders* extend from the lateral angles to the jugular processes; each articulates with the mastoid portion of the corresponding temporal bone. A variety of partially or wholly independent ossicles may occur at or near the lambda (*vide infra*, p. 338 and consult Strivastava 1977). Amongst others these include the 'interparietal' (Inca bone, or ossicle of Goethe).

The basilar part of the occipital bone extends forwards and upwards from the foramen magnum, and presents *anteriorly* a cut surface, more or less quadrilateral in shape, since it is fused with the sphenoid in adults. In the young skull this surface is rough and uneven and is joined to the body of the sphenoid bone by a growth plate of cartilage. By the twenty-fifth year this plate of cartilage has undergone ossification and the occipital and sphenoid bones are fused.

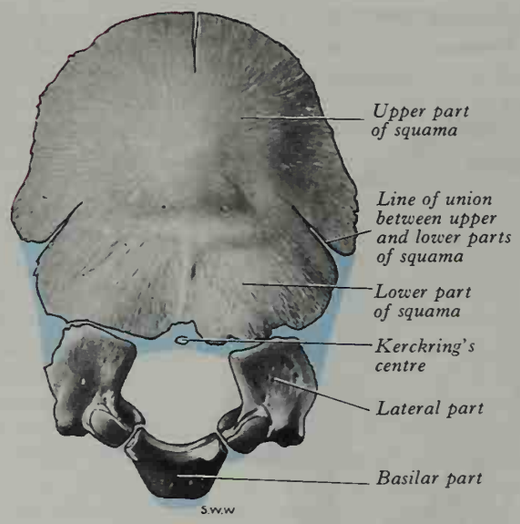


On the *inferior surface* of the basilar part, about 1 cm in front of the foramen magnum, a small elevation, the *pharyngeal tubercle*, gives attachment to the fibrous raphe of the pharynx. The longus capitis is inserted into the bone lateral to the pharyngeal tubercle, and the rectus capitis anterior, into a small depression in front of the occipital condyle. (The latter depression may, instead, be represented by a small *precondylar tubercle*. Its incidence is low in most crania but relatively frequent in Mexican and Burmese crania; *see* p. 348.) The anterior margin of the foramen magnum gives attachment to the anterior atlanto-occipital membrane.

The *superior surface* of the basilar part consists of a broad, shallow groove, the *clivus*, which inclines upwards and forwards from the anterior border of the foramen magnum; it supports the medulla oblongata and the lower part of the pons, and near the margin of the foramen gives attachment to the membrana tectoria and the apical ligament. On the lateral margins of this surface are the *sulci of the inferior petrosal sinuses*, and below each of these sulci the lateral margin of the basilar part is rough for articulation with the petrous part of the temporal bone.



The lateral (condylar) parts of the occipital bone are situated at the sides of the foramen magnum; on their *inferior surfaces* are the *occipital condyles*, two processes for articulation with the superior facets of the atlas. They are oval or reniform in



3.85 The occipital bone. Posterior aspect. The condylar canal was present on the left side only in this specimen.

3.86 The occipital bone. Inferior aspect. Drawn from the same specimen as **3**.85.

3.87 The occipital bone. Internal aspect.

shape, with their long axes running forwards and medially; their anterior ends encroach on the basilar portion, their posterior ends extend back to the level of the middle of the foramen magnum. The articular surfaces of the condyles are convex from before backwards and from side to side; they face downwards and laterally, and are occasionally constricted near their centres. Rarely a condyle may be in two parts, usually described as 'double' (*see* p. 348): It may be recalled that the superior articular facets of the atlas are likewise frequently constricted and occasionally 'double' (Singh 1965). On the medial side of each a rough impression or tubercle gives attachment to the alar ligament. Above the anterior part of each condyle the bone presents the *hypoglossal canal*, which begins on the cranial surface of the bone a short distance above the anterior part of the foramen magnum, and is directed laterally and forwards. It may be partially or completely divided into two by a spicule of bone; it transmits the hypoglossal nerve, and a meningeal branch of the ascending pharyngeal artery. A depression, the *condylar fossa*, lies behind the condyle and approximates to the posterior margin of the corresponding superior facet of the atlas when the head is extended; the floor of this fossa is sometimes perforated by the *condylar canal*, through which an emissary vein passes from the sigmoid sinus. The *jugular process* extends laterally from the posterior half of the condyle. It is a quadrilateral plate of bone, indented in front by the *jugular* notch, which forms the posterior part of the jugular foramen. The jugular notch is sometimes partly divided into two by a bony spicule named the *intrajugular process*, which projects forwards and laterally. The under surface of the jugular process is rough and affords attachment to the rectus capitis lateralis; from this surface an eminence, the *paramastoid process*, sometimes projects downwards, and may be of sufficient length to articulate with the transverse process of the atlas. Laterally the jugular process presents a rough quadrilateral or triangular area which is joined to the jugular surface of the temporal bone by a growth plate of cartilage; about the age of 25 this plate begins to ossify. For a study of variations of the jugular foramen, processes, and neighbouring features, in relation to age and sex, consult Solter and Paljan (1973). While it is apparently rare or absent in many populations, a paramastoid process was recorded in 44 per cent of 149 American Indian males, and in 31 per cent of 137 American Indian females (Finnegan 1972).

On the *superior surface* of the condylar part an oval eminence, the *jugular tubercle*, overlies the hypoglossal canal; its posterior part often presents a shallow furrow for the glossopharyngeal, vagus and accessory nerves. On the superior surface of the jugular process a deep groove curves medially and forwards around an upwardly directed, hook-shaped process and ends at the jugular notch; it contains the terminal part of the sigmoid sinus. Close to the medial end of the groove the condylar canal opens into the posterior cranial fossa.

The *foramen magnum* is considered on p. 307.

Structure. The occipital, like the other cranial bones, consists of two compact lamellae, called the *outer* and *inner plates*, between which there is spongy bone or *diploë*; the bone is thick at ridges, protuberances and condyles, and at the anterior portion of the basilar part; in the lower parts of the fossae for the cerebellar hemisphere it is thin, semi-transparent, and devoid of diploë.

Ossification (**3**.88). A commonly stated, but almost certainly *oversimplified* account of the ossification of the occipital bone (*see* further below) is that above the highest nuchal line the squamous part is developed in a membrane of fibrous tissue, and is ossified from two centres, one appearing on each side of the median plane about the second month of intrauterine life; this part may remain separate throughout life, and is then known as the *interparietal bone*. The rest of the occipital bone is preformed in cartilage. Below the highest nuchal line, the squamous part is ossified from two centres, which appear about the seventh week of intrauterine life and soon unite to form a single piece. The upper and lower portions of the squamous part unite in the third month of intrauterine life, but their line of union can be recognized in the bone at birth (**3**.88).

An occasional centre appears in the posterior margin of the foramen magnum about the sixteenth week (Kerckring); it unites with the rest of the squamous parts before birth. Having surveyed the previous literature, and examined a series of 620 human skulls for anomalies of the squamous part of the occipital, Strivastava (1977) has proposed a much more complex developmental history of the bone. He regards the *membranous* (*dermal*) part of the occipital squama, which lies above the nuchal lines as compounded of an *interparietal* and a *pre-interparietal* part: the interparietal consisting of *two lateral plates* and a *centre piece*. The intramembranous centres of ossification for these he proposes as—a pair of centres for each lateral plate and two centres for the central part of the interparietal, plus a pair of centres for the pre-interparietal. There may be partial or complete failure of fusion between any or all of these subregions. The *cartilaginous supra-occipital* he regards as presenting five endochondral centres of ossification, a pair for each of its right and left *lateral segments* and a single ossific centre for the *central segment*, (the latter may correspond to Kerckring's centre mentioned above). Each of the lateral (condylar, or exoccipital) parts of the occipital bone ossifies from a single centre, which appears during the eighth week of intrauterine life. The basilar portion is ossified from one centre which appears about the sixth week of intrauterine life. About the end of the second year the squamous part unites with the lateral portions, and by the sixth year the bone consists of a single piece. Between the eighteenth and twenty-fifth years the occipital and sphenoid bones unite to form a single bone. Metrical study of the occipital bone (Olivier 1975) suggests that the squamous and basilar parts of the complex evince independent parameters of growth. The same observations indicated that sexual differences are chiefly evident in the condylar regions of the bone.

The Sphenoid Bone

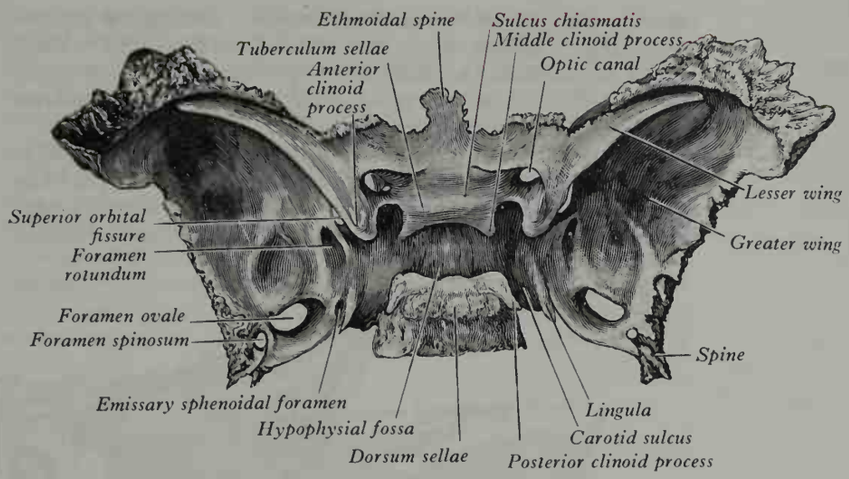
The sphenoid bone (**3**.89, 90, 91) is in the base of the skull, in front of the temporal bones and the basilar part of the occipital. In shape it resembles a bat or a bird with wings outstretched. It consists of a central portion or body, two greater and two lesser wings, which spread laterally from the sides of the body, and two pterygoid processes, which are directed downwards from the adjoining parts of the body and greater wings.

The body of the sphenoid bone is more or less cubical; it contains two large air sinuses, which are separated from each other by a septum.

The *cerebral* or *superior surface* of the body (**3**.89) articulates in front with the cribriform plate of the ethmoid bone. Anteriorly this surface is smooth and is termed the *jugum sphenoidale*; it supports the posterior ends of the gyri recti of the cerebrum and the olfactory tracts. It is bounded behind by a ridge, the anterior border of the *sulcus chiasmatis*; this sulcus leads laterally to the *optic canal* on each side. Posterior to the groove there is an

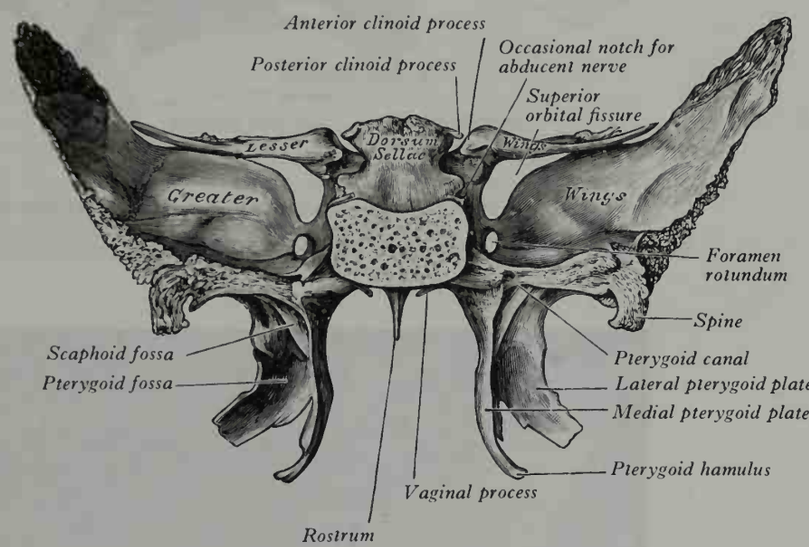
elevation, the *tuberculum sellae*; and behind this a hollow, the *sella turcica*, the deepest part of which, the *hypophysial fossa*, lodges the hypophysis cerebri. The anterior boundary of the sella turcica is completed laterally by two small eminences, the *middle clinoid processes*, whilst posteriorly is a square plate of bone, the *dorsum sellae*. The superior angles of this plate ends in two tubercles of varying size, the *posterior clinoid processes*, which give attachment to the fixed margin of the tentorium cerebelli. On each side of the body below the dorsum sellae a small projection articulates with the apex of the petrous portion of the temporal bone and is often termed the *petrosal process*. (For variations in the sella turcica *see* Kinnman 1977, and Lang 1977.)

The sloping area behind the dorsum sellae is the *clivus*, and is uninterruptedly continuous with the clivus of the occipital bone in the adult skull; it supports the upper part of the pons.



The *lateral surfaces* of the body are united with the greater wings and with the medial pterygoid plates. Above the attachment of each wing a broad groove, the *carotid sulcus*, forms a curve somewhat like the italic letter *f*; it lodges the internal carotid artery and the cavernous sinus. The carotid sulcus is deepest at its posterior end, where it is overhung medially by the petrosal process, and is limited laterally by a sharp margin called the *lingula*; the latter is continued backwards to overlie the posterior opening of the pterygoid canal.

The *anterior surface* of the body (**3**.91) presents, in the median plane, a triangular crest, which forms a small part of the septum of the nose and is termed the *sphenoidal crest*. The anterior border of this crest articulates with the perpendicular plate of the ethmoid bone. On each side of the crest a rounded opening leads into the corresponding *sphenoidal sinus*. The sphenoidal sinuses (p. 1149) are two large, irregular cavities in the body of the bone, separated from each other by a bony septum which is commonly deflected to one side or the other. They vary in form and size, are seldom symmetrical, and are often partially divided by bony laminae. A lateral recess may extend from one or other sinus into the greater wing and lingula (Cope 1917); the sinuses occasionally reach into the basilar part of the occipital bone nearly as far as the foramen magnum. In relation to the trans-sphenoidal surgical approach to the hypophysis cerebri the sphenoidal sinuses have been divided into three types: *conchal*—a small sinus separated from the sella turcica by cancellous bone some 10 mm thick; *presellar*—in which the sinus does not extend dorsal to the tuberculum sellae; and *sellar*—in which the sinus extends, as mentioned above, very variable distances beyond the tuberculum (Hammer and Rådberg 1961; for further details *see* Kinnman 1977). In the articulated skull they are closed in front and below by the *sphenoidal conchae* (p. 325), but a round opening is left in the anterior wall of each sinus, by which it communicates with the spheno-ethmoidal recess of the nasal cavity. Each half of the anterior surface of the body of the sphenoid bone consists of two parts: (*a*) an upper and lateral depressed area, which articulates with the labyrinth of the ethmoid bone and completes the posterior ethmoidal sinuses; its lateral margin articulates with the orbital plate of the ethmoid bone above, and with the orbital process of the palatine bone below; (*b*) a lower and medial, smooth, triangular area, which forms the posterior part of the roof of the nose; near its superior angle is the orifice of the sphenoidal sinus.

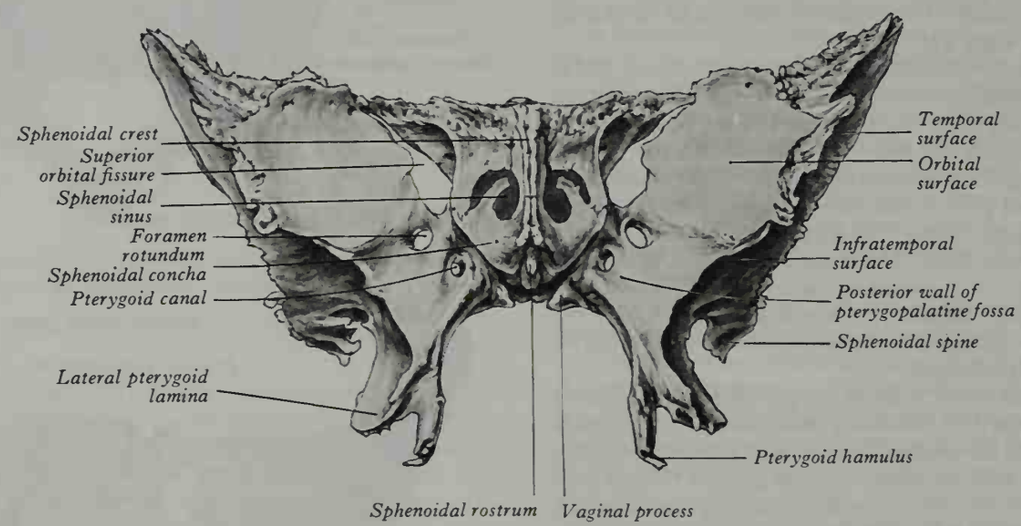


The *inferior surface* of the body presents in the median plane a triangular spine, the *sphenoidal rostrum* (**3**.91), which projects into a deep fissure between the anterior parts of the alae of the vomer. The posterior, triangular parts of the sphenoidal conchae extend backwards on the sides of the rostrum, and articulate with the alae of the vomer. On each side of the posterior part of the rostrum, and immediately behind the apex of the sphenoidal concha, a thin lamina, the *vaginal process*, projects medially from the base of the medial pterygoid plate (**3**.91).

The greater wings are two strong processes which curve laterally and upwards from the sides of the body. The posterior part of each is triangular and fits into the angle between the petrous and squamous parts of the temporal bone (**3**.71) forming the sphenosquamosal suture.

The *cerebral surface* of the greater wing (**3**.89) forms part of the floor of the middle cranial fossa; it is deeply concave and presents a pattern of elevations and depressions corresponding with the convolutions of the anterior part of the temporal lobe. At its anteromedial part the *foramen rotundum* gives passage to the maxillary nerve. Behind and lateral to this the *foramen ovale* transmits the mandibular nerve, the accessory meningeal artery, and sometimes the lesser petrosal nerve which may, however, pass through a special canal (*canaliculus innominatus*) on the medial side of the foramen spinosum. Medial to the foramen ovale, a small aperture, termed the *emissary sphenoidal foramen*, is present on one or both sides in nearly 40 per cent of skulls; it opens below at the lateral side of the scaphoid fossa and transmits a small vein from the cavernous sinus. In the posterior angle, anteromedial to the spine, there is a short canal, termed the *foramen spinosum*, which transmits the middle meningeal artery and the meningeal branch of the mandibular nerve.

3.89 The sphenoid bone. Superior aspect.



3.90 The sphenoid bone. Posterior aspect.

The *lateral surface* of the greater wing (**3**.70) is convex from above downwards, and is divided by a transverse ridge, termed the *infratemporal crest*, into an upper or temporal and a lower or infratemporal surface. The *temporal surface*, concave from before backwards, forms a portion of the temporal fossa and gives origin to a part of the temporalis. The *infratemporal surface* is concave and directed downwards; together with the infratemporal crest, it gives origin to the upper head of the lateral pterygoid. It is pierced by the *foramen ovale* and *foramen spinosum*, and its posterior part bears the *spine of the sphenoid* bone (p. 305), which forms a small, sometimes pointed process, projecting downwards. Its medial side may be marked by a faint groove, directed downwards and forwards, for the chorda tympani nerve, and helps to form the lateral wall of the sulcus for the auditory tube (p. 305). Its tip gives attachment to the sphenomandibular ligament. Medial to the

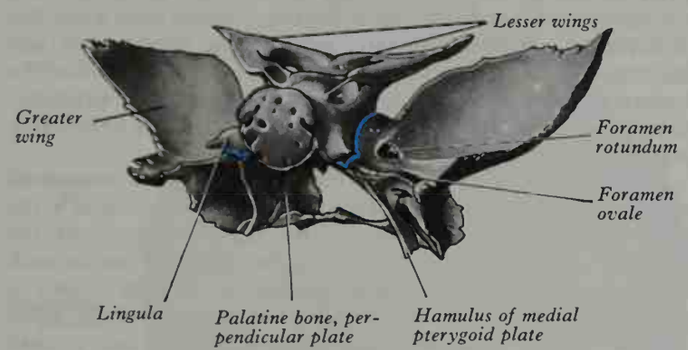
anterior extremity of the infratemporal crest a triangular process serves to increase the attachment of the lateral pterygoid. A ridge runs downwards and medially from this triangular process to the front of the lateral pterygoid plate; it forms the posterior boundary of the pterygomaxillary fissure.

The *orbital surface* of the greater wing (**3**.91 A), quadrilateral in shape, is directed forwards and medially and forms the posterior part of the lateral wall of the orbit. Its upper, serrated edge articulates with the orbital plate of the frontal bone, its lateral, serrated margin with the zygomatic bone. Its inferior smooth border forms the posterolateral boundary of the inferior orbital fissure. Its medial sharp margin constitutes the lower, or lateral, boundary of the superior orbital fissure, and from it a small tubercle affords attachment to part of the common tendinous ring, from which the rectus muscles of the eyeball take origin. Below the medial end of the superior orbital fissure there is a grooved area which forms the posterior wall of the pterygopalatine fossa and is pierced by the foramen rotundum.

3.91 A The sphenoid bone of an eight-year-old child. Anterior aspect.

3.91 B High resolution projection microradiograph of the sphenoid bone (anteroposterior projection). Note in particular the sphenoidal body and its contained sinuses, the architecture of the greater and lesser wings, and pterygoid processes, and the disposition of the optic canal, superior orbital fissure, foramen rotundum, and pterygoid canal. (Kindly contributed by Dr. C. Buckland-Wright, Department of Anatomy, Guy's Hospital Medical School, London.)

The *margin of the greater wing* (**3**.90), where it extends from the body to the spine of the sphenoid, is irregular. Its medial half forms the anterior boundary of the *foramen lacerum* and presents the posterior aperture of the pterygoid canal for the passage of the corresponding nerve and artery. Its lateral half articulates with the petrous portion of the temporal bone, by means of a cartilaginous joint, the *sphenopetrosal synchrondrosis*. Between the two bones, on the under surface of the skull, there is a furrow, the *sulcus tubae*, which lodges the cartilaginous part of the auditory tube. Extending forwards from the sphenoidal spine the *squamosal margin* forms a concave, serrated edge, bevelled at the expense of the inner surface below and of the outer surface above, for articulation with the squamous part of the temporal bone. The tip of the greater wing is bevelled at the expense of the inner surface and articulates with the sphenoidal angle of the parietal bone at the *pterion*. Medial to this, there is a triangular rough area, for articulation with the frontal bone; the medial angle of this area is continuous with the sharp edge which forms the lower boundary of the superior orbital fissure, and the anterior angle with the serrated margin for articulation with the zygomatic bone.



The lesser wings of the sphenoid bone are two triangular plates which project laterally from the upper and anterior parts of the body and end in sharp points (**3**.89, 90). The *superior surface* of each is smooth, and supports a small part of the frontal lobe of the cerebrum. The *inferior surface* forms the posterior part of the roof of the orbit and the upper boundary of the *superior orbital fissure*; it overhangs the anterior part of the middle cranial fossa. The *anterior border* of the lesser wing is serrated for articulation with the posterior edge of the orbital plate of the frontal bone. The *posterior border* is smooth and projects into the lateral cerebral fissure; the medial end of this border forms the *anterior clinoid process*, which gives attachment to the anterior end of the free border of the tentorium cerebelli. The anterior and middle clinoid processes are sometimes united by a spicule of bone, and when this occurs the end of the groove for the internal carotid artery is converted into a *caroticoclinoid foramen*. The lesser wing is connected to the body by two roots, the anterior thin and flat, the posterior thick and triangular; the *optic canal*, which lies between them, transmits the optic nerve and ophthalmic artery. The variations in the growth of the posterior root are closely associated with variations in the optic canal itself (Kier 1966). Its cranial opening may be duplicated (Warwick 1951). More commonly the division of this part of the canal is incomplete. (See also Lang, 1977.)

The superior orbital fissure is triangular in shape and leads from the cranial cavity into the orbit; it is bounded medially by the body of the sphenoid bone; above, by the lesser wing, below, by the medial margin of the orbital surface of the greater wing; it is completed laterally, between the greater and lesser wings, by the frontal bone. Through it the oculomotor, trochlear and abducent nerves, the three branches of the ophthalmic division of the trigeminal nerve, the orbital branch of the middle meningeal artery, and some filaments from the internal carotid plexus of the sympathetic enter the orbit; and the recurrent meningeal branch of the lacrimal artery, and the ophthalmic veins pass backwards into the cranial cavity.

The pterygoid processes of the sphenoid (**3**.90, 91), one on each side, descend perpendicularly from the regions where the greater wings unite with the body. Each process consists of a medial and a lateral plate, the upper parts of which are fused anteriorly. The plates are separated below by an angular cleft, termed the *pterygoid fissure*, the rough margins of which articulate with the pyramidal process of the palatine bone. The two plates diverge behind, and the wedge-shaped *pterygoid fossa* between them contains the medial pterygoid and tensor veli palatini muscles. Above this fossa there is a small, oval, shallow depression, named the *scaphoid fossa*, which is formed by the division of the upper part of the posterior border of the medial pterygoid plate; it gives origin to part of the tensor veli palatini. The anterior surface of the pterygoid process is broad and triangular near its root, where it forms the posterior wall of the pterygopalatine fossa; it is pierced by the anterior orifice of the *pterygoid canal*.

The lateral pterygoid plate is broad, thin and everted; its *lateral surface* forms part of the medial wall of the infratemporal fossa and gives origin to the lower head of the lateral pterygoid; its *medial surface* forms the lateral wall of the pterygoid fossa and gives origin to the greater part of the medial pterygoid. The upper part of the *anterior border* forms the posterior boundary of the pterygomaxillary fissure; the lower part articulates with the palatine bone; its *posterior border* is free.

The medial pterygoid plate is narrower and longer than the lateral; its lower end curves laterally into a hook-like process, the *pterygoid hamulus*, around which the tendon of the tensor veli palatini is deflected, and to which the pterygomandibular raphe is attached. The *lateral surface* of this plate forms the medial wall of the pterygoid fossa, and the tensor veli palatini lies against it; the *medial surface* is the lateral boundary of the corresponding

3.92 The sphenoid bone at birth. Viewed from behind and from the right side. The blue strip indicates the cartilage between the central and the lateral parts on the right side; this is only partly visible on the left. *Note.*—The two palatine bones are *in situ*.

posterior nasal aperture. Superiorly the medial pterygoid plate is prolonged on to the under surface of the body as a thin lamina, the *vaginal process*, which articulates anteriorly with the sphenoidal process of the palatine bone and medially with the ala of the vomer. Inferiorly it bears a furrow, the anterior part of which is converted into a canal by the sphenoidal process of the palatine bone; this is the *palatovaginal canal*, which transmits the pharyngeal branch of the maxillary artery and the pharyngeal branch of the pterygopalatine ganglion. To the whole of the posterior margin of the medial pterygoid plate is attached the pharyngobasilar fascia, and from its lower end the superior constrictor muscle of the pharynx takes origin. The upper end of this margin has a small projection, the *pterygoid tubercle*, which lies immediately below the posterior opening of the pterygoid canal. Projecting backwards from near the middle of the margin is an angular process, the *processus tubarius*, which supports the pharyngeal end of the auditory tube. The lower part of the anterior margin of the medial pterygoid plate articulates with the posterior border of the perpendicular plate of the palatine bone.

The sphenoidal conchae (**3**.91) are two thin, curved platelets, at the anterior and lower parts of the body of the sphenoid bone; the upper, concave surface of each forms the anterior wall and a part of the floor of the corresponding sphenoidal sinus. The sphenoidal conchae are usually more or less destroyed in the process of disarticulating the skull, but, when seen *in situ* each consists of an anterior, vertical, quadrilateral part and a posterior, horizontal, triangular part. The anterior part consists of (*a*) an upper and lateral depressed area, which completes the posterior ethmoidal sinuses and articulates below with the orbital process of the palatine bone, and (*b*) a lower and medial area, smooth and triangular, which forms part of the roof of the nasal cavity, and is perforated above by a round opening through which the sphenoidal sinus communicates with the spheno-ethmoidal recess of the nasal cavity. The anterior vertical parts of the two bones meet in the median plane and are protruded forwards as the sphenoidal crest. The horizontal triangular portion of the concha forms a part of the roof of the nasal cavity and completes the sphenopalatine foramen; its medial edge articulates with the rostrum of the sphenoid and the ala of the vomer; its apex, directed backwards, lies medial to and above the vaginal process of the medial pterygoid plate, and articulates with

the posterior part of the ala of the vomer. A small piece of the sphenoidal concha sometimes appears in the medial wall of the orbit, between the orbital plate of the ethmoid in front, the orbital process of the palatine bone below, and the frontal bone above.

Ossification. Until the seventh or eighth month of intrauterine life the body of the sphenoid consists of two parts—viz.: one in front of the tuberculum sellae, the *presphenoidal part*, with which the lesser wings are continuous; the other comprising the sella turcica and dorsum sellae, forming the *postsphenoidal part*, with which the greater wings and pterygoid processes are associated. A considerable part of the bone is preformed in cartilage. There are six centres for the presphenoidal and eight for the postsphenoidal part. This multiplicity of ossific centres and of parts in the development of the mammalian sphenoid bone corresponds with its evolution in land vertebrates from a number of separate sphenoid elements, such as the presphenoid and basisphenoid in the midline and homologous with the parts of the human sphenoid defined above. The lesser wings are primarily separate as the orbitosphenoids, but show a tendency to fusion in mammals.

Presphenoidal part. About the ninth week a centre of ossification appears for each of the lesser wings, just lateral to the optic canal; shortly afterwards two centres appear in the presphenoidal part of the body. The sphenoidal conchae are each developed from a centre which appears in the fifth month of intrauterine life in the upper and posterior part of the nasal capsule. As the centre enlarges it partially surrounds a small backward expansion of the upper and posterior part of the nasal cavity, which subsequently becomes the sphenoidal sinus. The posterior wall of the concha becomes absorbed, allowing the sinus to invade the presphenoid. In the fourth year the concha fuses with the ethmoidal labyrinth, and before puberty it fuses with the sphenoid and palatine bones. The deficiency in its anterior wall persists at the opening of the sphenoidal sinus.

Postsphenoidal part. The first centres of ossification are those for the greater wings. About the eighth week one appears below the foramen rotundum in the cartilage which forms the base of each wing. This centre forms only the root of the greater wing in the neighbourhood of the foramen rotundum and the pterygoid canal. The whole of the rest of the greater wing is ossified in membrane and the process extends downwards into the lateral pterygoid plate. About the fourth month, two centres appear in the postsphenoidal part of the body, one on each side of the sella turcica, and soon fuse. Each medial pterygoid plate is ossified in membrane, and its centre probably appears about the ninth or tenth week; the hamulus is *chondrified* during the third month and almost at once begins to ossify (Fawcett 1905). The medial and lateral pterygoid plates join about the sixth month. About the fourth month a centre appears for each lingula and speedily joins the rest of the bone.

The presphenoidal and the postsphenoidal parts of the body fuse about the eighth month of intrauterine life, but a wedge-shaped piece of cartilage persists for some time after birth in the lower part of the line of fusion. At birth the bone is in three pieces (**3**.92): a central, consisting of the body and lesser wings, and two lateral, each comprising a greater wing and pterygoid process. In the first year after birth the greater wings and body unite around the margins of the pterygoid canal, and the lesser wings extend medially above the anterior part of the body and meet to form an elevated smooth surface, termed the *jugum sphenoidale*. By the twenty-fifth year the sphenoid and occipital bones are completely fused. In the *anterior part* of the hypophysial fossa there is occasionally a vascular foramen, which is usually, but erroneously, termed the *craniopharyngeal canal* (p. 199). (For an analysis and bibliography concerning the cartilage canals in the fetal spheno-occipital synchondrosis consult Moss-Salentÿn 1975.)

The sphenoidal sinus is present before birth as an extension of the nasal cavity into the sphenoidal concha. In the second or third year it extends backwards into the presphenoid and subsequently invades the postsphenoid, reaching its full, normal size in adolescence. As age advances it frequently undergoes a further enlargement, associated with absorption of its bony walls.

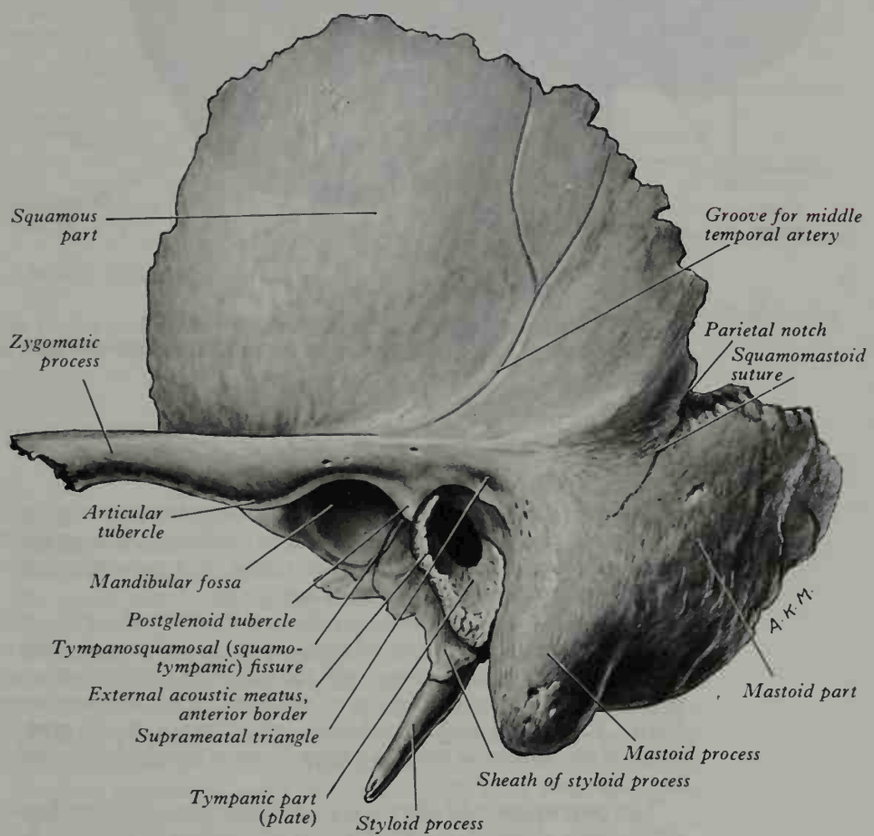
Certain parts of the sphenoid bone are connected by ligaments which occasionally ossify. The more important of these ligaments are: the *pterygospinous*, stretching between the spine of the sphenoid and the upper part of the lateral pterygoid plate (p. 307); the *interclinoid*, joining the anterior to the posterior clinoid process; and the *caroticoclinoid*, connecting the anterior to the middle clinoid process. For details of the fetal and perinatal development of the optic foramen and canal consult Kier (1966). Lang (1977) has surveyed the literature of ossificatory variations of the sella turcica.

Premature ossification or synostosis of the suture between the pre- and post-sphenoidal parts and of the spheno-occipital suture produces a characteristic physiognomy. This is best seen in profile, and consists of an abnormal depression of the bridge of the nose; it is a feature often observed in achondroplasia. Anomalous development of the presphenoidal elements may lead to excessive separation between the orbits and an abnormally broad nasal bridge (*hypertelorism*).

The Temporal Bones

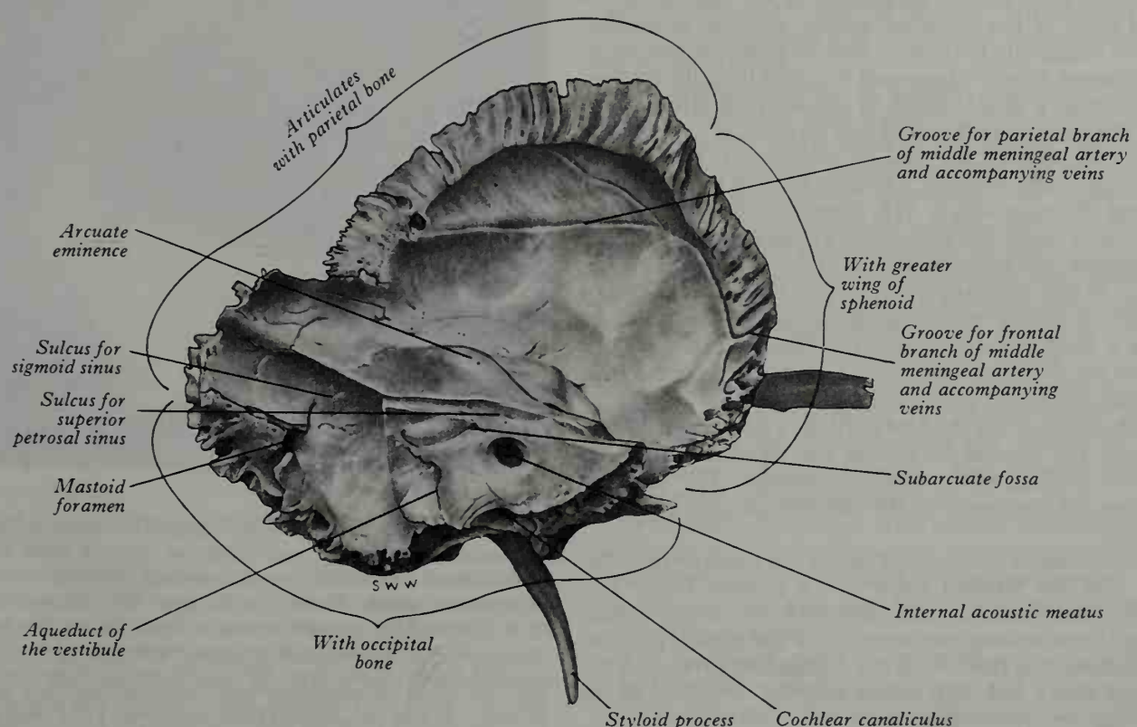
The temporal bones (**3**.93–96) take part in the formation of the sides and base of the skull. Each consists of four parts, viz.: the *squamous*, *petromastoid*, and *tympanic parts*, and the *styloid process*. These are morphologically distinct elements which have become fused with one another during the evolution of higher vertebrates. The squamous part is a dermal bone developed to assist in enclosure of the cerebrum. The petromastoid portion is preformed in cartilage and it stabilizes and preserves a precise orientation for the membranous labyrinth. The tympanic part, formed in membrane, is homologous with the angular bone, which constitutes a part of the composite lower jaw of many reptilians and bony fishes; it has become incorporated in the skull and adapted to form part of the walls of the tympanic cavity and external acoustic meatus and to support the tympanic membrane—all concerned with sound wave transmission. The styloid process represents the dorsal end of the skeletal element of the hyoid arch. The fusion of these distinct elements to form the temporal bone and the inclusion of the tympanic cavity and auditory ossicles within the bone during the process have been considered on p. 180.

The squamous part of the temporal forms the anterior and upper part of the bone, and is scale-like, thin and partly translucent. Its *temporal surface* (**3**.93) is smooth and slightly convex; it forms part of the temporal fossa and gives origin to the temporal muscle; above the opening of the external acoustic meatus it is marked by a vertical groove for the middle temporal artery. A curved line, often termed the *supramastoid crest*, extends backwards and upwards across its posterior part; it marks the attachment of the temporal fascia and limits the origin of the temporal muscle. The boundary between the squamous and mastoid portions of the bone lies about 1·5 cm below the supramastoid crest and is frequently indicated by traces of the original squamomastoid suture. Between the anterior end of the supramastoid crest and the posterosuperior sector of the opening of the external acoustic meatus there is a depression, the *suprameatal triangle*; this triangle marks the mastoid antrum, which lies medial to it, at a depth of about 1·25 cm (p. 331). The anterior part of the depression is usually marked by a small projection, the *suprameatal spine*.



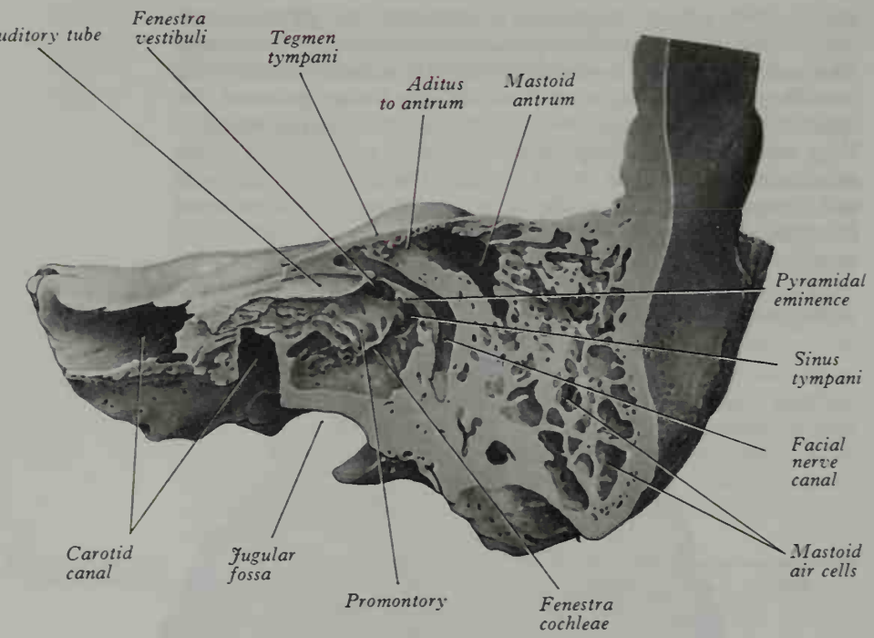
The *zygomatic process*, part of the **zygoma**, projects anteriorly from the lower region of the temporal surface. Its posterior part is triangular in shape and springs from a broad base; it is directed laterally, and its surfaces are superior and inferior. The process is then twisted forwards and medially, and the surfaces of its anterior portion are therefore medial and lateral. The superior surface of the posterior part is concave, and continuous with the temporal surface of the squamous part; the inferior surface is bounded by two roots, *posterior* and *anterior*, which converge as they approach the anterior part of the process. At the meeting point of the two roots the *tubercle of the root of the zygoma* gives attachment to the lateral ligament of the temporomandibular joint. The posterior root is prolonged forwards from the surface of the squamous part immediately above the opening of the external acoustic meatus; its

upper border is continuous behind with the supramastoid crest. The anterior root juts almost horizontally from the side of the squamous temporal; its inferior surface, with an anteroposterior convexity covered by cartilage, is in contact with the articular disc of the joint, and the whole root presents the form of a short semicylindrical bar, the *articular tubercle*, which forms the anterior boundary of the mandibular fossa. Very rarely the squamous part is perforated just above the posterior root of the zygoma. When present, this *squamosal foramen* transmits the petrosquamous sinus (p. 746).



The anterior part of the temporal zygomatic process is thin and flat. To the superior border, which is long and thin, the temporal fascia is attached; the inferior border, which is short and arched, gives origin to some fibres of the masseter. The lateral surface is convex and subcutaneous; the medial is concave and gives origin to part of the masseter. The anterior end is deeply serrated and cut obliquely at the expense of the lower border, it articulates with the temporal process of the zygomatic bone. In front of the articular tubercle a small triangular area forms a part of the roof of the infratemporal fossa and is separated from the temporal surface of the squamous part by a ridge; this ridge is continuous behind with the anterior root of the zygomatic process, and in front, in the articulated skull, with the infratemporal crest on the greater wing of the sphenoid bone.

The mandibular fossa is bounded in front by the articular tubercle; it consists of an anterior, articular portion, formed by the squamous part of the temporal bone, and a posterior, non-articular part, formed by the tympanic element. The *articular surface*, smooth, oval and deeply concave, articulates with the articular disc of the temporomandibular joint; the non-articular portion sometimes lodges a small part of the parotid gland. A small, conical eminence, the *postglenoid tubercle*, separates the lateral region of the articular surface from the anterior margin of the tympanic part of the bone, and is the representative of a prominent tubercle which, in some mammals, descends behind the condyle of the mandible and prevents its backwards displacement; the postglenoid tubercle is sometimes described as the third root of the zygomatic process. (For a multivariate analysis of the conformation of this articular surface in modern and fossil mankind and the great apes, and an evaluation of the validity of functional deductions from such data, consult Ashton *et al.* 1976.) The medial part of the articular fossa is separated from the tympanic part of the bone by the *squamotympanic fissure*, into which projects the downturned anterolateral edge of the tegmen tympani of the petrous bone; the *petrotympanic fissure* is situated between this plate and the tympanic part. This fissure leads into the tympanic cavity; it contains the anterior ligament of the malleus and the anterior tympanic branch of the maxillary artery. The medial end of the fissure presents the anterior opening of the *anterior canaliculus for the chorda tympani*. Very rarely a *postglenoid foramen* is present just in front of the external acoustic meatus and in the line of fusion of the squamous and tympanic portions of the bone. It replaces the squamosal foramen already mentioned, and transmits the petrosquamous sinus (p. 746).



The *cerebral surface* of the squama (**3**.94) is concave; its depressions correspond to the convolutions of the temporal lobe

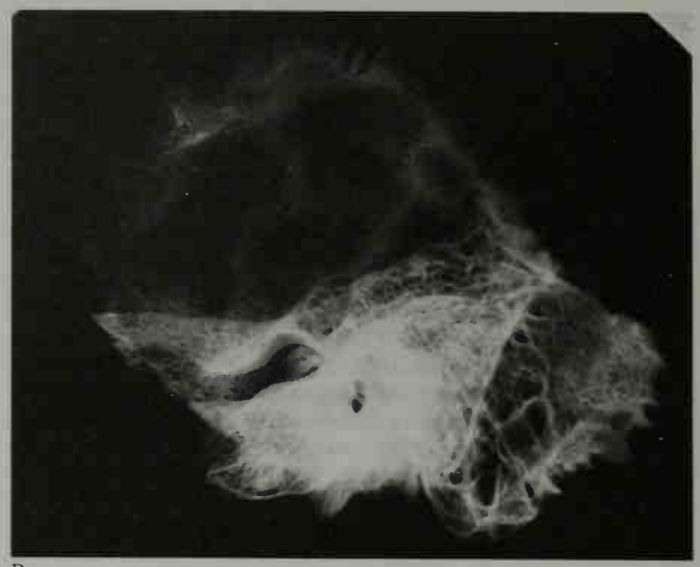
3.93 The left temporal bone. External aspect.

3.94 The left temporal bone. Internal aspect.

3.95A A section through the left temporal bone in the long axis of the tympanic cavity. The lateral surface of the medial half of the bone is shown.

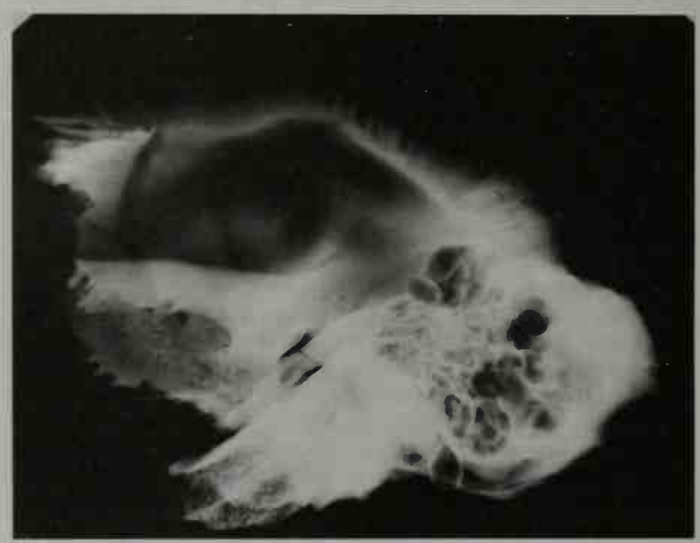
of the cerebrum, and the grooves to the branches of the middle meningeal vessels; its lower border is united to the anterior surface of the petrous portion but traces of a petrosquamosal suture are frequently seen in the adult bone.

The *superior border* is thin, bevelled on its cerebral aspect, and overlaps the inferior border of the parietal bone forming with it the squamosal suture. Posteriorly the superior border forms an angle with the mastoid portion of the bone. The *antero-inferior border*, thin above and thick below, articulates with the greater wing of the sphenoid bone; its upper part is bevelled internally, the lower part externally.



The petromastoid part of the temporal bone is morphologically a single element (p. 326) but it is convenient to describe it in two parts.

The mastoid part forms the posterior part of the temporal bone. Its *outer surface* (**3**.93) is roughened by the attachments of the occipital belly of the occipitofrontalis, and the auricularis posterior. It is frequently perforated near its posterior border by the *mastoid foramen*, which is traversed by a vein from the sigmoid sinus and transmits a small branch of the occipital artery to the dura mater; the position and size of this foramen are variable; it may be situated in the occipital bone, or in the suture between the temporal and the occipital bones. (This foramen is parasutural in 40–50 per cent of crania—*see* p. 348; it may also be absent.) The mastoid portion is continued below into a conical projection, **the mastoid process**; it is larger in the male than in the female. The lateral surface of this process gives insertion to the sternocleidomastoid, splenius capitis, and longissimus capitis; on its medial side there is a deep groove, termed the *mastoid notch*, for the attachment of the posterior belly of the digastric; medial to this notch the shallow *occipital groove* lodges the occipital artery.



On the *inner surface* of the mastoid portion (**3**.94) there is a deep, curved groove, the *sigmoid sulcus*, for the sigmoid sinus; and posteriorly the opening of the mastoid foramen. The sulcus is separated from the innermost of the mastoid air cells by a thin lamina of bone.

The *superior border* of the mastoid part is thick and serrated for articulation with the mastoid angle of the parietal bone. The *posterior border*, also serrated, articulates with the inferior border of the occipital bone between the lateral angle and jugular process. The mastoid element is fused with the descending process of the squamous part above: below, it enters into the formation of the posterior wall of the tympanic cavity.

The *mastoid air cells*, which occupy the mastoid process (**3**.95),

B

C

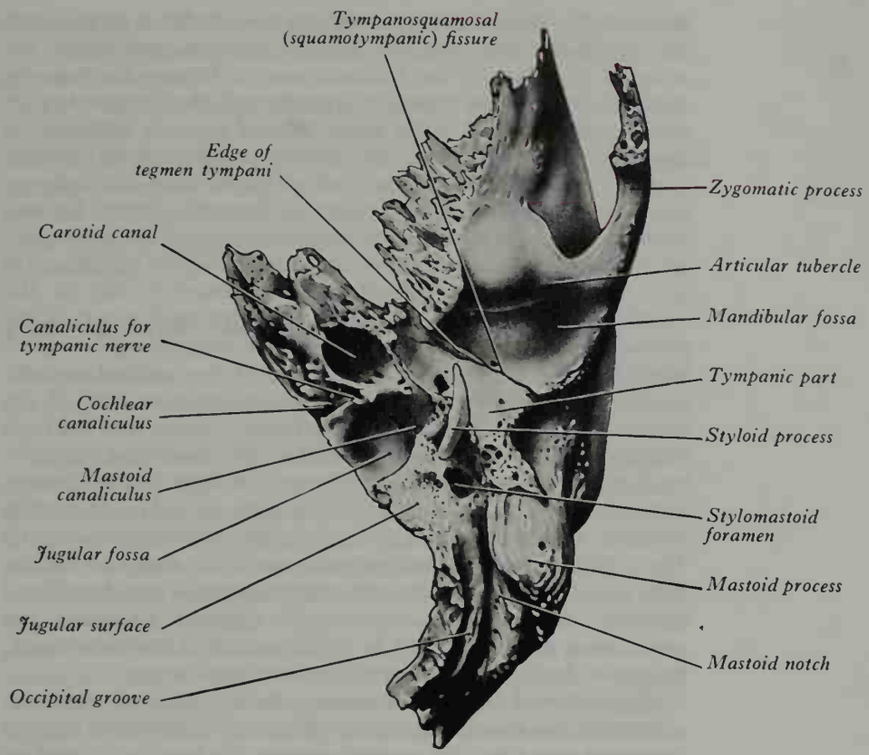
D

3.95B, C and D High resolution projection microradiographs of the petromastoid, tympanic, and squamous parts of three temporal bones (mediolateral projection), showing marked variation in extent and mode of pneumatization. Above, the air-cells are comparatively large and extend beyond the mastoid process as far as the mandibular fossa. In the middle photograph the cells are large but restricted to the post-otic and mastoid regions of the bone. Below, obvious pneumatization is absent; a fine meshwork of trabecular bone occupies the core of the mastoid process. (Kindly prepared and contributed by Dr. C. Buckland-Wright, Department of Anatomy, Guy's Hospital Medical School, London.)

and the *mastoid antrum*, by which they communicate with the tympanic cavity, are described on p. 1196.

The petrous part of the temporal bone is wedged between the sphenoid and occipital bones at the base of the skull (**3**.75A and B). It is directed medially, forwards, and a little upwards; it has a base, an apex, three surfaces, and three margins. The labyrinth lies within it.

The *base* is a somewhat artificial concept; it corresponds to the suture between the petrous and squamous elements of the temporal bone until this disappears by fusion soon after birth. Since the mastoid process is a post-natal development of the petrous element, the base is here an arbitrary division, but is indicated by the partial separation of the two by the mastoid antrum.



The *apex*, blunt and irregular, projects into the angular interval between the posterior border of the greater wing of the sphenoid bone and the basilar part of the occipital bone; in it is the anterior orifice of the carotid canal and it forms the posterolateral boundary of the foramen lacerum.

The *anterior surface* helps to form the floor of the middle cranial fossa and is continuous with the cerebral surface of the squamous part, although remains of the petrosquamosal suture are often distinct even at a late period of life.

The whole surface is marked by impressions for the gyri of the inferior surface of the temporal lobe. Immediately behind the apex is a slight hollow for the trigeminal ganglion, the *trigeminal impression*. The bone, anterior and slightly lateral to the impression, forms the roof of the anterior part of the carotid canal; it is often deficient here. An irregular ridge separates the trigeminal impression posteriorly from a second hollow, which forms part of the roof of the internal acoustic meatus and covers the cochlea. This concavity is limited behind by an elevation, the *arcuate eminence* (**3**.94), raised by the anterior semicircular canal. In its lateral part it roofs in the vestibule and the beginning of the facial canal. Between the squamous part on the lateral side, and the arcuate eminence and the hollows just described on the medial side, the surface is formed by the *tegmen tympani*. This thin plate of bone forms the roof of the mastoid antrum behind and extends forwards above the tympanic cavity (**3**.95) and the canal for the tensor tympani. Its lateral margin meets the squama at the site of the petrosquamosal suture and turns downwards in front to form the lateral wall of the canal for the tensor tympani and the bony part of the auditory tube; the lower edge of this downturned portion has already been observed in the floor of the squamotympanic fissure (p. 307). Anteriorly the tegmen tympani presents a narrow groove, which runs backwards and laterally and enters the bone through an opening placed in front of the lateral part of the arcuate eminence. This hiatus transmits the greater petrosal nerve, which runs forwards to the foramen lacerum. A second, smaller hiatus, lying lateral to the one just described, transmits the lesser petrosal nerve from the tympanic plexus; the bone in front of the opening may be grooved. The posterior slope of the arcuate eminence covers the posterior and lateral semicircular canals, and lateral to it the posterior part of the tegmen tympani roofs in the mastoid antrum.

The *posterior surface* (**3**.94) forms the anterior part of the posterior cranial fossa and is continuous with the inner surface of the mastoid portion. Near the centre of the posterior surface is the orifice of **the internal acoustic meatus** (p. 313). Behind this orifice there is a small slit almost hidden by a thin plate of bone; it leads to a canal, the *aqueduct of the vestibule*, which contains the saccus and ductus endolymphaticus together with a small artery and vein. The terminal half or more of the saccus endolymphaticus protrudes through the narrow orifice and lies between the periosteum and the covering dura mater. Above and between these two openings the *subarcuate fossa* (p. 313) forms an irregular depression.

The *inferior surface* (**3**.96), rough and irregular, is part of the external surface of the base of the skull. Near the apex a quadrilateral rough area serves partly for the attachment of the levator veli palatini and the cartilaginous portion of the auditory tube, and partly for connexion with the basilar part of the occipital bone, some dense fibrocartilage intervening. Behind this a large, nearly circular aperture leads into **the carotid canal** (p. 306).

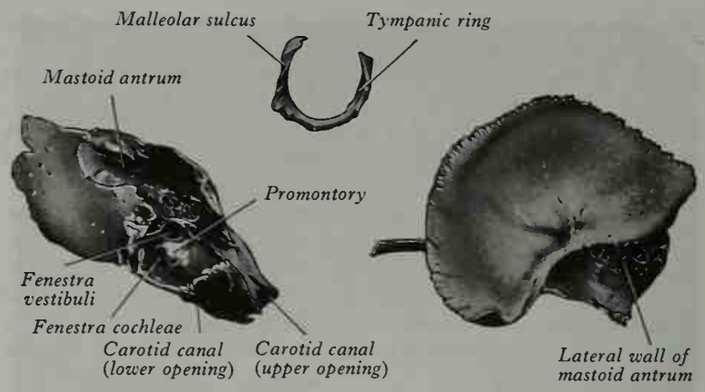
3.96 The left temporal bone. Inferior aspect.

Behind this opening there is a deep depression, termed **the jugular fossa**, of variable depth and size in different skulls; it lodges the superior bulb of the internal jugular vein. In front of the medial part of the jugular fossa and directly below the internal acoustic meatus, the bone is marked by a triangular depression, which lodges the inferior ganglion of the glossopharyngeal nerve. At the apex of this notch a small opening leads into the *cochlear canaliculus*, which is occupied by the perilymphatic duct and a tubular prolongation of the dura mater, and transmits a vein from the cochlea to join the internal jugular vein. On the bony ridge dividing the carotid canal from the jugular fossa there is a small *canaliculus for the tympanic nerve*, which is derived from the glossopharyngeal nerve (p. 308). In the lateral part of the jugular fossa the bone is pierced by the *mastoid canaliculus* for the entrance of the auricular branch of the vagus nerve. Behind the jugular fossa is the *jugular surface*, a rough quadrilateral area covered with cartilage and articulating with the jugular process of the occipital bone.

The *superior border*, the longest, is grooved for the superior petrosal sinus, the dura mater of the tentorium cerebelli being attached to the sharp edges of the groove, except at its medial extremity, where it is crossed by the roots of the trigeminal nerve. The *posterior border* is intermediate in length between the superior and the anterior. Its medial part is marked by a sulcus, which forms, with a corresponding sulcus on the occipital bone, the channel for the inferior petrosal sinus. Behind this there is **the jugular fossa**, which, with the jugular notch on the occipital bone, forms the jugular foramen; it presents a notch for the glossopharyngeal nerve, and bone on either or both sides of the notch may meet the occipital bone and divide the foramen into two parts, sometimes three. The *anterior border* is divided into two parts: a lateral, joined to the squamous part at the *petrosquamosal suture*; a medial, free, for articulation with the greater wing of the sphenoid bone.

At the angle of junction of the petrous and squamous parts two canals are placed one above the other, and separated by a thin plate of bone. Both canals lead into the tympanic cavity; the upper contains the tensor tympani; the lower is the osseous part of the canal of the auditory tube.

The tympanic part of the temporal bone (**3**.96) is a curved plate lying below the squamous part and in front of the mastoid process. Internally, it is fused with the petrous part, and appears in the angle between it and the squamous part, where it lies below

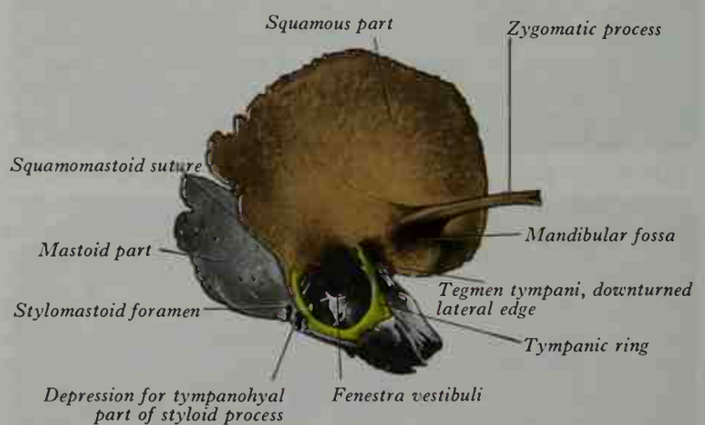


and lateral to the orifice of the auditory tube. Behind, it fuses with the squamous part and the mastoid process, and forms the anterior boundary of the tympanomastoid fissure. Its *posterior surface* is eoneave and forms the anterior wall, the floor, and a part of the posterior wall of the bony external aeoustie meatus (the postero-inferior wall of the external meatus oeeasionally presents a smooth to roughened longitudinal elevation—the *auditory torus*); at the medial end of this surfaee there is a narrow furrow, termed the *tympanic sulcus*, for the attaehment of the circumference of the tympanic membrane. Its *anterior surface*, quadrilateral and slightly concave, eonstitutes the posterior wall of the mandibular fossa and is sometimes in contact with a part of the parotid gland. Its *lateral border* is free and roughened; it forms a large part of the margin of the opening of the external acoustie meatus and is eontinuous with the cartilaginous part of the meatus. The lateral part of the *upper border* is fused with the back of the postglenoid tuberele; its medial part forms the posterior boundary of the petrotympanie fissure. The *lower border* is sharp; its lateral part splits to enelose the root of the styloid proeess and is therefore named the *sheath of the styloid process* (vaginal proeess). The eentral portion of the tympanic part of the temporal bone is thin, and in a eonsiderable pereentage of skulls is perforated by a foramen. Between the styloid and mastoid proeesses the *stylomastoid foramen*, whieh is the lower end of the facial canal, transmits the faeial nerve and the stylomastoid artery.

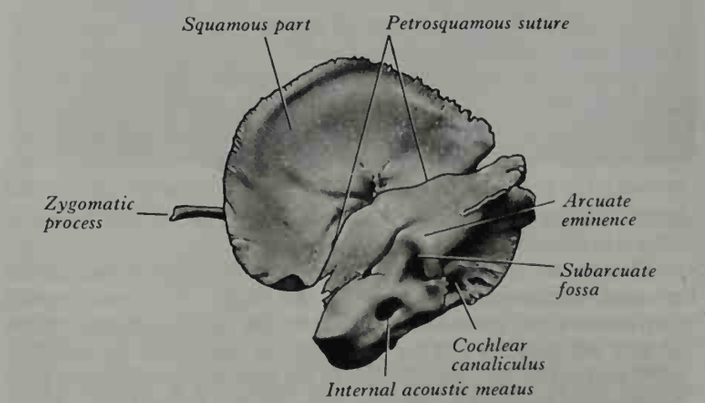
The external acoustic meatus, whieh is about 16 mm long, is direeted inwards and slightly forwards and downwards; its floor is convex upwards. On sagittal seetion the meatus is oval or elliptieal in shape with the long axis directed downwards and slightly baekwards. Its anterior wall, its floor and the lower part of its posterior wall are formed by the tympanie part of the bone, its roof and the upper part of its posterior wall by the squamous part. Its inner end is closed by the tympanic membrane; its outer end is bounded above by the posterior root of the zygomatie proeess, below which the small *suprameatal spine* is sometimes seen at the upper and posterior part of the orifice.

The styloid process of the temporal bone, slender, pointed, and averaging about 2·5 cm in length, projects downwards and forwards, from the under surfaee of the bone. Its proximal part (the *tympanohyal*) is surrounded by a bony sheath, derived from the tympanic plate and best marked on its anterolateral aspect, while its distal part (the *stylohyal*) gives attachment to certain museles and ligaments (p. 302). The process is covered laterally by the parotid gland, the facial nerve crosses its base, and the external carotid artery its tip, as they lie within the gland. On its deep surfaee the process is separated from the commencement of the internal jugular vein by the origin of the stylopharyngeus.

The strueture of the squamous part is like that of the other eranial bones: the mastoid portion is trabeeular and variably pneumatized, and the petrous portion dense and hard.



Ossification. The four elements of the temporal bone are ossified independently (**3**.97). The *squamous part* is ossified in membranous eondensed mesenehyme from a single eentre which appears in the region of the roots of the zygomatie proeess about the seventh or eighth week of intrauterine life. The *petromastoid part* is ossified from several eentres whieh appear in the eartilaginous *otic capsule* (p. 178) during the fifth month of intrauterine life. As many as fourteen eentres have been deseribed and their order of appearanee is somewhat variable. Several of these eentres are small and ineonstant and soon fuse with adjaeent eentres. This multiplicity of eentres aeords with numerous otic bones existing in lower forms. The whole otic eapsule is more or less eompletely ossified by the end of the sixth month of intrauterine life. The *tympanic part* is ossified in collagenous fibrous tissue (membrane) from a eentre which appears about the third month of intrauterine life. At birth it is represented by an ineomplete ring, the *tympanic ring*, whieh is defieient above (**3**.97, 98A). Its eoneavity is grooved by the tympanie sulcus for the attaehment of the circumferenee of the tympanie membrane. Running obliquely downwards and forwards across the inner aspeet of the anterior part of the ring is the *malleolar sulcus* (**3**.97), whieh lodges the anterior proeess of the malleus, the ehorda tympani nerve and the anterior tympanic artery. The *styloid process* is developed from the cranial end of the eartilage of the



3.97 The three principal parts of the right temporal bone at birth. From left to right: lateral aspect of petromastoid part; medial aspect of tympanic ring; medial aspect of squama.

seeond viseeral or hyoid areh (p. 151) by two eentres: one for the proximal part of the process, termed the tympanohyal, appears before birth; the other, for the distal part of the proeess, termed the stylohyal, does not appear until after birth. The tympanie ring unites with the squamous part shortly before birth, the petromastoid fuses with the squamous part during the first year, and with the tympanohyal portion of the styloid proeess about the same time. The stylohyal does not unite with the rest of the bone until after puberty, and in some skulls never.

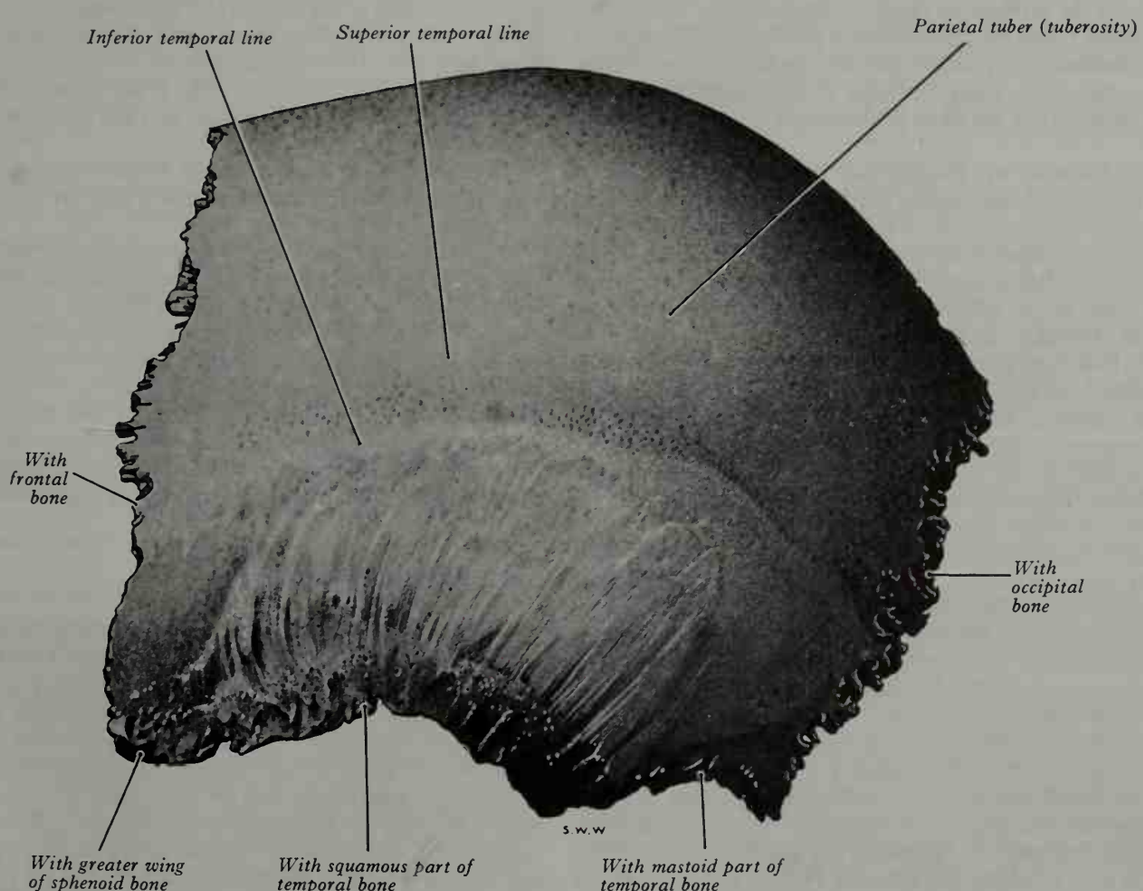
During ossifieation, the tympanic cavity, the mastoid antrum and the posterior end of the auditory tube are all enelosed within the bone. The petrous part forms the roof, floor and medial wall of the cavity, while the squamous and tympanie parts, together with the membrana tympani, form the lateral wall. *At birth*, the tympanie eavity, mastoid antrum and tympanic membrane are all of approximately *adult size*; so also are the auditory ossieles, but the anterior process of the malleus does not join the rest of the

3.98A The right temporal bone at birth. Lateral aspect. *Note.*—The petromastoid part has not been coloured: the tympanic part is coloured *yellow* and the squamous part is coloured *brown*. The whole of the styloid process has been removed.

3.98B The right temporal bone at birth. Medial aspect.

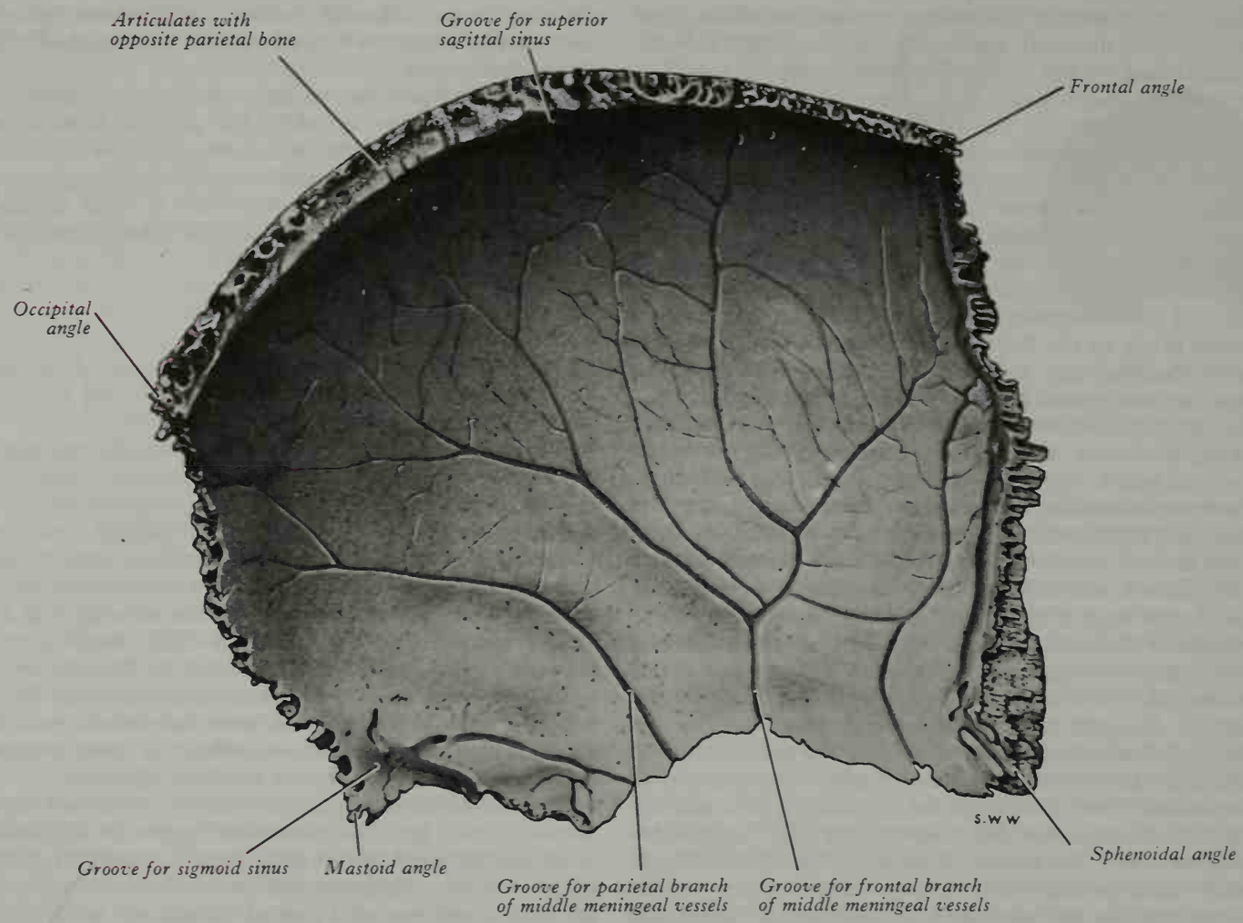
bone until six months later. The internal acoustic meatus is about 6 mm in horizontal diameter, 4 vertically, and 7 in length at birth, adult values being 7·7 and 11 mm (Bergström 1973).

After birth the chief changes in the temporal bone, apart from the increase in size, are: (1) The tympanic ring extends laterally and backwards to form a more cylindrical structure, the tympanic part of the bone. It grows into a fibrocartilaginous plate, sometimes termed the *fibrous tympanic plate*, which forms the adjacent part of the external acoustic meatus at this stage. This growth does not, however, take place at an equal rate all round the ring, but occurs most rapidly on its anterior and posterior portions, and these outgrowths meet and blend, and thus, for a time, there exists in the floor of the meatus an opening (the *foramen of Huschke*); this deficiency is usually closed about the fifth year, but may persist through life. Its persistence has been noted in 5 to 46 per cent of adult crania from several ancient and modern populations (p. 348). In Burmese crania a marked sexual difference was noted: 25 per cent in males, 40 per cent in females. In its backward extension the tympanic element ensheathes the styloid process, and also extends medially over the petrous part as far as the carotid canal. (2) The mandibular fossa is at first extremely shallow and looks more laterally than downwards; it becomes deeper and is ultimately directed downwards. The postero-inferior portion of the squamous part grows downwards behind the tympanic ring and forms the lateral bony wall of the mastoid antrum. (3) The mastoid part is at first flat, and the stylomastoid foramen and rudimentary styloid process lie immediately behind the tympanic ring. With the development of the mastoid air cells the lateral part of the mastoid portion grows downwards and forwards to form the mastoid process, and the styloid process and stylomastoid foramen come to lie on the under surface of the bone. The descent of the stylomastoid foramen is necessarily accompanied by a corresponding increase in the length of the canal for the facial nerve. It is not until the latter part of the second year that the mastoid process forms a definite elevation on the surface of the skull. (4) The subarcuate fossa on the posterior surface of the petrous portion is gradually filled and almost obliterated.



The external acoustic meatus is relatively as long in the child as in the adult, but in the child the canal is fibrocartilaginous, whereas in the adult the inner two-thirds of it are osseous. Surgical access to the tympanic cavity is through the mastoid antrum. In the child only a thin scale of bone requires to be removed from the suprameatal triangle to open into the antrum (p. 1196).

The Parietal Bones



The parietal bones (**3**.99, 100) form the sides and the roof of the cranium. Each is irregularly quadrilateral, and hence has two surfaces, four borders, and four angles.

The *external surface* (**3**.99) is convex, smooth, and marked near the centre by a slight elevation, the *parietal tuber* (*tuberosity*). Two curved lines, the *superior and inferior temporal lines*, cross the middle of the surface, forming an arch which is convex upwards and backwards; to the former is attached the temporal fascia; the latter marks the upper limit of origin of the temporal muscle. The bone above these lines is covered by the *galea aponeurotica* (epicranial aponeurosis); that below the lines forms a part of the temporal fossa. Posteriorly, and close to the upper or sagittal border, the *parietal foramen* transmits a vein from the superior sagittal border, the *parietal foramen* transmits a vein from the superior sagittal sinus and, sometimes, a small branch of the occipital artery; the foramen is not always present.

The *internal surface* (**3**.100) is concave; it presents impressions for the cerebral gyri, and numerous furrows for the ramifications of the middle meningeal vessels; these furrows run upwards and backwards from the *sphenoidal* (*antero-inferior*) *angle*, and from the middle and posterior part of the inferior border. Along the sagittal border there is the shallow *groove for the superior sagittal*

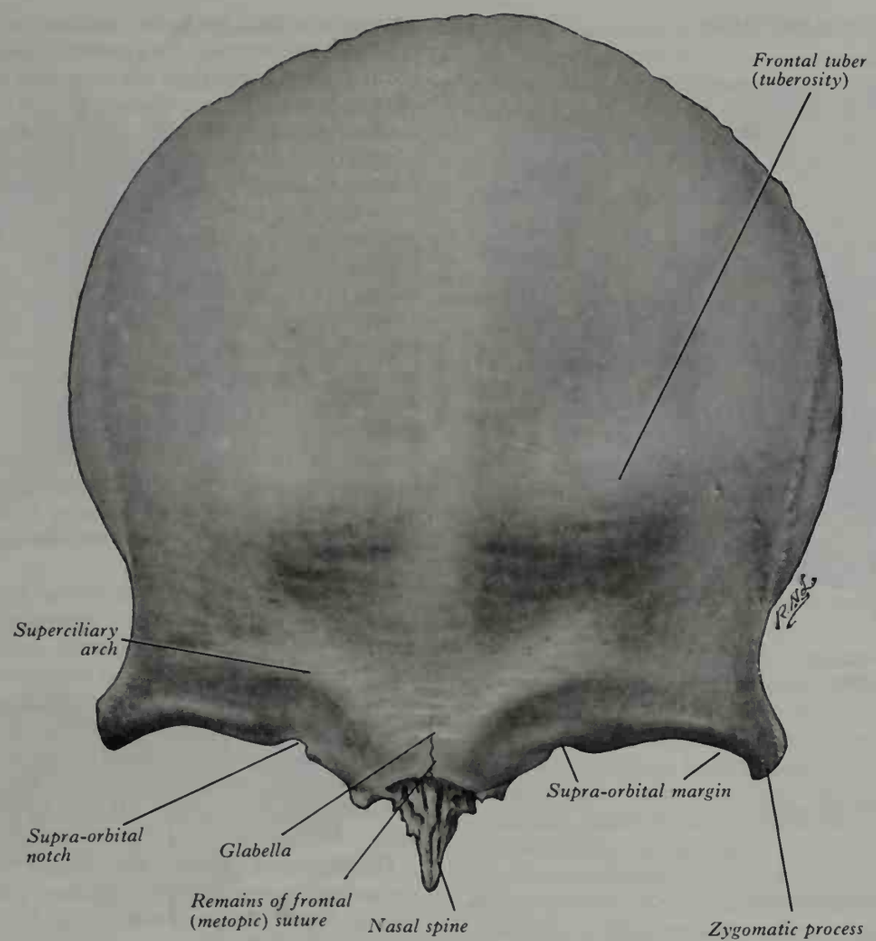
3.99 The left parietal bone. External surface.

3.100 The left parietal bone. Internal aspect.

sinus, which, in the articulated skull, is completed by that on the opposite parietal bone; the falx cerebri is attached to the edges of this groove. A number of *granular foveolae*, small pits which lodge arachnoid granulations, mark the bone in the neighbourhood of the sagittal sulcus; they are most pronounced in the skulls of old persons.

The *sagittal border*, the longest and thickest, is dentated; it articulates with the corresponding border of the opposite parietal bone to form the sagittal suture. The *squamosal (inferior) border* is divided into three parts: of these, the anterior is short, thin and truncated; it is bevelled externally, and is overlapped by the tip of the greater wing of the sphenoid; the middle portion is arched, also bevelled externally, and overlapped by the squamous part of the temporal bone; the posterior part is short, thick and serrated, and articulates with the mastoid portion of the temporal bone. The *frontal border* is deeply serrated, and bevelled externally above and internally below; it articulates with the frontal bone, forming one-half of the coronal suture. The *occipital border*, which is deeply dentated, articulates with the occipital bone, forming one-half of the lambdoid suture.

The *frontal (anterosuperior) angle* is almost a right angle, and corresponds with the *bregma* or point of meeting of the sagittal and coronal sutures. The *sphenoidal (antero-inferior) angle* is received into the interval between the frontal bone and the greater wing of the sphenoid. Its internal surface is marked by a deep groove—sometimes a canal—for the frontal branch of the middle meningeal vessels. In some skulls the frontal bone articulates with the squama of the temporal bone, and the parietal bone then fails to reach the greater wing of the sphenoid. The region where these four bones approach closely to one another is the *pterion* (p. 302). (Fronto temporal articulation demonstrates strong racial variation probably epigenetic in character. Its incidence varied from practically zero in a British seventeenth-century cemetery to 9·8 per cent in a group of Nigerian crania.) The *occipital (postero-superior) angle* is rounded and corresponds with the *lambda* or point of meeting of the sagittal and lambdoid sutures. The *mastoid (postero-inferior) angle* is blunt and articulates with the occipital bone and with the mastoid portion of the temporal. On the internal surface of this angle there is the broad, shallow groove, for the end of the transverse sinus and the commencement of the sigmoid sinus.



At birth there are unossified or membranous intervals in the skull at the angles of the parietal bones; they are named *fontanelles* and are described on p. 345.

Ossification. The parietal bone is ossified from two centres, which appear one above the other at the parietal tuber about the seventh week of intrauterine life in fibrous, condensed mesenchyme. These centres unite early, and ossification gradually extends in a centrifugal manner towards the margins of the bone; the angles are consequently the parts last to be ossified; and it is here that the fontanelles exist. At birth the temporal lines are situated low down; they reach their permanent position only after the eruption of the molar teeth. Occasionally the parietal bone is divided into upper and lower parts by an anteroposterior suture.

The Frontal Bone

The frontal bone is shaped like a shallow, irregular cap and forms the region of the forehead; on each side it has a horizontal *orbital part*, which forms most of the roof of the orbital cavity.

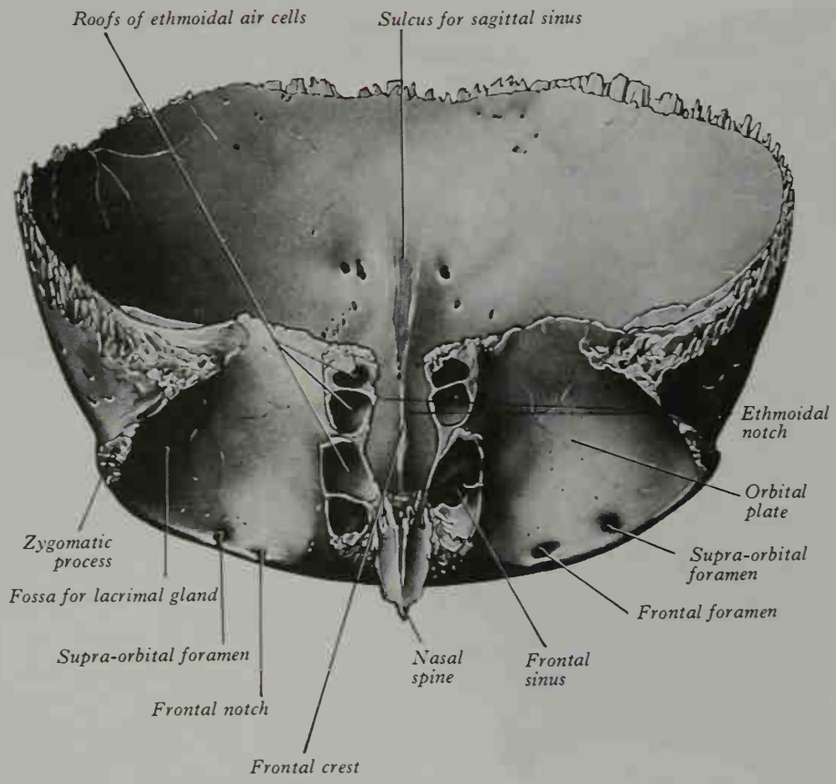
The *external surface* (3.101) presents a rounded elevation, the *frontal tuber (tuberosity)*, on each side of the median plane, about 3 cm above the supra-orbital margin. These eminences vary in size in different individuals and are especially prominent in young skulls, and more so in female than male adults. Below the frontal tuberosities, and separated from them by a shallow groove, there are two curved *superciliary arches*, the medial parts of which are prominent and joined to each other by a smooth elevation named the *glabella*. These arches are more prominent in the male, to a

3.101 The frontal bone. External aspect.

degree dependent to some extent on the size of the frontal sinuses; prominent superciliary arches are, however, occasionally associated with small sinuses. Beneath the superciliary arches the curved *supra-orbital margins* form the upper borders of the orbital openings. The lateral two-thirds of each supra-orbital margin are sharp; the medial one-third is rounded. At the junction of these two parts is the *supra-orbital notch*, which may, on occasion, be a *foramen*, and contains the supra-orbital vessels and nerve. Medial to this notch, the small *frontal notch* or *foramen* is present in about 50 per cent of skulls. Berry (1975) has recorded the incidences of frontal and supra-orbital *foramina* and *notches* (incisures). While usually a notch, the supra-orbital feature is as frequently a foramen in some populations (e.g. 51 per cent of Mexican crania). The frontal foramen also shows great racial variation from 15 to 87 per cent in different ethnic groups. Both features show a sexual dimorphism. For further information on racial variation consult Kimura (1977).

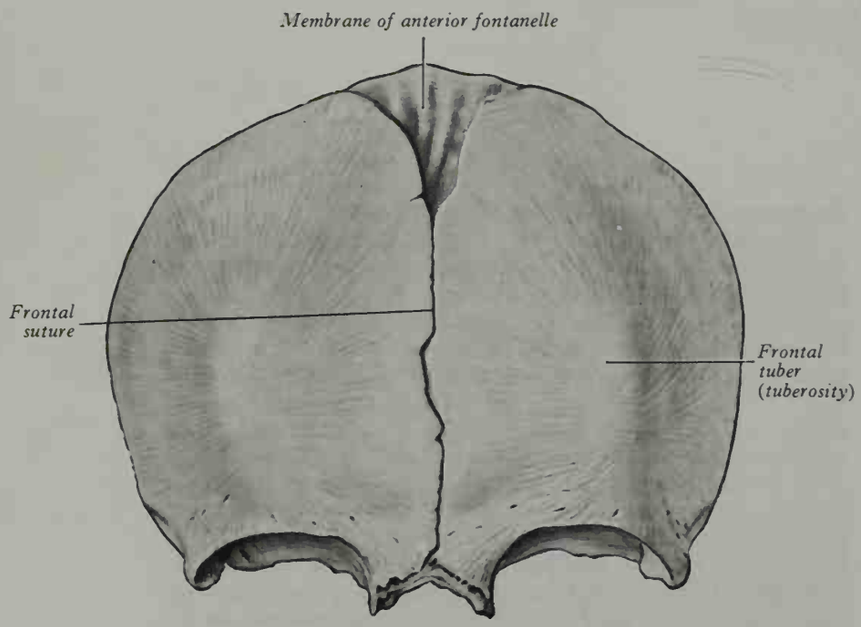
The supra-orbital margin ends laterally in the *zygomatic process*, which is strong and prominent and articulates with the zygomatic bone. From this process a line curves upwards and backwards and soon divides into the *superior* and *inferior temporal lines*.

The portion of the bone which projects downwards between the supra-orbital margins is named the *nasal part*. It presents a rough, serrated area, sometimes termed the *nasal notch*, which articulates on each side of the median plane with the nasal bone, and lateral to this with the frontal process of the maxilla and with the lacrimal bone. From the centre of the notch posteriorly, the nasal part projects downwards and forwards behind the nasal bones (**3**.77) and frontal processes of the maxillae, and supports the bridge of the nose. The nasal part ends below in a sharp *nasal spine*, and on each side of this there is a small grooved surface which forms a part of the roof of the corresponding nasal cavity. The nasal spine forms a very small part of the septum of the nose; in front it articulates with the crest of the nasal bones, behind with the perpendicular plate of the ethmoid bone (**3**.77).



The *temporal surface*, below and behind the temporal lines, forms the anterior part of the temporal fossa and gives origin to a part of the temporal muscle (**3**.61).

The *internal surface* (**3**.102) of the frontal bone is concave. In the upper part of the median plane it is marked by a vertical groove, the sulcus for the sagittal sinus, the edges of which unite below to form the *frontal crest*; the sulcus lodges the anterior part of the superior sagittal sinus, while to its margins and to the frontal crest the anterior part of the falx cerebri is attached. The crest ends below in a small notch, which is converted into the *foramen caecum* (p. 309) by articulation with the ethmoid bone. On each side of the median plane the surface is marked by impressions for the cerebral gyri, and minute furrows for meningeal vessels. Several small, irregular pits, *granular foveolae*, may be seen on each side of the sulcus for the sagittal sinus, for the reception of arachnoid granulations.



The *parietal (posterior) margin* is thick, strongly serrated and bevelled at the expense of the internal surface above and the temporal surface on each side; it is continued below into a triangular, rough surface, for articulation with the greater wing of the sphenoid bone.

The orbital parts of the frontal bone consist of two thin triangular laminae, which form the major part of the roofs of the orbits, and are separated from each other by a wide gap named the *ethmoidal notch*.

The *orbital surface* (**3**.102) of each orbital plate is smooth and concave, and presents, in its anterolateral part, a shallow depression, the *fossa for the lacrimal gland*. Below and behind the medial end of the supra-orbital margin, about midway between the supra-orbital notch and the frontolacrimal suture, there is a small depression, sometimes a tiny spine, the *trochlear fovea* or *spine*, for the attachment of the fibrocartilaginous trochlea of the superior oblique muscle. The *internal surface* is convex, and marked by impressions for the gyri on the inferior surface of the

3.102 The frontal bone. Inferior aspect.

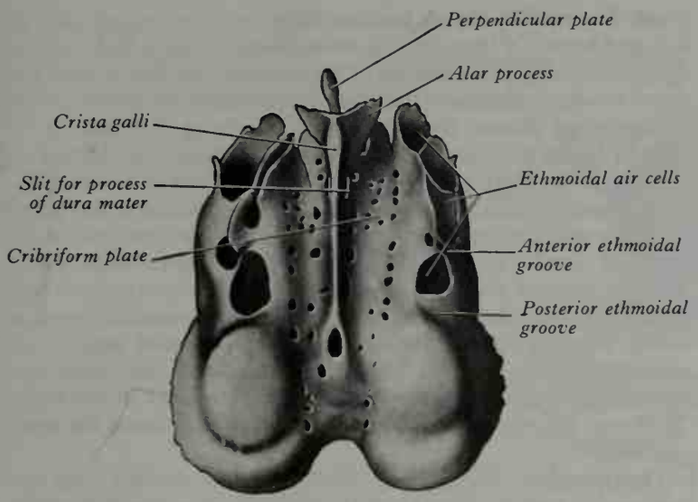
3.103 The frontal bone at birth. Anterior aspect. Note that at this stage the bone consists of right and left halves connected by the frontal suture.

frontal lobe of the brain, and by faint grooves for the meningeal branches of the ethmoidal vessels.

The *ethmoidal notch* (3.102) is quadrilateral and is occupied, in the articulated skull, by the cribriform plate of the ethmoid bone. On the under surfaces of the lateral margins of the notch parts of several air cells are present: they complete the ethmoidal air cells when the ethmoid bone is in position. Two transverse grooves cross each margin of the notch; they are converted into the *anterior* and *posterior ethmoidal canals* by the ethmoid bone, and open on the medial wall of the orbit; they transmit the anterior and posterior ethmoidal nerves and vessels.

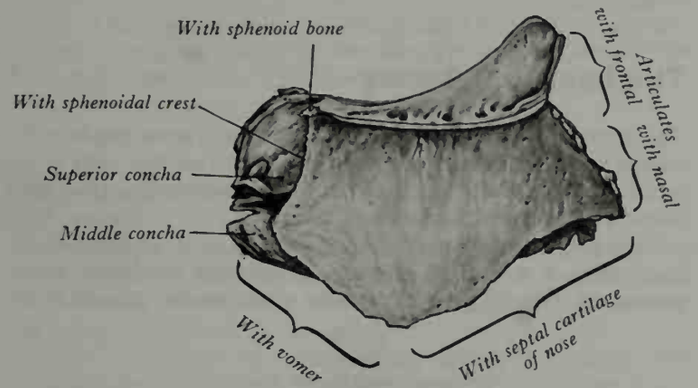
The openings of the *frontal sinuses* (3.102) are situated in front of the ethmoidal notch, and lateral to the nasal spine. These sinuses are two irregular cavities, which extend backwards, upwards, and laterally for a variable distance between the laminae of the frontal bone; they are separated from each other by a thin bony septum, which is often deflected to one or other side of the median plane, with the result that the sinuses are seldom symmetrical. Rudimentary at birth, the frontal sinuses are usually fairly well developed by the seventh and eighth years, but reach their full size only after puberty. They vary in size in different persons and are larger in males. Each communicates with the middle meatus of the corresponding half of the nasal cavity by means of a passage called the *frontonasal canal*. The development of the frontal sinuses is associated with the appearance of the superciliary arches, and the latter owe their origin to the mechanical stresses to which the frontal bone is subjected by the masticatory apparatus (Weinmann and Sicher 1955). The sinuses undergo a primary expansion with the eruption of the first deciduous molars, and a secondary expansion when the permanent molars begin to appear at the sixth year. With advancing age absorption of bone from the inner walls of the sinuses may occur as an atrophic change leading to further enlargement.

The *posterior borders of the orbital plates* are thin and serrated, and articulate with the lesser wings of the sphenoid; the lateral part of each usually appears in the middle cranial fossa between the greater and lesser wings of the sphenoid bone.



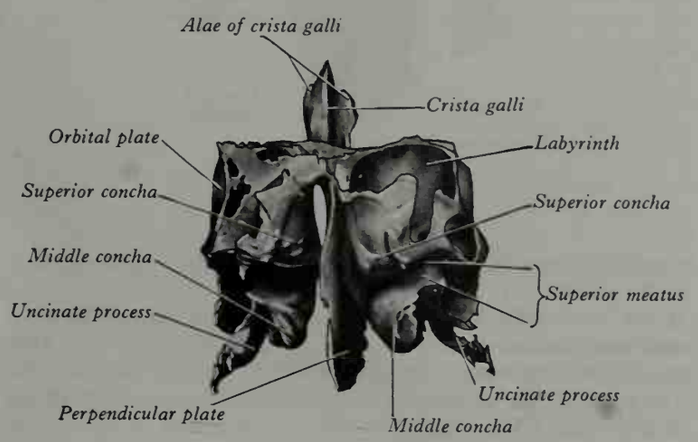
Structure. The frontal bone is thick and consists of cancellous tissue contained between two compact laminae; the former is absent in the regions occupied by the frontal sinuses. The orbital part, composed entirely of compact bone, is thin and translucent in its posterior two-thirds. It may be absorbed in patches in old age.

Ossification (3.103). The frontal bone is ossified in fibrous tissue (membrane) from two primary centres which appear in the eighth week of intrauterine life, one in the region of each frontal tuber. From each of these centres ossification extends upwards to form the corresponding half of the bone, backwards to form the orbital part and downwards to form the nasal part of the bone. No secondary centres of ossification occur in connexion with any part of the bone, with the possible exception of the nasal spine, for which two secondary centres have been described as appearing about the tenth year (Inman and Saunders 1937). At birth the bone consists of two halves separated by the *frontal* or *metopic suture*, but union begins in the second year, and the suture is usually obliterated by the eighth year. In a percentage of persons this shows some racial variation: the two halves of the frontal bone remain separate, and the metopic suture persists (Ashley Montagu 1951; Tongerson 1951; Linc and Fleischmann 1968). Recently, metopism has been assessed at 0–7·4 per cent of individuals in various ethnic groups (Berry 1975).



The Ethmoid Bone

The ethmoid bone is cuboidal, and exceedingly light in build; it is situated at the anterior part of the base of the cranium, and assists in forming the medial walls of the orbits, the septum of the nose, and the roof and lateral walls of the nasal cavity. It consists of four parts: a horizontal, perforated lamina named the cribriform plate, a perpendicular plate and two lateral masses, named labyrinths.



The cribriform plate (3.104) occupies the ethmoidal notch of the frontal bone, and forms a part of the roof of the nasal cavity. A thick, smooth, triangular process, called the *crista galli* from its resemblance to a cock's comb, projects upwards from this lamina in the median plane. Its posterior border, long, thin and curved, gives attachment to the falx cerebri. Its anterior border, short and thick, articulates with the frontal bone by two small projecting *alae* which complete the foramen caecum (p. 309). Its sides are smooth but sometimes bulge owing to the presence of a small air sinus in the interior. On each side of the crista galli the cribriform plate is narrow and depressed; the gyrus rectus and the olfactory bulb are immediately above it, and it presents numerous foramina for the passage of the olfactory nerves. In the front part of the cribriform plate, on each side of the crista galli, there is a small slit-like fissure, which is occupied by a process of dura mater. The

3.107 The ethmoid bone. Right lateral aspect.

foramen which transmits the anterior ethmoidal nerve to the nasal cavity is placed lateral to the anterior end of the fissure, and to it a groove runs forwards from the orifice of the anterior ethmoidal canal.

The perpendicular plate (**3**.105, 106), is thin, flat and quadrilateral. It descends from the cribriform plate and forms the upper part of the nasal septum; it is generally deflected a little to one or other side. Its *anterior border* articulates with the nasal spine of the frontal bone and the crest of the nasal bones. The *posterior border* articulates with the sphenoidal crest above and with the vomer below. The *superior border* is attached to the cribriform plate. The *inferior border* is thick, and serves for the attachment of the septal cartilage of the nose. The surfaces of the lamina are smooth, except above, where numerous grooves and canals are seen; these lead to the medial foramina in the cribriform plate and contain filaments of the olfactory nerves.

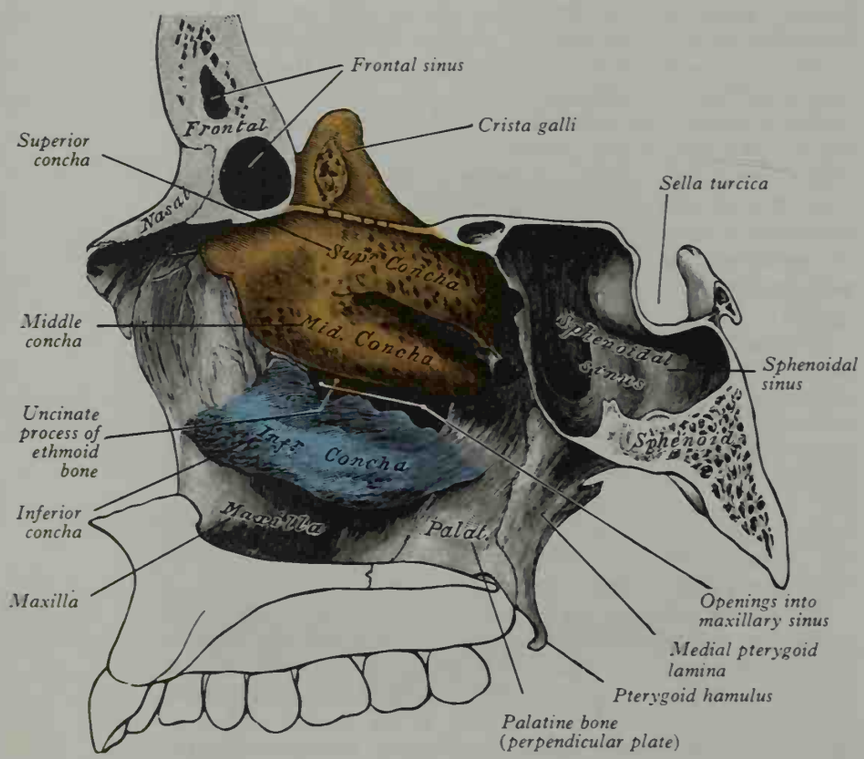
The ethmoidal labyrinths consist of a number of thin-walled *ethmoidal air cells*, arranged in three groups—*anterior*, *middle* and *posterior*—and interposed between two vertical plates of bone (p. 1149); the lateral or *orbital plate* forms part of the medial wall of the orbit, the medial plate, part of the lateral wall of the nasal cavity. In the disarticulated bone many of these ethmoidal air cells are opened, but in the articulated skull they are everywhere closed, except at their apertures of communication with the nasal cavity. The *upper surface* of the labyrinth (**3**.104) presents a number of open air cells, the walls of which are completed, in the articulated skull, by the edges of the ethmoidal notch of the frontal bone (**3**.102). This surface is crossed by two grooves which are converted into the *anterior* and *posterior ethmoidal canals* by articulation with the frontal bone. On the *posterior surface* of each labyrinth (**3**.106) large air cells are visible, and their walls are completed by the sphenoidal concha and the orbital process of the palatine bone. The *lateral surface* (**3**.107) consists of a thin, smooth, oblong plate, named the *orbital plate*, which covers the middle and posterior ethmoidal sinuses and forms a large part of the medial wall of the orbit; it articulates superiorly with the orbital part of the frontal bone, inferiorly with the maxilla and the orbital process of the palatine bone, anteriorly with the lacrimal bone, and posteriorly with the sphenoid bone (**3**.67).

A few air cells lie in front of the orbital plate and their walls are completed by the lacrimal bone and the frontal process of the maxilla. A thin, curved bar of bone, termed the *uncinate process*, subject to considerable variation in size, projects downwards and backwards from this part of the labyrinth; it can be seen in the medial wall of the maxillary sinus (**3**.67) as it crosses the anterior part of the hiatus maxillaris to reach the ethmoidal process of the inferior nasal concha, with which it articulates. The upper edge of this process is free and forms the medial boundary of the hiatus semilunaris in the middle meatus of the nose.

The *medial surface* of the labyrinth (**3**.108) forms a part of the lateral wall of the corresponding half of the nasal cavity; it consists of a thin lamella, which descends from the inferior surface of the cribriform plate and ends in a free, convoluted portion, named the *middle nasal concha*. The upper part of the medial surface is marked by numerous grooves, directed nearly vertically downwards; they lodge branches of the olfactory nerves. The posterior part of the medial surface is subdivided by a narrow, oblique fissure, termed the *superior meatus* of the nose, which is bounded above by a thin, curved plate, named the *superior nasal concha*; the posterior ethmoidal air cells open into this meatus. Below and in front of the superior meatus the convex surface of the middle nasal concha extends along the whole length of the medial surface of the labyrinth. Its lower margin is free and thick, while its lateral surface is concave and assists in forming the *middle meatus* of the nose. The middle ethmoidal air cells produce a rounded swelling, named the *bulla ethmoidalis*, on the lateral wall of the middle meatus (**3**.79); on the bulla, or immediately above it, these cells open into the meatus. A curved passage, named the *infundibulum*, extends upwards and forwards from the middle meatus; it communicates with the anterior ethmoidal sinuses, and in rather more than 50 per cent of crania is continued superiorly as the frontonasal duct into the frontal sinus.

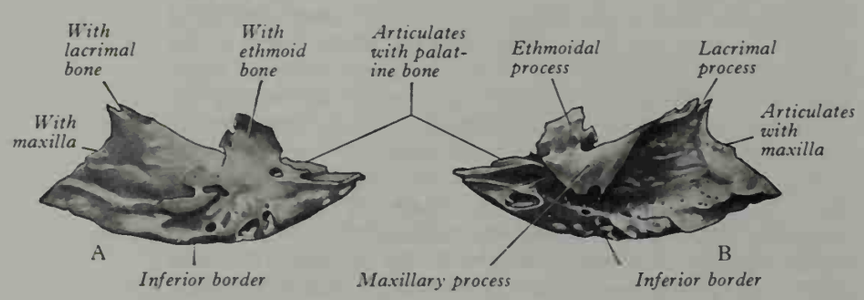
Ossification. The ethmoid bone is ossified in the cartilaginous

nasal capsule from three centres: one for the perpendicular plate, and one for each labyrinth.



The centre for each labyrinth appears in the region of the orbital plate between the fourth and fifth months of intrauterine life, and extends into the conchae. At birth, the two labyrinths, which are small and ill developed, are partially ossified, but the rest of the bone is cartilaginous. During the first year after birth, the perpendicular plate and crista galli begin to ossify from a single centre, and they fuse with the labyrinths about the beginning of the second year. The cribriform plate is ossified partly from the perpendicular plate and partly from the labyrinth. The ethmoidal air cells begin to develop during intrauterine life, and in the newborn infant have the form of narrow pouches.

The Inferior Nasal Conchae



The inferior nasal conchae are curved laminae which lie horizontally in the lateral walls of the nasal cavity (**3**.108). Each bone has two surfaces, two borders, and two ends.

The *medial surface* (**3**.109A) is convex, perforated by numerous apertures, and traversed by longitudinal grooves for the lodgement of vessels. The *lateral surface* is concave (**3**.109B), and forms part of the inferior meatus of the nasal cavity. The *superior border* is thin and irregular, and may be divided into three parts, of which the anterior articulates with the conchal crest of the maxilla, and the posterior with the conchal crest of the palatine bone. The middle region presents *three processes*, which vary in size and form. Of these, the *lacrimal process* is small and pointed and is situated at the junction of the anterior one-fourth with the posterior three-fourths of the bone. It articulates, by its apex, with a descending process from the lacrimal bone (**3**.110) and, by its margins, with the edges of the nasolacrimal groove on the medial surface of the body of the maxilla; it thus assists in forming the canal for the nasolacrimal duct. Behind this process a thin plate, the *ethmoidal process*, ascends to join the uncinate process of the ethmoid (**3**.79). From the middle part of the superior border a thin lamella, termed the *maxillary process*, curves downwards and laterally; it articulates with the maxilla and the maxillary process of the palatine bone, forming a part of the medial wall of the maxillary sinus (p. 340). The *inferior border* is free, thick and spongy in structure, more especially in the middle of the bone. Both *ends* are more or less pointed, the posterior being the more tapered.

Ossification. The inferior nasal concha is ossified from one centre; this appears about the fifth month of intrauterine life in the incurved lower border of the lateral wall of the cartilaginous nasal capsule. It loses continuity with the nasal capsule during ossification.

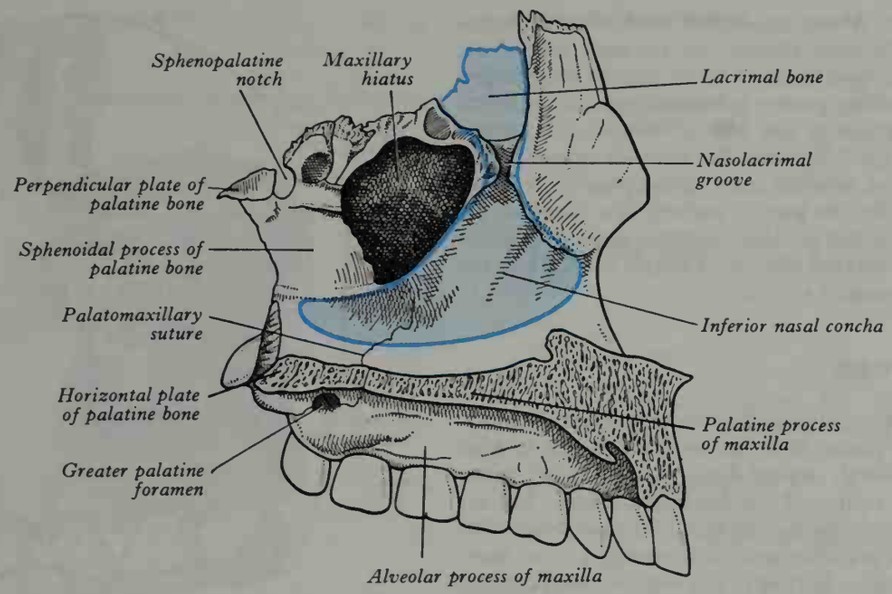
3.109A and B The right inferior nasal concha. (A) Medial aspect. (B) Lateral aspect.



The Lacrimal Bones

The lacrimal bones, which are the smallest and most fragile of the cranial bones, are situated at the front of the medial walls of the orbits (**3**.67A). Each lacrimal bone has two surfaces and four borders. The *lateral* or *orbital surface* (**3**.110) is divided by a vertical ridge, termed the *posterior lacrimal crest*. In front of this crest there is a vertical groove, the anterior border of which articulates with the posterior border of the frontal process of the maxilla to complete the *fossa for the lacrimal sac*. The medial wall of the groove is prolonged downwards as a descending process (**3**.111) to assist in forming the bony canal for the nasolacrimal duct by articulating with the lips of the nasolacrimal groove of the maxilla, and with the lacrimal process of the inferior nasal concha. The portion behind the crest is smooth and forms a part of the medial wall of the orbit. The crest, with a part of the orbital surface immediately posterior to it, gives origin to the lacrimal part of the orbicularis oculi. The crest ends below in a small hook, termed the *lacrimal hamulus*, which articulates with the maxilla and completes the upper orifice of the bony canal for the nasolacrimal duct (**3**.66); the lacrimal hamulus sometimes exists as a separate piece, and is then called the *lesser lacrimal bone*. The lower and anterior part of the *medial* or *nasal surface* forms part of the middle meatus of the nose; its upper and posterior part articulates with the ethmoid bone and completes some of the anterior ethmoidal air cells. The *anterior border* of the lacrimal bone articulates with the frontal process of the maxilla, the *posterior border* with the orbital plate of the ethmoid, the *superior border* with the frontal bone. The *inferior border* articulates with the orbital surface of the maxilla (**3**.66).

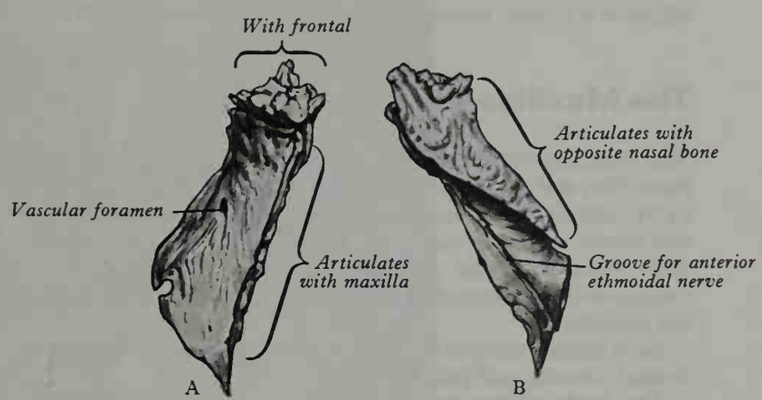
3.110 The right lacrimal bone. Lateral aspect.

Ossification. The lacrimal bone is ossified from one centre, which appears about the twelfth week of intrauterine life in the mesenchyme around the cartilaginous nasal capsule. In later life the lacrimal bone is subject to patchy erosion.

3.111 A drawing to show how the medial wall of the nasolacrimal canal is formed by the articulation of the descending process of the lacrimal bone with the lacrimal process of the inferior nasal concha.

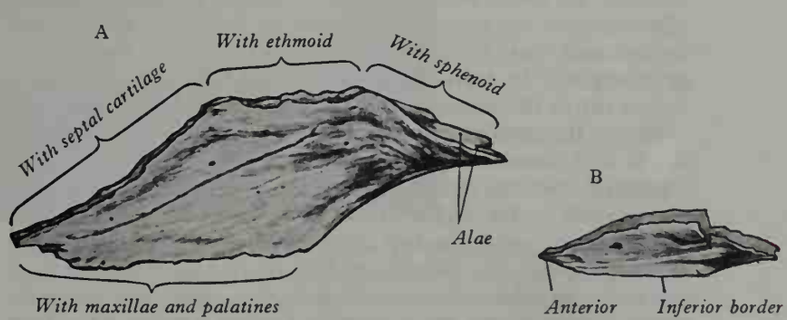
The Nasal Bones

The nasal bones are two small oblong bones, varying in size and form in different individuals; they are placed side by side between the frontal processes of the maxillae, and form, by their junction, the bridge of the nose (**3**.63A and B, 79).



Each nasal bone has two surfaces and four borders. The *external surface* (**3**.112A), is concavoconvex from above downwards, and convex from side to side; it is covered by the procerus and nasalis muscles, and is perforated near its centre by a foramen for the transmission of a small vein. The *internal surface* (**3**.112B) is concave from side to side, and is traversed from above downwards by a groove for the anterior ethmoidal nerve. The *superior border*, thick and serrated, articulates with the nasal part of the frontal bone. The *inferior border*, thin and notched, is continuous with the lateral cartilage of the nose. The *lateral border* articulates with the frontal process of the maxilla. The *medial border*, thicker above than below, articulates with the opposite nasal bone and is prolonged behind into a vertical crest, which forms a small part of the septum of the nose, and articulates from above downwards with the nasal spine of the frontal, the perpendicular plate of the ethmoid, and the cartilage of the nasal septum.

Ossification. The nasal bone is ossified from one centre, which appears at the beginning of the third month of intrauterine life in the membrane overlying the anterior part of the cartilaginous nasal capsule.

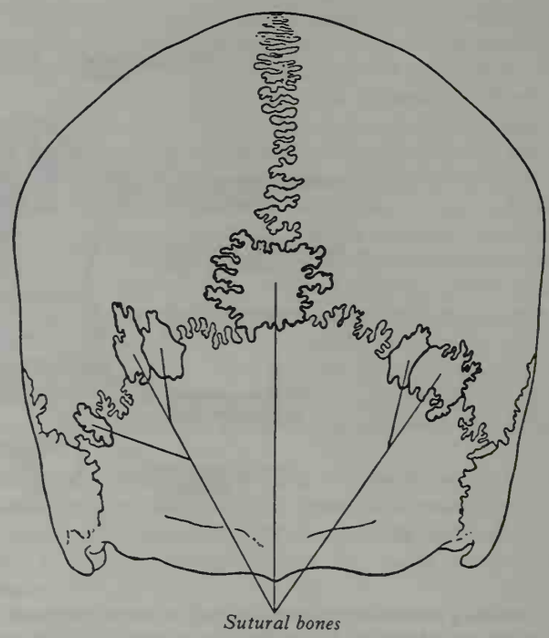


The Vomer

The vomer is a thin, flat bone, almost trapezoid in shape; it forms the postero-inferior part of the septum of the nose (**3**.77) and has two surfaces and four borders. Each *surface* (**3**.113A) is marked by small furrows for blood vessels, and is traversed by a groove which runs obliquely downwards and forwards, and lodges the nasopalatine nerve and vessels. The *superior border* is the thickest, and presents a deep furrow, bounded on each side by a projecting *ala*: the furrow fits over the rostrum of the sphenoid; the alae articulate with the sphenoidal conchae, the sphenoidal processes of the palatine bones and the vaginal process of the medial pterygoid plates. When the edge of the ala occupies the interval between the body of the sphenoid and the vaginal process, its lower surface takes part in the formation of the vomerovaginal canal (p. 306). The *inferior border* articulates with the nasal crest formed by the maxillae and palatine bones. The *anterior border* is the longest; its upper half articulates with the perpendicular plate of the ethmoid, its lower is cleft for the reception of the inferior margin of the cartilage of the septum of the nose. The *posterior border* is free, concave, and separates the posterior nasal apertures; it is thick and bifid above, thin below. The anterior end of the vomer articulates with the posterior margin of the incisor crest of the maxillae and projects downwards between the incisive canals.

Ossification. At an early period the septum of the nose consists of a plate of cartilage. The superior part of this cartilage is ossified to form the perpendicular plate of the ethmoid; its antero-inferior portion persists as the septal cartilage, whilst the vomer is ossified in the strata of connective tissue covering each aspect of

3.112A and B The left nasal bone. (A) External aspect. (B) Internal aspect.



3.113A and B The vomer. (A) Left lateral aspect. (B) The vomer at birth.

its postero-inferior part. About the eighth week of intrauterine life two centres of ossification appear, one on each side of the median plane. About the twelfth week these centres unite below the cartilage, and thus a deep groove is formed (**3**.113B) in which the cartilage of the septum of the nose is lodged. As growth proceeds the union of the bony lamellae extends upwards and forwards, and at the same time the intervening plate of cartilage undergoes absorption. By the age of puberty the lamellae are almost completely united, but evidence of the bilaminar origin of the bone is seen in the everted alae of its upper border and the groove on its anterior margin (**3**.113A).

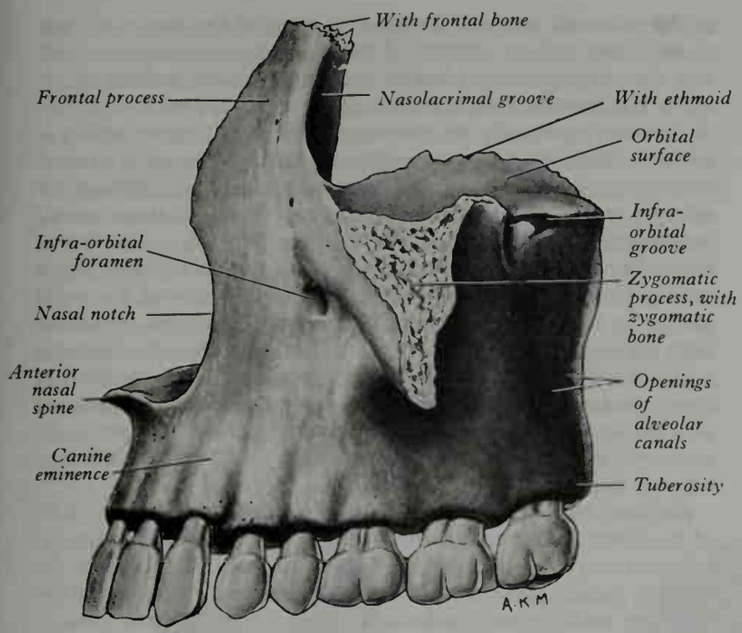
The Sutural Bones

In addition to the usual centres of ossification of the cranial bones, others may occur in the course of the sutures, giving rise to what are often irregular, isolated, *sutural bones* (**3**.114). They occur most frequently in the course of the lambdoid suture, but are occasionally seen at the fontanelles, especially the posterior. The latter may represent a *pre-interparietal* element, a true *interparietal* element or some partially or wholly compounded variation of the two. An isolated bone at the lambda is sometimes termed the *Inca bone* or *Goethe's ossicle* (p. 322). One or more *pterion ossicles* or *epipteric bones*, sometimes exist between the sphenoidal angle of the parietal bone and the greater wing of the sphenoid bone. These bones vary much in size, but have a tendency to be more or less symmetrical on the two sides of the skull. Often, a sutural bone or bones appear to have little morphological significance, but there are notable exceptions (*vide infra* and p. 322). Their number is generally limited to two or three; but they may be present in great numbers in the skulls of hydrocephalic subjects. Sutural bones have therefore been associated with rapid cranial expansion but no causal relationships have been established For a detailed analysis of these, and many other *epigenetic variations* in the human cranium, derived from a study of 585 adult crania, consult Berry and Berry (1967). These authors discuss the anthropological and anatomical implications of being able to characterize populations genetically by such criteria; subsequently many quantitative data have been provided (Berry 1975). A recent report of the occurrence of sutural bones in a small series of fetal skulls (El-Najjar and Davson 1977) also supports a genetic rather than an overt pathological causation.

3.114 Sutural bones in the lambdoid and sagittal sutures.

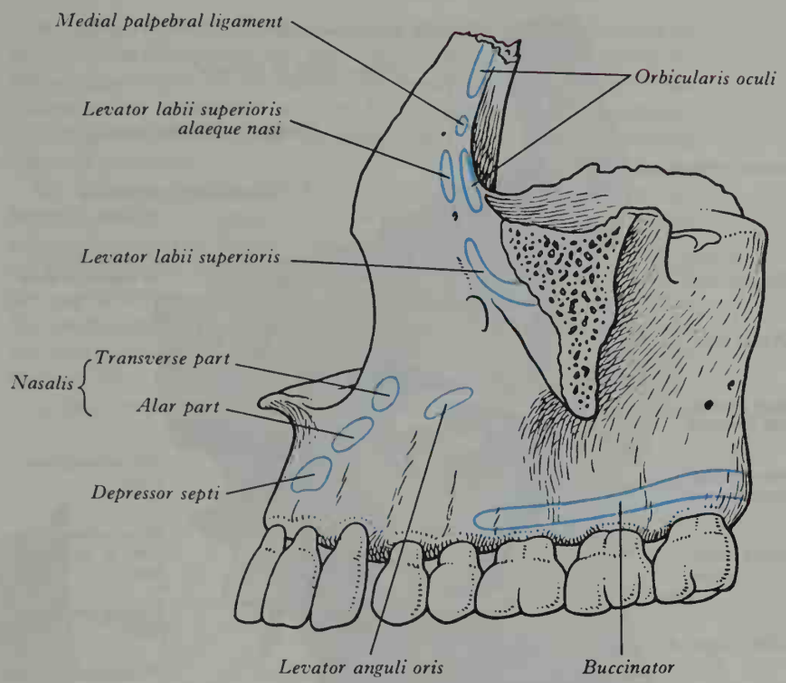
The Maxillae

The maxillae are the largest bones in the face, excepting the mandible, and by their union form the whole of the upper jaw (**3**.63A and B). They form most of the roof of the mouth, the floor and lateral wall of the nasal cavity, and the floor of the orbit; they also enter into the formation of the infratemporal and pterygopalatine fossae, and the inferior orbital and pterygomaxillary fissures.



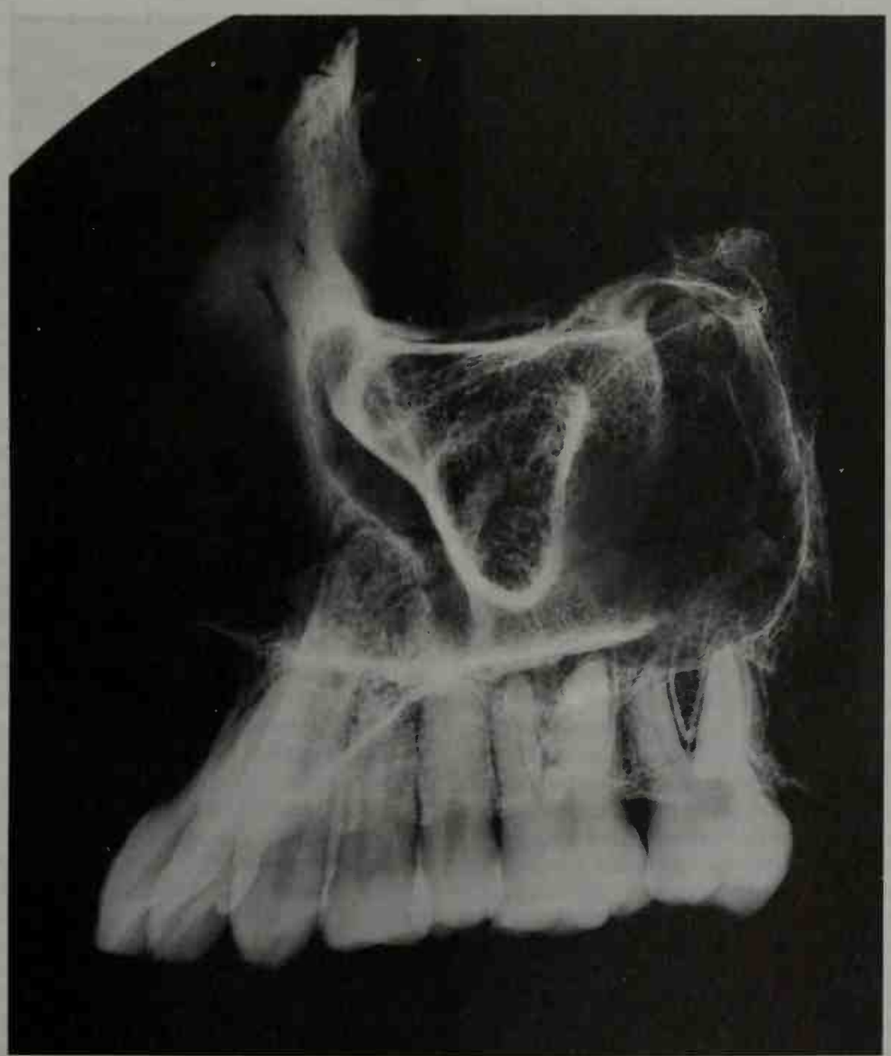
Each maxilla consists of a body and four processes—zygomatic, frontal, alveolar and palatine (**3**.115, 116, 117).

The body of the maxilla is roughly pyramidal. It has four surfaces—anterior, infratemporal (or posterior), orbital and nasal—which enclose a large cavity, the maxillary sinus.

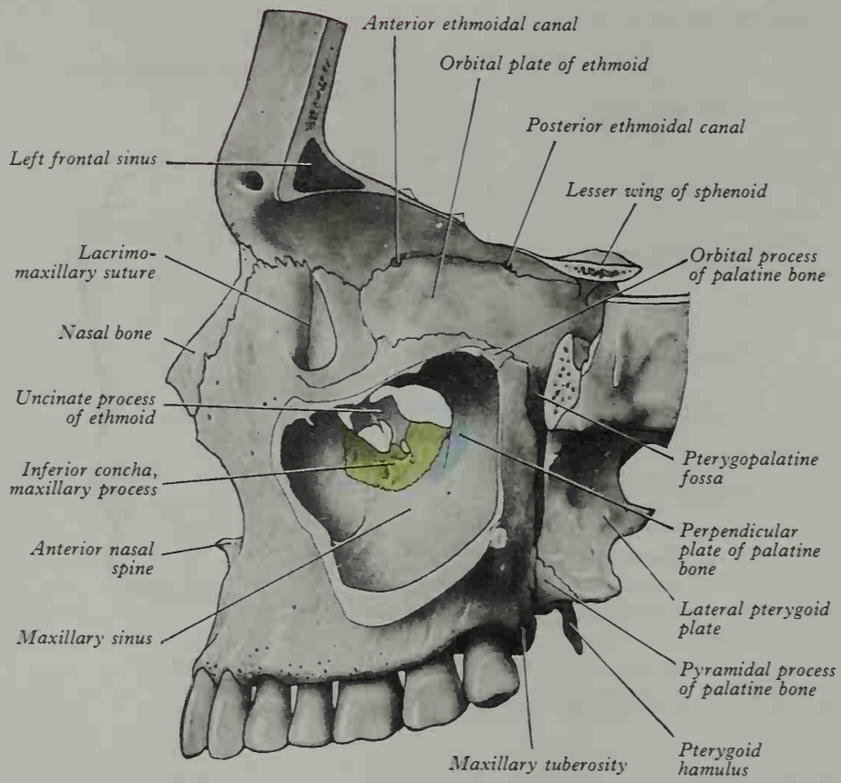


The *anterior surface* (**3**.115A and B) is directed forwards and laterally. Its lower part displays a number of slight elevations, which overlie the roots of the upper teeth. Above those of the incisor teeth there is a slight depression, the *incisive fossa*, which gives origin to the depressor septi; to the alveolar border below the fossa a slip of the orbicularis oris is attached; above and lateral to the fossa, the nasalis arises. Lateral to the incisive fossa there is a larger and deeper depression, named the *canine fossa*; it is separated from the incisive fossa by the *canine eminence*, which corresponds to the socket of the canine tooth; in the fossa the levator anguli oris is attached. Above the canine fossa is the *infra-orbital foramen*, the anterior end of the infra-orbital canal; it transmits the infra-orbital vessels and nerve. Above the foramen a sharp border marks the junction of the anterior and orbital surfaces. This border forms a small part of the circumference of the orbital opening, and attached to it is the levator labii superioris. Medially the anterior surface terminates at a deeply concave border, the *nasal notch*, ending below in a pointed process which, with the corresponding process of the opposite maxilla, forms the *anterior nasal spine*. The anterior surface bordering the notch gives origin to the nasalis and depressor septi.

The *infratemporal surface* (**3**.115A) is convex, directed backwards and laterally, and is the anterior wall of the infratemporal fossa. It is separated from the anterior surface by the zygomatic process and by a ridge which runs upwards to that process from the socket of the first molar tooth. It presents near its centre the apertures of two or three *alveolar canals*, which contain the posterior superior alveolar vessels and nerves. At the lower and posterior part of this surface there is a round eminence, the *maxillary tuberosity*, which is roughened on the upper part of its medial aspect where it articulates with the pyramidal process of the palatine bone (**3**.115, 117); it gives origin to a few fibres of the medial pterygoid muscle and, in some cases, articulates with the lateral pterygoid plate of the sphenoid bone. Above this a smooth surface forms the anterior boundary of the pterygopalatine fossa and is grooved by the maxillary nerve; the groove for this nerve is directed laterally and slightly upwards and is continuous with the infra-orbital groove on the orbital surface.



The *orbital surface* (**3**.115A) is smooth and triangular, and forms the greater part of the floor of the orbit. Its *medial border* presents a depression anteriorly, the *lacrimal notch*, behind which it articulates from before backwards with the lacrimal bone, the orbital plate of the ethmoid, and the orbital process of the palatine bone (**3**.117). Its *posterior border* is smooth and rounded; it forms most of the anterior margin of the inferior orbital fissure, and its middle part is notched by the commencement of the infra-orbital groove. The *anterior border* forms a small part of the circumference of the orbital opening and is continuous medially with the lacrimal crest on the frontal process (p. 340). The *infra-orbital groove*, for the passage of the infra-orbital vessels and nerve, begins at the middle of the posterior border, where it is continuous with the groove near the upper edge of the posterior surface; it passes forwards and ends in the *infra-orbital canal*, which opens on the anterior surface of the bone just below the infra-orbital margin. Near its midpoint the canal gives off a small branch from its lateral side for the passage of the anterior superior alveolar nerve and vessels. This small canal, sometimes called the *canalis sinuosus* (Wood Jones 1939), passes forwards and downwards in the floor of the orbit lateral to the infra-orbital canal and then curves medially in the anterior wall of the maxillary sinus, passing below the infra-orbital foramen.



3.115A The left maxilla. Lateral aspect.

3.115B Outline of left maxilla, showing muscular attachments.

3.116 High resolution projection microradiograph of a maxilla (mediolateral view). Note particularly the distribution of compact and trabecular bone, the extent of the profile of the maxillary sinus and its relation to the dental alveoli, the compact bone of the *laminae durae* of the latter, the hard tissues, pulp cavities, root canals and foramina of the teeth. Contrast the dense shells of compact bone in the frontal, zygomatic and palatine processes, with the fine filigree of trabecular bone in much of the alveolar process, interior of the zygomatic process, and the posterior wall of the sinus. (Kindly contributed by Dr. C. Buckland-Wright, Department of Anatomy, Guy's Hospital Medical School, London.)

3.117 An oblique sagittal section through the anterior part of the skull, showing the medial wall of the left orbit and the medial wall of the left maxillary sinus. The inferior concha is shown in *yellow* and the perpendicular plate of the palatine bone in *blue*.

Reaching the margin of the anterior nasal aperture just in front of the anterior end of the inferior concha, it then follows the lower margin of the aperture and opens at the side of the nasal septum in front of the incisive canal. At the medial and front part of the orbital surface, and lateral to the lacrimal groove, the origin of the inferior oblique muscle of the eyeball may be marked by a small depression.

The *nasal surface* (**3**.116) displays posterosuperiorly a large, irregular opening, the *maxillary hiatus*, which leads into the maxillary sinus. At the upper border of this aperture there are parts of air sinuses, which are completed by the ethmoid and lacrimal bones. Below the maxillary hiatus a smooth concave surface forms part of the inferior nasal meatus, and behind it there is a rough surface for articulation with the perpendicular plate of the palatine bone; this surface is traversed by a groove, which begins near the middle of the posterior border, runs obliquely downwards and forwards, and is converted into the *greater palatine canal* by the perpendicular plate of the palatine bone. In front of the maxillary hiatus a deep groove, continuous above with the groove on the lacrimal bone (p. 338), constitutes about two-thirds of the circumference of the nasolacrimal canal, the remaining one-third being formed by the descending part of the lacrimal bone and the lacrimal process of the inferior nasal concha (**3**.111); this canal opens into the inferior meatus (**3**.79) and contains the nasolacrimal duct. More anteriorly the bone has an oblique ridge, the *conchal crest*, for articulation with the inferior nasal concha. The shallow concavity below this ridge forms part of the inferior meatus, and the surface above the ridge, part of the atrium of the middle meatus.

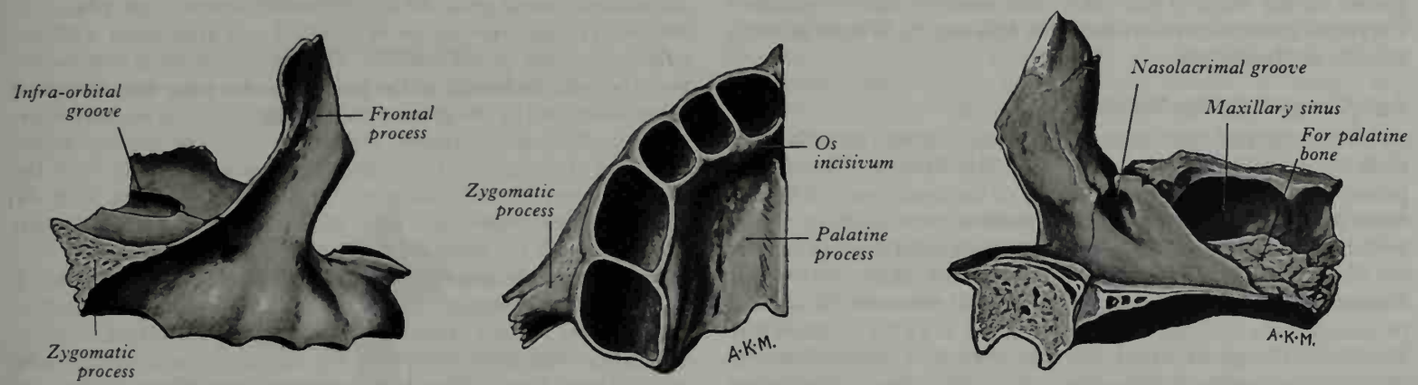
The maxillary sinus (**3**.116, 117) is a large pyramidal cavity in the body of the maxilla. Its walls are thin and correspond to the orbital, alveolar, anterior and infratemporal aspects of the body of the bone. Its *apex*, directed laterally, extends into the zygomatic process and may reach the zygomatic bone itself; its *base*, which faces medially, is the lateral wall of the nasal cavity and presents the maxillary hiatus in the disarticulated bone. In the articulated skull this aperture is much reduced in size by the uncinate process of the ethmoid and the descending part of the lacrimal bone above, the maxillary process of the inferior nasal concha below, and the perpendicular plate of the palatine bone behind (**3**.79, 117). The maxillary sinus communicates with the middle meatus of the nose, generally by two small apertures, one of which is usually closed by mucous membrane in life. Its *posterior wall* contains the *alveolar canals*, which transmit the posterior superior alveolar vessels and nerves to the molar teeth; these canals occasionally project as ridges into the maxillary sinus. The *floor* is formed by the alveolar process of the maxilla, and its lowest part is usually about 1·25 cm below the level of the floor of the nasal cavity. In a large proportion of bones, radiating septa of varying sizes spring from the floor of the sinus in the intervals between the adjacent teeth; in some cases the floor is perforated by the roots of the molar teeth (p. 1149). The infra-orbital canal usually projects into the sinus, a well-marked ridge extending from the *roof* to the *anterior wall*. The size of the cavity varies in different skulls, and even on the two sides of the same skull (p. 1149).

Applied Anatomy. Because of the extreme thinness of the walls of the sinus a tumour growing in it and encroaching upon the adjacent parts may push up the floor of the orbit and displace the eyeball, project into the nasal cavity, protrude forwards on to the cheek, or make its way backwards into the infratemporal fossa or downwards into the mouth. Extraction of molar teeth may damage the floor of the sinus.

The zygomatic process is an irregular, pyramidal projection, where the anterior, infratemporal and orbital surfaces converge. *In front* it forms part of the anterior surface of the body of the bone; *behind*, it is concave, and continuous with the infratemporal surface; *above*, it is rough and serrated for articulation with the zygomatic bone; *below*, an arched border separates the anterior from the infratemporal surface.

The frontal process projects upwards and backwards between the nasal and lacrimal bones (**3**.61, 118A). Its *lateral surface* (**3**.115A) is divided by a vertical ridge, the *anterior lacrimal crest*, which gives attachment to the medial palpebral ligament and is continuous below with the infra-orbital margin. At the junction of the crest with the orbital surface there is a small tubercle, a guide to the position of the lacrimal sac. The area in front of the lacrimal crest is smooth and merges below with the anterior surface of the body; a portion of the orbicularis oculi and the levator labii superioris alaeque nasi are attached here. Behind the anterior lacrimal crest there is a vertical groove which combines with a similar groove on the lacrimal bone to complete a fossa for the lacrimal sac.

The *medial surface* of the frontal process (**3**.116) is part of the lateral wall of the nasal cavity. A rough, uneven area at its upper part articulates with the ethmoid bone and closes the anterior ethmoidal air cells. Below this there is an oblique ridge, the *ethmoidal crest*, the posterior part of which articulates with the middle nasal concha, while the anterior underlies the *agger nasi*, a ridge anterior to the middle concha, on the lateral wall of the nasal cavity; the ethmoidal crest forms the upper limit of the atrium of the middle meatus of the nose. The *upper end* of the frontal process articulates with the nasal part of the frontal bone, the *anterior border* with the nasal bone, and the *posterior border* with the lacrimal bone.



The alveolar process of the maxilla is thick and arched, broader behind than in front, and excavated to form sockets for the reception of the roots of the teeth. These cavities are eight in number and vary in size and depth according to the teeth they contain. That for the canine tooth is the deepest; those for the molars are the widest, and are subdivided into three minor sockets by septa; those for the incisors and the second premolar are single; that for the first premolar is sometimes divided into two. The buccinator arises from the outer surface of this process, as far forwards as the first molar tooth. When the maxillae are articulated with each other, their alveolar processes together form the *alveolar arch*. Occasionally a longitudinal ridge, of variable prominence and roughness, the *maxillary torus*, is present on the palatal aspect of the alveolar process opposite the subcervical parts of the upper molar tooth sockets.

The palatine process of the maxilla, which is thick and strong, is horizontal and projects medially from the lowest part of

the nasal surface of the bone. It forms a considerable part of the floor of the nasal cavity and the roof of the mouth, and is much thicker in front than behind. Its *inferior surface* (**3**.72) is concave, rough and uneven, and forms, with the palatine process of the opposite bone, the anterior three-fourths of the bony palate. It is marked by numerous vascular foramina and displays depressions for the palatine glands; it is channelled at the posterior part of its lateral border by two grooves, which contain the greater palatine vessels and nerve. When the two maxillae are articulated, a funnel-shaped depression, the *incisive fossa*, is seen in the median plane, immediately behind the incisor teeth. Caudal to the incisive fossa, the midline palatal intermaxillary suture on its oral aspect, although a little uneven, is usually relatively flat. However, in some cases its bony margins are raised, forming a longitudinal prominent ridge, the *palatine torus* (see also p. 305).

bone appears above the canine fossa at about the sixth week of intrauterine life; two others have been ascribed to the anterior or *premaxillary* part of the bone, the so-called *os incisivum*. This corresponds, in position at least, with the premaxilla, a distinct and separate entity in most mammalian upper jaws, including those of primates.

Of the two 'premaxillary' centres, reputed to occur in the human embryonic upper jaw (Woo 1949; Noback and Moss 1953), the main one is said to appear above the incisor tooth germs in the seventh week. The second centre, sometimes called *paraseptal* or *prevomerine*, is considered to commence ossifying on the medial wall of the paraseptal cartilage, at the ventral margin of the nasal septum; it fuses almost at once with the palatal process of the maxilla. Classically, the bone formed by the main premaxillary centre is considered to be overgrown superficially by

3.118 The right maxilla at birth. Note alveoli for deciduous teeth in B and rough articular area for opposite maxilla in C.

Its incidence shows racial variation in modern and ancient populations (p. 348). It is rare in Burmese, for example, but is frequent in English crania (29 per cent in males, 48 per cent in females of a group of nineteenth-century Londoners). In the depths of the *incisive fossa* the orifices of two lateral canals are visible: they are named the *incisive canals*; each leads upwards into the corresponding half of the nasal cavity and through it pass the terminal branch of the greater palatine artery and the nasopalatine nerve. Occasionally there are two additional apertures in the median plane: the *anterior* and *posterior incisive foramina*; when present, these transmit the nasopalatine nerves, the left passing through the anterior, and the right through the posterior foramen. On the inferior surface of the palatine process, a delicate groove, sometimes termed the *incisive suture*, prominent in young skulls, may sometimes also be noticed in adults extending laterally and forwards from the incisive fossa to the interval between the lateral incisor and the canine teeth. The small volume of bone anterior to this supposed suture is the *os incisivum*, and has been considered for a long time to represent the premaxilla, which is a separate bone in most vertebrates, including primates. This classical view has been seriously challenged (*vide infra*). The *superior surface* of the palatine process is concave from side to side, smooth, and forms the greater part of the floor of the nasal cavity; close to the anterior part of its median margin the bone is traversed by its incisive canal. The *lateral border* of the process is fused with the rest of the bone. The *medial border*, thicker in front than behind, is raised into a ridge, the *nasal crest*, which, with the same ridge on the opposite maxilla, forms a groove for the reception of the vomer. The front of this ridge rises to a considerable height and is sometimes termed the *incisor crest* (**3**.116); it is prolonged forwards into a sharp process, which forms with the similar process of the opposite bone, the *anterior nasal spine*. The posterior border is serrated for junction with the horizontal plate of the palatine bone.

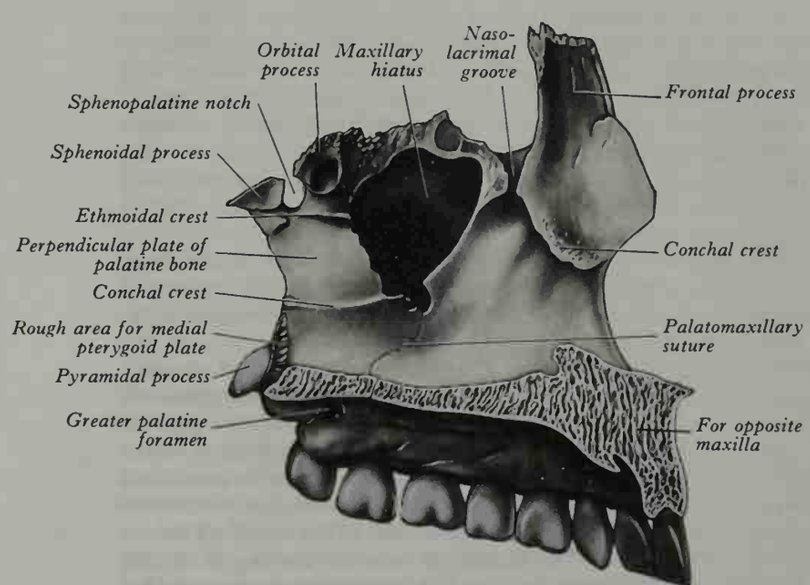
Ossification. The maxilla develops by ossification in a sheet of mesenchymal tissue superficial to the nasal capsule. Three centres of ossification have been described; one for the main mass of the

bone from the main mass of the maxilla, fusing along its anterior limit with the maxilla's alveolar process (this junction may remain discernible for a time as the *interalveolar suture of Jarmer*). This explains the fact that after the third month of intrauterine life there is no indication on the facial aspect of the upper jaw of a premaxilla (os incisivum). However, a suture, or what appears to be a suture, may be observed somewhat rarely on the floor of the nasal cavity, a little behind its anterior margin (Ashley Montagu 1953). This groove, when identifiable in the skull post-natally, passes medially on each side to the incisive canal. Furthermore, a suture line, or cleft, can always be seen at birth in the anterior region of the palate, diverging on each side from the incisive fossa. It runs into the septum between the lateral incisor and canine teeth (rarely between the canine and first premolar). This *palatal* indication of separation between the os incisivum and the rest of the maxilla may persist until the middle decades. Considered with the inconstant grooves in the floor of the nasal cavity mentioned above, these palatal features apparently delineate a separate element, anterior to the incisive fossa and canals, and forming parts of the alveoli of the incisor teeth. Being fused anteriorly with an overlap of bone derived from the maxillary centre, this os incisivum has no facial representation.

The regular occurrence of a premaxilla in other primates, as an undeniable separate osseous element, has naturally prompted attempts to identify its homologue in man. Despite early disagreements (Fawcett 1911), the above description of the development of the upper jaw has become the standard account, conveniently equating the os incisivum with the mammalian premaxilla. This argument depends primarily upon the supposed centres of ossification in the os incisivum. In this respect, a recent study of serial sections of the region in human embryos provides a denial, the evidence strongly supporting the view that ossification in the os incisivum is merely an extension of the maxillary centre (Wood *et al.* 1969). The lamina of bone developing from this displays, as in the case of the mandible, a complex shape, such that it appears in more than one place in some sections, suggesting multiple centres. It is claimed that the essential continuity of these

can be clearly established by serial sectioning. This provides an agreeable simplification for the complexities of maxillary development. The extension of bone from the supposed initial 'premaxillary' centre to form frontal and palatine processes, can thus be ascribed to the main maxillary centre. Nevertheless, this simplification of the ossific process does not explain the various sutures, clefts and grooves which are held to delineate the os incisivum in the human upper jaw. Whether the pattern of pre-ossification mesenchymal condensations in the region has any relevant phylogenetic implication remains uncertain; the status of the premaxilla in man thus becomes problematical. There is strong evidence, at least, that it is not distinguished by any specific centre of ossification.

The maxillary sinus appears as a shallow groove (**3**.118C) on the nasal aspect of the bone about the fourth month of intrauterine life. The infra-orbital vessels and nerve are for a time in an open groove in the floor of the orbit, the anterior part of which is converted into the infra-orbital canal by a lamina of bone growing in from the lateral side.



Age Changes in the Maxilla

At birth the horizontal (transverse and anteroposterior) diameters of the maxilla are both greater than the vertical. The frontal process is well marked, but the body of the bone consists of little more than the alveolar process, the tooth sockets reaching almost to the floor of the orbit. The maxillary sinus is a mere furrow on the lateral wall of the nasal cavity. In the adult the vertical diameter is the greatest, owing to the development of the alveolar process and the increase in size of the sinus. If all the teeth are lost, whether in old age or earlier, the bone reverts in some measure to the infantile condition: its height is diminished and, after the loss of the teeth, the alveolar process is absorbed (p. 346) and the lower part of the bone contracted and reduced in thickness at the expense of the labial wall (p. 319). The differences in the way in which the alveolar processes are absorbed in the maxilla and in the mandible are of considerable practical importance in the provision of dentures.

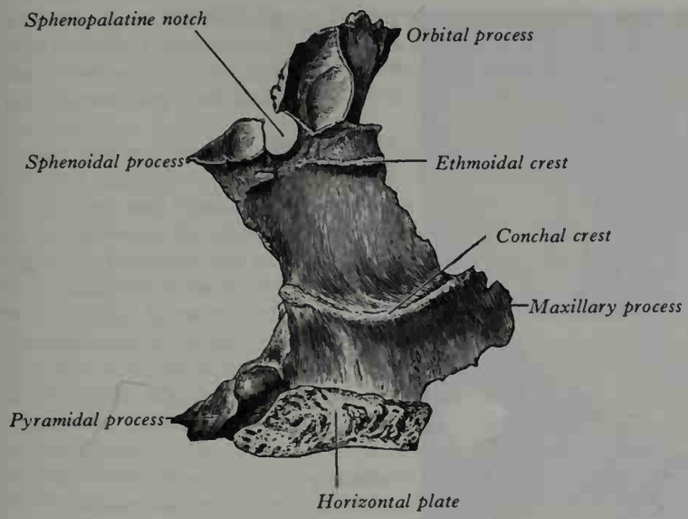
The Palatine Bones

The palatine bones are in the posterior part of the nasal cavity, between the maxillae and the pterygoid processes of the sphenoid bone (**3**.79). Each assists in forming the floor and lateral wall of the nasal cavity, the roof of the mouth, and the floor of the orbit, parts of the pterygopalatine and pterygoid fossae, and the inferior orbital fissure.

The palatine bone bears some resemblance to the letter L, consisting of horizontal and perpendicular plates, and three processes, *pyramidal* directed backwards, laterally and downwards from the junction of the horizontal and perpendicular plates, *orbital* and *sphenoidal*, which surmount the perpendicular plate and are separated by the deep sphenopalatine notch.

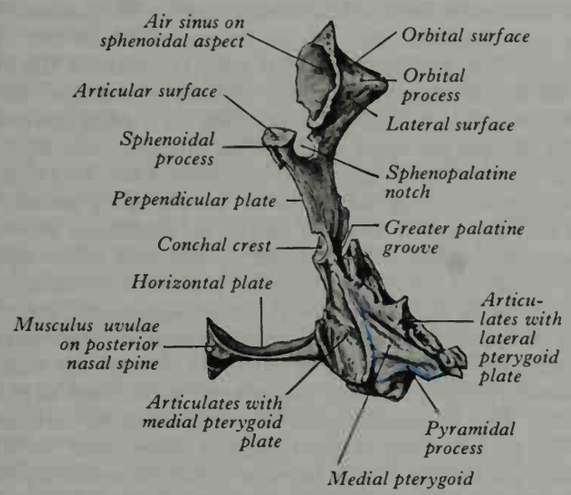
3.119 The left palatine bone in articulation with the left maxilla. Medial aspect.

The horizontal plate of the palatine bone (**3**.72, 121) is quadrilateral, with two surfaces and four borders. The *nasal surface*, concave from side to side, forms the posterior part of the floor of the nasal cavity. The *palatine surface* forms, with the corresponding surface of the opposite bone, the posterior quarter of the bony palate; near its posterior margin there is often a curved ridge, the *palatine crest*. The *posterior border* is thin and concave; to it, and to the palatine surface as far forwards as the palatine crest, the expanded tendon of the tensor veli palatini is attached. The medial end of the posterior border is pointed and, when united with that of the opposite bone, forms a projecting process, the *posterior nasal spine*, which gives attachment to the musculus uvulae. The *anterior border* is serrated and articulates with the palatine process of the maxilla. The *lateral border* is continuous with the inferior border of the perpendicular plate and is marked at the lower end by the greater palatine groove. The *medial border*, which is thick and serrated, articulates with the corresponding border of the opposite bone, and the opposed borders from the posterior part of the *nasal crest*. This crest articulates with the posterior part of the lower edge of the vomer and is continuous anteriorly with the nasal crest of the maxillae.



The perpendicular plate of the palatine bone (**3**.120, 121) is thin and of an oblong form, and has two surfaces and four borders.

The *nasal surface* exhibits at its lower part a broad, shallow depression which forms part of the inferior meatus of the nasal cavity. Immediately above this the *conchal crest* forms a horizontal ridge for articulation with the inferior nasal concha; still higher there is a second broad, shallow depression, which forms part of the middle meatus and is limited above by the *ethmoidal crest* for articulation with the middle nasal concha. Above the ethmoidal crest there is a narrow, horizontal groove, which forms part of the superior nasal meatus.



The *maxillary surface* is rough and irregular throughout the greater part of its extent, for articulation with the nasal surface of the maxilla; its upper and posterior part is smooth and forms the medial wall of the pterygopalatine fossa; its front portion, which is also smooth, projects beyond the posterior border of the maxillary hiatus and forms the posterior part of the medial wall of the maxillary sinus (**3**.117). On the posterior part of the maxillary surface there is a deep vertical groove, named the *greater palatine groove*, which in the articulated skull is converted into the *greater palatine canal* by the maxilla; this canal transmits the greater palatine vessels and nerve.

The *anterior border* is thin and irregular; at the level of the conchal crest a pointed lamina projects forwards below and behind the maxillary process of the inferior nasal concha. It articulates with the latter and assists in forming the medial wall of the maxillary sinus (**3**.117). The *posterior border* (**3**.121) is serrated for articulation with the medial pterygoid plate of the sphenoid bone. This border is continuous above with the sphenoidal process; it expands below into the pyramidal process of the palatine bone. The *superior border* supports the orbital process in front and the sphenoidal process behind. These processes are separated by the *sphenopalatine notch*, which is converted into the *sphenopalatine foramen* by the inferior surface of the body of the sphenoid. In the articulated skull this foramen leads from the pterygopalatine fossa into the posterior part of the superior meatus of the nose, and transmits the sphenopalatine vessels and posterior superior nasal nerves. The *inferior border* is continuous with the lateral border of the horizontal plate and, in front of the pyramidal process, is marked by the lower end of the greater palatine groove.

The pyramidal process of the palatine bone projects backwards, laterally, and downwards from the junction of the horizontal and perpendicular plates of the bone, and fits into the angular interval between the lower ends of the pterygoid plates. On its *posterior surface* there is a smooth, grooved triangular area, limited on each side by a rough articular furrow. The furrows articulate with the pterygoid plates, while the grooved triangular

3.120 The left palatine bone. Medial aspect. (Enlarged.)

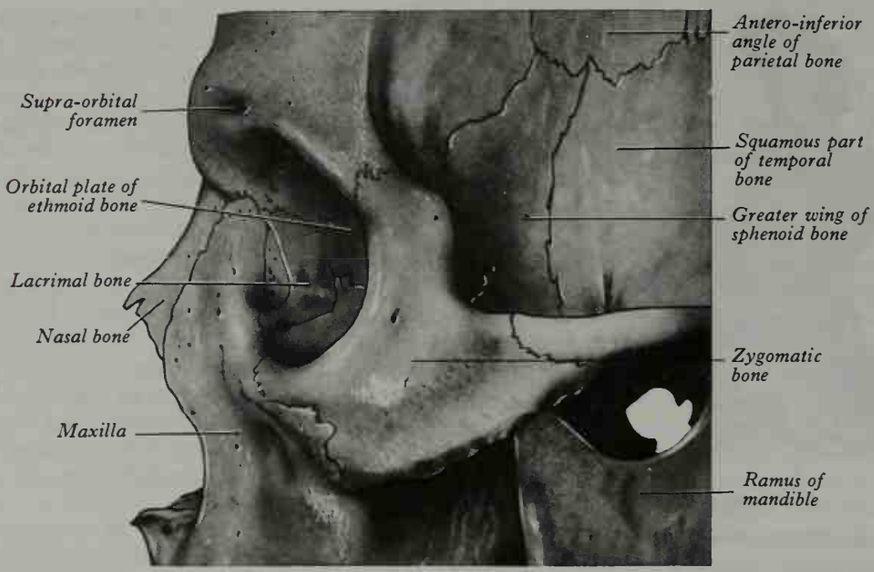
3.121 The right palatine bone. Posterior aspect.

area completes the lower part of the pterygoid fossa for attachment of some fibres of the medial pterygoid. The anterior part of the *lateral surface* is rough for articulation with the maxillary tuberosity; the posterior part consists of a smooth triangular area, which appears at the lower part of the infratemporal fossa between the maxillary tuberosity and the lateral pterygoid plate (**3**.70). The *inferior surface* of the pyramidal process, close to its union with the horizontal plate of the bone, presents the *lesser palatine foramina* for the transmission of the lesser palatine nerves and arteries (**3**.72).

The orbital process (**3**.120, 121) is directed upwards and laterally from the front of the perpendicular plate, to which it is joined by a constricted neck. It encloses an air sinus, and presents three articular and two non-articular surfaces. Of the articular surfaces, (1) the *anterior* or *maxillary*, of an oblong form, is directed forwards, laterally, and downwards, and articulates with the maxilla; (2) the *posterior* or *sphenoidal*, directed backwards, upwards, and medially, presents the opening of the air sinus, which usually communicates with the sphenoidal sinus; the margins of the opening articulate with the sphenoidal concha; (3) the *medial* or *ethmoidal* is directed medially and forwards, and articulates with the labyrinth of the ethmoid bone. In some cases, the air sinus opens on this surface and then communicates with the posterior ethmoidal air cells: more rarely it opens on the ethmoidal *and* sphenoidal surfaces, and them communicates with the posterior ethmoidal air cells and the sphenoidal sinus. Of the non-articular surfaces, (1) the *superior* or *orbital*, triangular in shape, is directed upwards and laterally, and forms the posterior part of the floor of the orbit (**3**.66); (2) the *lateral*, of an oblong form, is directed towards the pterygopalatine fossa and is separated from the orbital surface by a rounded border, which forms the medial part of the lower margin of the inferior orbital fissure; the lower part of this surface may present a groove, directed laterally and upwards, which lodges the maxillary nerve and is continuous with the groove on the upper part of the posterior surface of the maxilla (p. 338). The border between the lateral and posterior surfaces is prolonged downwards as the anterior boundary of the sphenopalatine notch.

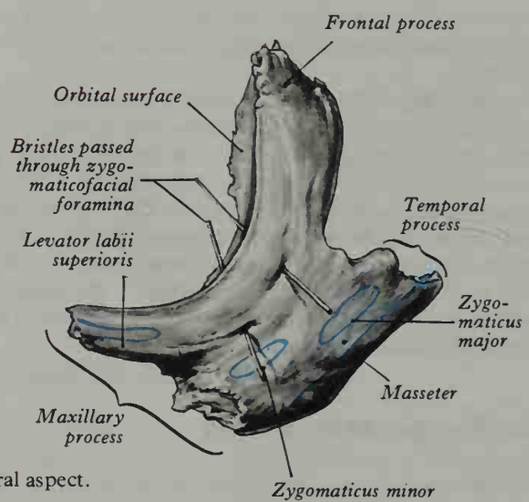
The sphenoidal process (**3**.120, 121) is a thin, compressed plate, smaller and on a lower level than the orbital process; it is directed upwards and medially. Its *superior surface* articulates with the under surface of the sphenoidal concha and the root of the medial pterygoid plate; it presents a groove which contributes to the formation of the palatovaginal canal. The *inferomedial surface* is concave and forms a small part of the roof and lateral wall of the nasal cavity. The posterior part of the *lateral surface* articulates with the medial pterygoid plate; the anterior part is smooth and forms a portion of the medial wall of the pterygopalatine fossa. The *posterior border* is rough and articulates with the vaginal process of the medial pterygoid plate. The *anterior border* forms the posterior boundary of the sphenopalatine notch. The *medial border* articulates with the ala of the vomer.

The orbital and sphenoidal processes are separated from each other by the *sphenopalatine notch*, which is converted into the sphenopalatine foramen by the under surface of the body of the sphenoid; sometimes the two processes are united by bone to form a foramen.



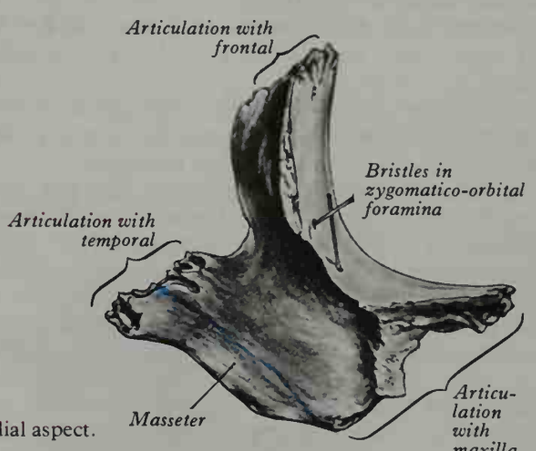
Ossification. The palatine bone is ossified in a membrane of connective tissue from one centre, which appears during the eighth week of intrauterine life in the perpendicular plate. From this point ossification spreads upwards into the orbital and sphenoidal processes, medially into the horizontal plate, and downwards into the pyramidal process. At the time of birth the height of the perpendicular plate is about equal to the transverse width of the horizontal plate, whereas in the adult it measures nearly twice as much, a change in proportions which accords with the growth changes in the adjoining maxilla.

The Zygomatic Bones



The zygomatic bones are superolateral elements in the facial skeleton. Each forms the prominence of the cheek, and contributes to the formation of the lateral wall and floor of the orbit and to the walls of the temporal and infratemporal fossae (**3**.122).

The zygomatic bone is roughly quadrangular in shape, with a flange-like anteromedial projection, the frontal process. It has three surfaces, five borders and two processes.



The *lateral surface* (**3**.122, 123A), directed laterally and forwards, is convex and pierced near its orbital border by the *zygomaticofacial foramen* (often double), for the passage of the zygomaticofacial nerve and vessels; below this foramen a slight elevation provides attachment for the zygomaticus minor and more posteriorly the zygomaticus major takes origin. (The zygomaticofacial foramen is also absent in a proportion of cases, *see* p. 299.) The *temporal surface* (**3**.123B), which is directed medially and backwards, is concave. It presents anteriorly a roughened area for articulation with the maxilla, and posteriorly a smooth, concave area which extends upwards on the posterior aspect of the frontal process as the anterior boundary of the temporal fossa. It also extends backwards on the medial aspect of temporal process to form an incomplete lateral wall for the infratemporal fossa. The *zygomaticotemporal foramen*, for the nerve of the same name, pierces this surface near the base of the frontal process. The *orbital surface* (**3**.123B), smooth and concave, forms the anterolateral part of the floor and the adjoining part of the lateral wall of the orbit, extending upwards on to the medial aspect of the frontal process. It usually presents the orifices of two canals, the *zygomatico-orbital foramina*, one of which leads to the zygomaticofacial and the other to the zygomaticotemporal foramen.

3.122 The left zygomatic bone *in situ*.

A Lateral aspect.

B Medial aspect.

3.123 The left zygomatic bone, showing muscular attachments.

The *anterosuperior* or *orbital border* is smooth and concave, and forms a considerable part of the circumference of the orbital opening, below and on the lateral side. It separates the orbital from the lateral surface. The *antero-inferior* or *maxillary border* is rough and articulates with the maxilla; its medial extremity is pointed and lies above the infra-orbital foramen; near the orbital margin a part of the levator labii superioris is attached to it. The *posterosuperior* or *temporal border* is curved, being convex in its upper and concave in its lower part; it is continuous above with the posterior border of the frontal process and below with the upper border of the zygomatic arch; it gives attachment to the temporal fascia. A little below the frontozygomatic suture this border frequently presents a small, rounded projection, the *marginal tubercle*, which can be felt easily through the skin. The *postero-inferior border* affords attachment by its rough edge to the masseter. The *posteromedial border* is serrated for articulation with the greater wing of the sphenoid above, and the orbital surface of the maxilla below. Between these two serrated portions there is usually a short, concave, non-articular part, which forms the lateral boundary of the inferior orbital fissure. This non-articular part is sometimes absent, and the fissure is then completed by the junction of the maxilla and the sphenoid, or by the interposition of a small sutural bone in the angular interval between them.

The *frontal process* is thick and serrated; it articulates above with the zygomatic process of the frontal bone and behind with the greater wing of the sphenoid. On its orbital aspect, just within the orbital opening and about 1 cm below the frontozygomatic suture, there is a tubercle of varying size and form in 95 per cent of skulls (Whitnall 1921). Attached to this are the lateral check ligament of the rectus lateralis, part of the aponeurosis of the levator palpebrae superioris, the suspensory ligament of the eyeball and the lateral palpebral ligament (p. 1178). The *temporal process* is directed backwards and ends in an oblique, serrated margin which articulates with the zygomatic process of the temporal bone, and helps to form the zygomatic arch.

Ossification. The zygomatic bone is ossified from one centre, which appears in a fibrous tissue precursor about the eighth week of intrauterine life. The bone is sometimes divided by a horizontal suture into an upper larger, and a lower smaller division.

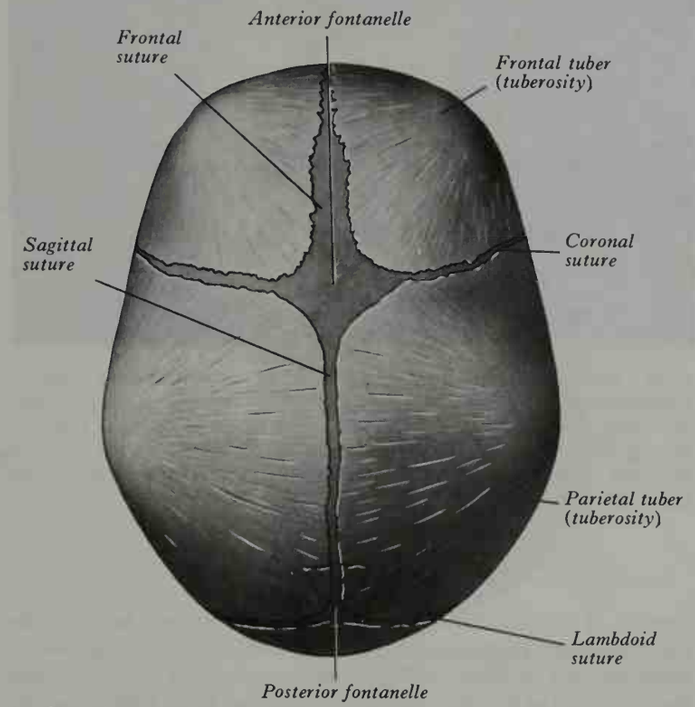
CRANIAL CHARACTERISTICS AT DIFFERENT AGES

The skull at birth is large in proportion to other parts of the skeleton; but the facial part of the cranium is relatively small, forming but one-eighth of the neonatal cranium, compared with a half in adult life. The smallness of the face at birth is due to the rudimentary condition of the mandible and maxillae, the non-eruption of the teeth and the small size of the maxillary sinus and the nasal cavity. The latter lies almost entirely between the orbits, the lower border of the piriform aperture of the nose being only a little below the orbital floor. On the other hand, the large size of the calvaria—especially the cranial vault—is related to the

precocious growth of the brain. At this stage the base of the skull is relatively short and narrow, and though the middle and internal ear are almost adult in size, the petrous part of the temporal bone is not yet approaching its adult length as measured from its apex to lateral surface.

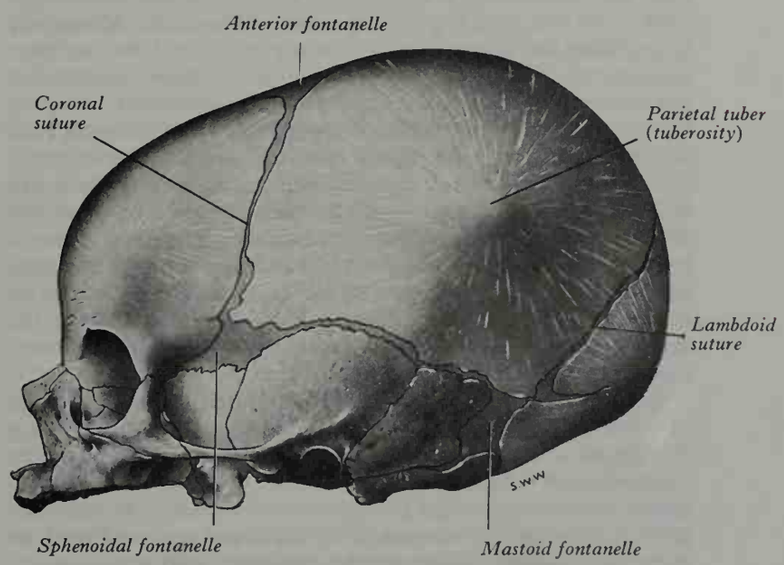
The bones of the cranial vault are smooth and unilaminar and without diploë. The frontal and parietal tuberosities are prominent, and from above the greatest width of the skull is seen to be between the parietal tuberosities (p. 348). The glabella, superciliary arches and mastoid processes are not developed.

Ossification of the skull bones is incomplete, many consisting of several bony elements united by fibrous tissue or cartilage. The 'os incisivum' is continuous with the maxilla (p. 341) and the pre- and post-sphenoids have united just before birth, but the two halves of the frontal bone and mandible are separate, as are the squamous, lateral and basilar parts of the occipital bone. The second centre for the styloid process (stylohyal) has not appeared and the bony elements of the temporal bone are separate except for the commencing union of the tympanic with the petrous and squamous parts. Areas of the fibrous tissue membrane, which forms the primitive cranial vault before ossification begins, are still unossified at the angles of the parietal bone. These *fonticuli* or *fontanelles* are six in number; two, the *anterior* and *posterior*, are in the median plane, and two pairs, the *sphenoidal* and *mastoid*, appear on each side.



The *anterior fontanelle* (**3**.124A), the largest, is at the junction of the sagittal, coronal and frontal sutures; it is diamond-shaped and measures about 4 cm in anteroposterior and 2·5 cm in transverse diameters. The *posterior fontanelle* (**3**.124A) is triangular and situated at the junction of the sagittal and lambdoid sutures. The *sphenoidal* (anterolateral) and *mastoid* (posterolateral) *fontanelles* (**3**.124B) are small and irregular in shape, and lie respectively at the sphenoidal and mastoid angles of the parietal bones.

At birth the orbits are large and the germs of the developing teeth lie close to their orbital floors. The temporal bone shows marked differences from that of the adult. While the internal ear, tympanic cavity, auditory ossicles and mastoid antrum are almost adult in size, the tympanic plate is represented by an incomplete ring, and the mastoid process has not commenced to develop. The external acoustic meatus is short and straight and its bony part unossified and represented by a fibrocartilaginous plate. The external aspect of the tympanic membrane faces caudally rather than laterally, coinciding with the contour of the skull base at this point. Owing to the absence of a mastoid process, the stylomastoid foramen is exposed on the lateral surface of the skull. The styloid process has not fused with the temporal bone and the mandibular fossa is flat and more laterally placed; the articular tubercle has not developed. The paranasal sinuses are rudimentary or absent, only the early maxillary sinuses being usually identifiable.



During birth the skull is altered in shape or moulded by slow compression and the part of the scalp which lies more centrally in the birth canal is often temporarily swollen and oedematous due to interference with the venous return. The swollen area is called the *caput succedaneum*. Owing to the presence of the fontanelles and the width and lack of interlocking of sutures, the bones of the skull cranial vault are able to overlap to a small extent. The skull is compressed in one plane and shows compensatory elongation at right angles to this. These effects disappear within a week of birth.

Postnatal growth of the skull. Though co-ordinated, the postnatal growth of the calvaria and facial skeleton proceed at different rates and over different periods, that of the cranial cavity being related to the growth of the brain and that of the facial skeleton to the development of dentition, muscles of mastication and tongue. Growth of the base of the skull does not proceed at the same rate as that of the vault; in the following account the three parts, vault, base and facial skeleton, will be considered separately. The anterior part of the cranial base is thus a zone of interaction between facial and cranial growth (Brash 1924; Scott 1967).

The growth of the vault proceeds rapidly during the first year and thereafter more slowly to the seventh year, by which time it has almost reached adult dimensions. Over most of this period its expansion is, broadly speaking, concentric and its form is determined in the early part of the first year, after which time it remains largely unaltered (Weinmann and Sicher 1955; Scott and Symon 1971; Brodie 1941; Hoyte 1966). That the *shape* of the vault is not directly related to the growth of the brain but to independent genetic factors is to some extent supported by the great range of cranial indices and the association of certain forms of head shape with racial groups. During the first and early part of the second years the growth of the vault is achieved principally by ossification at the apposed margins of the bones, which are covered by an osteogenic layer (p. 420). This expansion is necessarily accompanied by some accretion and absorption of bone at the surfaces in order to adapt them to the continually altering curvatures of the vault. Growth in breadth occurs at the sagittal suture, the sutures bordering the greater wing of the sphenoid, the occipitomastoid sutures and the petro-occipital cartilaginous joints in the base of the skull. Growth in height occurs at the frontozygomatic suture, the pterion (p. 302), the squamosal suture and the asterion (p. 347). During this period the fontanelles are closed by growth and expansion of the bones which surround them, but sometimes they are the sites of separate

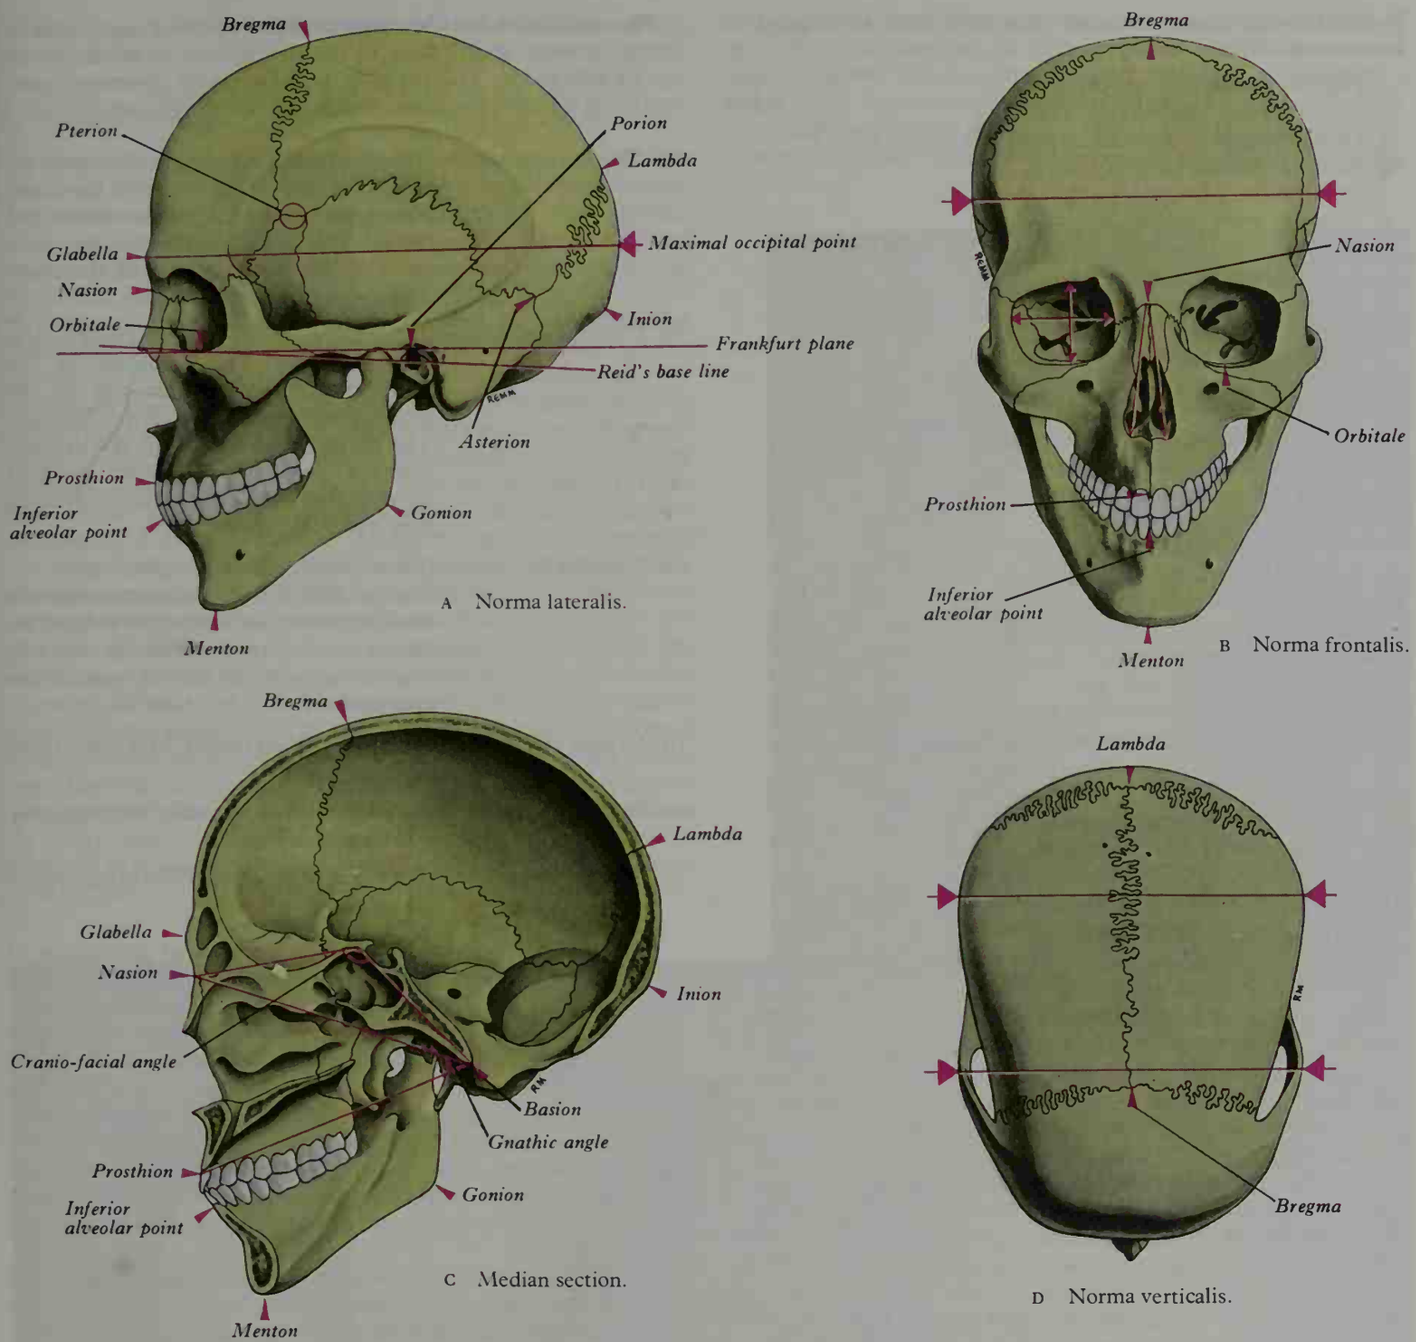
Second permanent molar tooth, not yet erupted.

centres of ossification which develop into sutural bones. The sphenoidal and posterior fontanelles are obliterated within two or three months of birth; the mastoid fontanelle is usually closed about the end of the first year and the anterior fontanelle about the middle of the second year. By the second year the bones of the vault have interlocked at the sutures, a process which commences early in the first year. Further expansion of the vault is principally by accretion and absorption on their superficial and deep surfaces respectively (Ford 1956). At the same time the bones thicken, but not uniformly. At birth the cranial vault is unilaminar, the two tables and the intervening diploë appearing about the fourth year, the differentiation reaching its maxim about thirty-five years, when diploic veins form a characteristic and prominent feature in radiographs. The thickness of the bones of the vault and the development of muscular markings on the outer table are related to the development of the muscles of mastication and the posterior muscles of the neck. The mastoid process forms a visible bulge on the surface in the second year and is invaded by air cells in the sixth year. Galli, Ottaviani, and Galli (1976) have recorded metrical studies of the process.

The growth of the base is responsible for much of the lengthening of the skull and mostly occurs at the cartilaginous joints between the sphenoid and ethmoid on the one hand and between the sphenoid and occipital on the other, especially the latter. It is largely independent of the growth of the brain. Growth continues at the synchondrosis between the occipital and sphenoid until the eighteenth to twenty-fifth year; this prolonged period is related to the continued expansion of the jaws to accommodate the erupting teeth, provision of room for the muscles of mastication and growth of the nasopharynx. Doubts have been expressed regarding this dating; there is some evidence that growth may cease at about 15 years (Latham 1966). A pubertal growth spurt has been ascribed to both sexes, occurring about two years earlier in females. The same study indicated considerable post-pubertal growth, up to 17·5 years in males (Roche and Lewis 1974). For a recent review of the literature on basal growth consult Hoyte (1975), and for labelling studies of growth in craniofacial cartilages (in rats) *see* Kvinnsland and Kvinnsland (1975).

The growth of the face occupies a period long in comparison with that of the calvaria. Much of our knowledge has been obtained from studies of serial lateral radiographs (Salymann 1961).



The ethmoid bone, orbital cavities and upper part of the nasal cavities have almost completed their growth by the seventh year. Growth of the orbits and upper nasal region is achieved by sutural growth in their walls with deposition of bone on the facial aspects of the orbital margins. The maxilla is carried downwards and forwards by the expansion of the orbits, growth of the nasal septum and sutural growth, especially at the fontanelles and at the zygomaticomaxillary and pterygomaxillary sutures. In the first year, growth in width occurs at the midpalatal sutures and the symphysis menti in association with growth at the internasal and frontal sutures, but growth at these sutures is considerably diminished or even terminated when the symphysis menti and frontal sutures are closed during the first few years of life, even though the midpalatal suture persists until mature years. Much facial growth occurs during this period; it continues, however, to puberty and later, in association with the eruption of the permanent dentition. After the termination of sutural growth, around the end of the second year, expansion of the facial skeleton occurs by surface accretion on the face, alveolar processes and palate associated with resorption in the walls of the maxillary sinus, upper surface of the hard palate and inner surface of the alveolar process. Associated growth and divergence of the pterygoid processes occurs due to deposition and resorption of bone of their surfaces. The growth of the mandible is correlated with that of the facial skeleton and is described on pp. 317–319.

Obliteration of the sutures of the vault of the skull takes place as age advances. It may commence between the ages of 30 and 40 on the inner surface, and about ten years later on the outer surface of the skull, but the times at which the sutures close are subject to great variations (Todd and Lyon 1924, 1925; Abbie 1950; Singer 1953). Obliteration usually occurs first at the bregma, extending into the sagittal, coronal and lambdoid sutures, in that order.

In old age the skull generally becomes thinner and lighter, but in a small proportion of cases it increases in thickness and weight. The most striking feature of the senile skull is the diminution in the size of the mandible and maxillae consequent on the loss of the teeth and the absorption of the alveolar processes. This is associated with a marked reduction in the vertical measurement of the face and with an alteration in the angles of the mandible (**3**.83) already described (pp. 317–319).

Sexual and Racial Differences in the Cranium

Until the age of puberty there is little difference between the skulls of the two sexes. The skull of an adult female is as a rule a little lighter and smaller, and its capacity is about 10 per cent less than that of the male. Its walls are thinner and its muscular ridges less marked; the glabella, superciliary arches, and mastoid processes are less prominent, and the corresponding air sinuses are smaller. The tympanic part of the temporal bone is smaller and its margins less roughened than in the male. The upper margin of the orbit is sharp, the forehead vertical, the frontal and parietal tuberosities are prominent, and the vault somewhat flattened. The contour of the face is rounder, the facial bones are smoother, and the mandible and maxillae and their contained teeth smaller. Speaking generally, more of the childhood characteristics are retained in the skull of the adult female. A well-marked male or female skull can easily be recognized as such, but in some skulls the characteristics are so indistinct that the determination of the sex may be difficult or impossible.

3.126A These diagrams illustrate the cranial points used, by international agreement, in making linear and certain angular measurements in anthropometry. In all four views the skull is in the standard orientation, that is, with the Frankfurt plane as a horizontal. The point at which the cranio-facial angle is measured (**3.126C**) is not named; it corresponds to the midpoint of the chiasmal groove.

Sexual dimorphism is generally less marked in mankind than in some other primates. This is to be associated with the *paedomorphic* tendency of the human stock, not only in females but also males being less divergent in adult development, from their own juvenile form, than is the case among some other primates, especially in the males (Abbie 1952; Schultz 1956). Exaggerated sexual differences in the skull occur in most of the anthropoid apes and some monkeys, in the form of enlarged canines in the male, together with associated jaw development, accentuated muscular ridges, and in the total size of the skull. These excessive developments are typified in the gorilla, orang-utan, and in many species of baboon, in which the male also exceeds the female considerably in general stature and physique. Even in extinct species of mankind sexual dimorphism appears—on the slender fossil evidence available—to have been less than in other primates. In modern man the differences are further reduced, but the degree of divergence between the sexes in cranial dimensions and proportions varies in different racial groups. These sexual differences have attracted less exact evaluation than have general studies of ethnic variation. In both cases, assessment depends upon observation of two kinds of feature: (*a*) those which cannot be measured, or have so far not been subjected to a satisfactory technique of quantitative study (e.g. size of mastoid process, prominence of chin), and (*b*) those which are customarily expressed as actual measurements or indices (e.g. cranial capacity, orbital index). Examples of the former category in distinguishing sex have been cited above and more exhaustive lists can be consulted in appropriate texts (Keen 1950). The use of such features in judging sex or race in the case of isolated crania is much dependent upon the observer's experience; but where a number of crania, known to be from a single ethnic group, are available, both assessments are more certain. Distinction of the three major races by non-metrical morphological traits can be effected with some confidence (Todd and Tracey 1930). The incidences of a number of variations have been observed in a number of racial groups; these include metopism and other sutural variants (Berry and Berry 1967), and are of considerable ethnological but lesser forensic interest. Berry (1975) has made a special study of *non-*

metrical human cranial characteristics; these include the presence or absence of the following:

1. Highest nuchal line (p. 361).
2. Os suturale at lambda (pp. 322, 328).
3. Ossa suturalia in lambdoid suture (pp. 332, 325).
4. Parietal foramen (p. 298).
5. Os suturale at bregma (p. 338).
6. Frontal suture (metopism) (p. 334).
7. Ossa suturalia in coronal suture (p. 332).
8. Epipteric os suturale (p.338).
9. Frontotemporal articulation (p. 302).
10. Parietomastoid os suturale (p. 302).
11. Os suturale at asterion (p. 302).
12. Tympanic foramen of Hüschke (p. 331).
13. Extrasutural mastoid foramen (p. 328).
14. Absence of mastoid foramen (p. 328).
15. Patent condylar canal (p. 332).
16. Double condylar facet (p. 322).
17. Precondylar tubercle (p. 332).
18. Double hypoglossal canal (p. 322).
19. Incomplete foramen ovale (p. 305).
20. Incomplete foramen spinosum (p. 307).
21. Accessory palatine foramina (p. 304).
22. Maxillary torus (p. 305).
23. Palatine torus (pp. 305, 341).
24. Absence of zygomaticofacial foramen (pp. 299, 343).
25. Supra-orbital foramen or incisure (p. 333).
26. Frontal foramen or incisure (p. 333).
27. Extrasutural anterior ethmoid foramen (p. 301).
28. Absence of posterior ethmoid foramen (p. 301).
29. Accessory infra-orbital foramen (p. 338).
30. Interparietal (Inca) bone (pp. 322, 338).
31. Paramastoid process (p. 332).
32. Auditory torus (p. 330).

Although many observers have studied these and other cranial variants (e.g. the mandibular torus, p. 316), few of these studies have been quantitative. The literature has been reviewed by Berry and Berry (1967) and Berry (1975), who also provide most extensive statistical data, and have assessed which cranial variations exhibit racial (and sometimes sexual) correlation. The interested reader should also consult Czarnetzki (1971), and Hjarno *et al.* (1974).

To achieve more objective judgement of the racial affinities of crania, metrical studies have long been practised, and internationally accepted techniques of *craniometry* have led to the accumulation of a large corpus of comparable data for the males, and to a lesser extent the females, of many ethnic groups. The number of standard measurements used is considerable, and only the major dimensions and examples of the indices derived from them can be included here (**3**.126). The calvarial part of the skull is characterized as follows:

A. Maximal cranial length	from the glabella to the furthest point at the occiput.
B. Maximal cranial breadth	greatest breadth, measured at right angles to the median plane.
C. Cranial height	from the basion (median point on the anterior rim of the foramen magnum) to the bregma.

All measurements are made to the nearest millimetre. From these three dimensions, three indices are calculated: B/A, C/A, and C/B, and these are expressed as percentages.

The breadth/length ratio is the *cranial index* (or *cephalic index* if measured in the living subject). Its recorded range of variation is high, as with other skull or head indices. In all of these the range of values encountered is arbitrarily divided into several steps, usually covering 5 per cent sections of the total range, and to each of the steps an appropriate term is applied. For example:

(*Maximal breadth*/*Maximal length*) × 100	= Cranial index or Cephalic index
Up to 74·9	= Dolichocranic or Dolichocephalic
75·0–79·9	= Mesocranic or Mesocephalic
80·0–84·9	= Brachycranic or Brachycephalic

The distinction between measurement of dried crania and of living subjects, in the form of the two groups of terms, is not rigidly adhered to. The 'cephalic' terms are more commonly used and often for both purposes. Other indices in common use are:

(a) Total facial index = (Nasion–Gnathion height/Bizygomatic breadth) × 100. The nasion is the point where the internasal suture meets the frontal bone. The gnathion is the midpoint of the lower border of the mandible.

(b) Upper facial index = (Nasion–Prosthion length/Bizygomatic breadth) × 100. The prosthion is the midpoint of the alveolar rim of the maxilla, between the two central incisors. The bizygomatic breadth is the greatest distance that can be found by trial between the two zygomatic arches on their external aspects.

(c) Nasal index = (Nasal breadth/Nasal height) × 100. The breadth is the maximum across the nasal aperture, and the height is from the nasion to the mean between the two lowest points on the lower border of the aperture.

(d) Orbital index = (Maximal orbital height/Maximal orbital breadth) × 100.

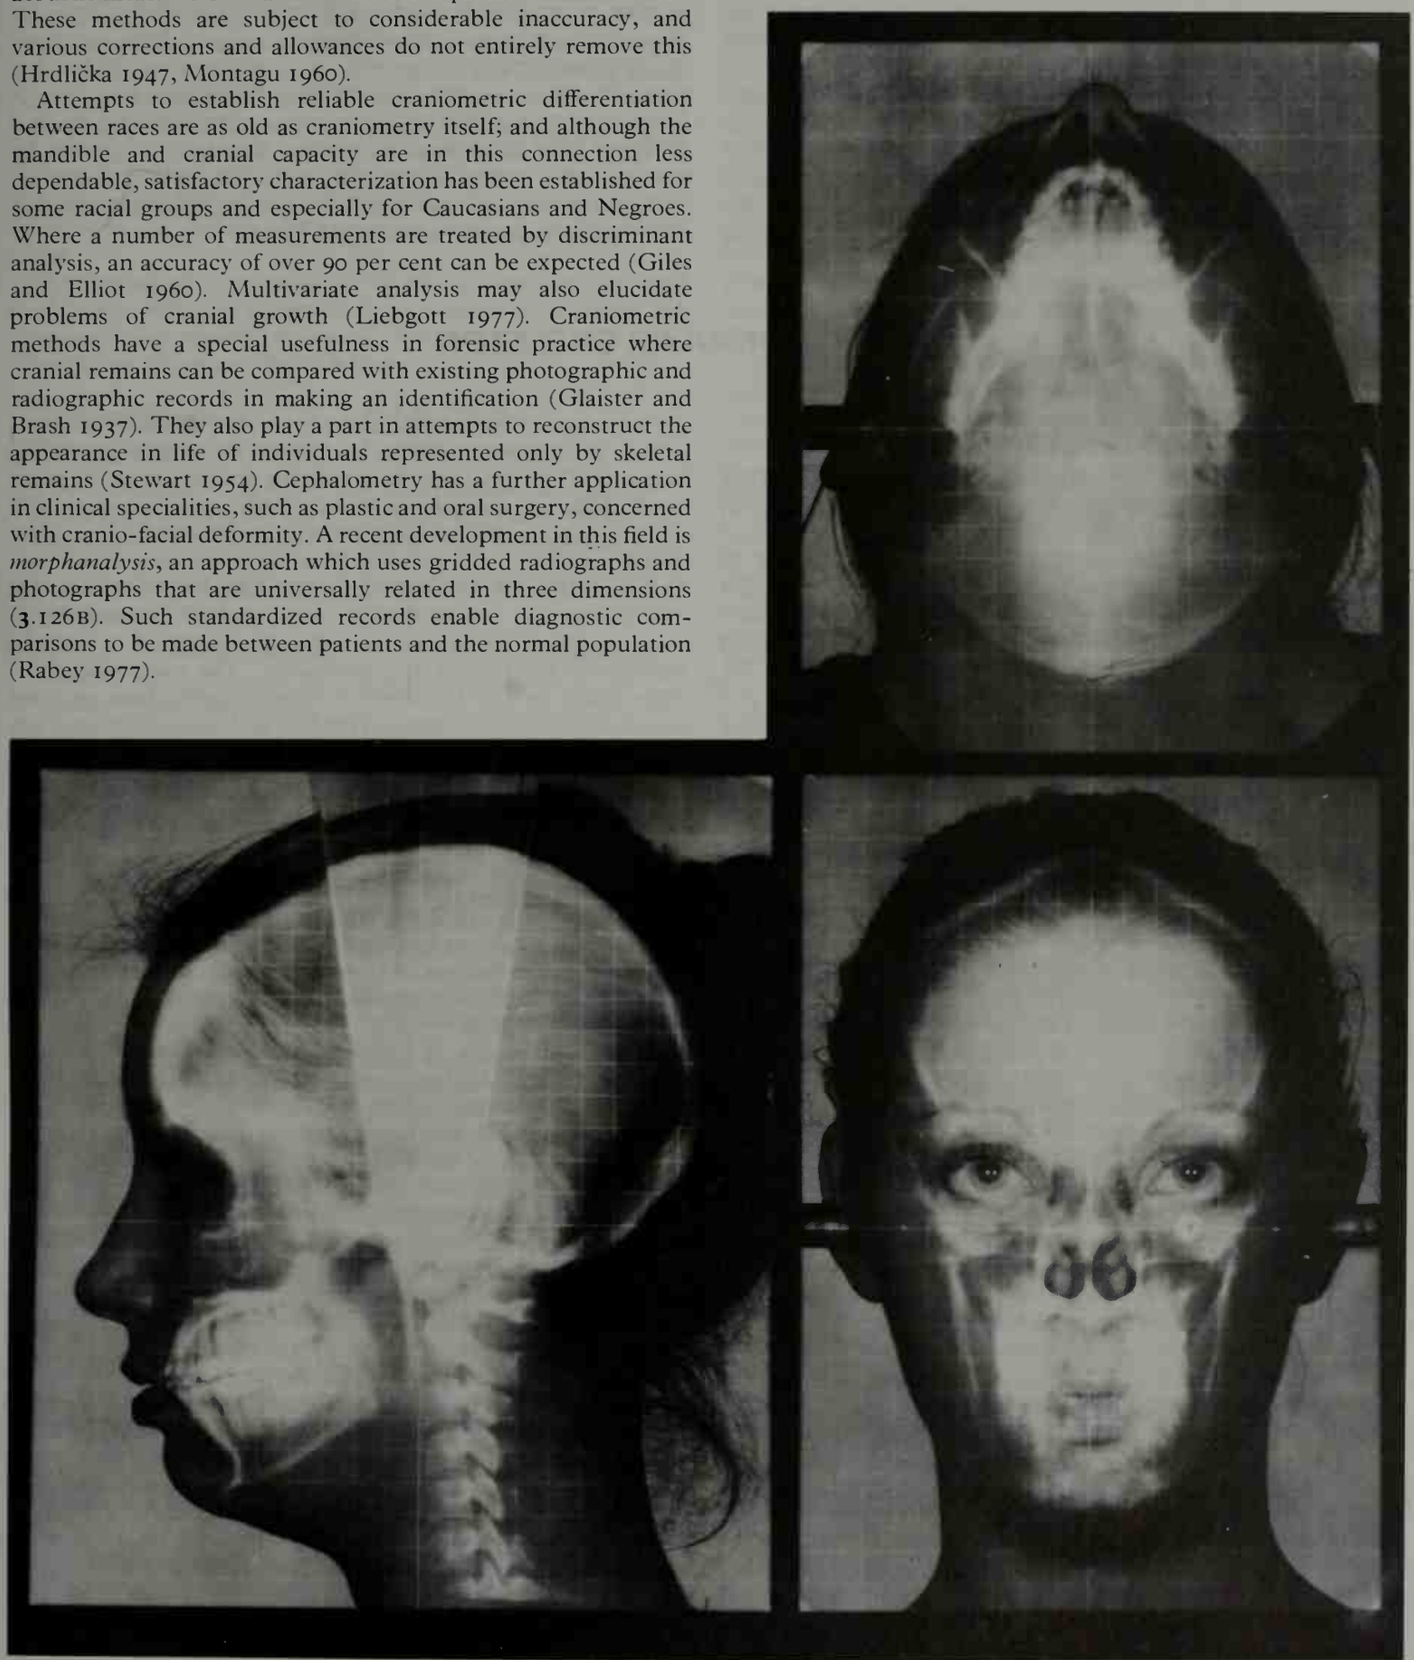
(e) Palatal index = (Maximal palatal breadth/Maximal palatal length) × 100.

(f) Gnathic index = (Basion–Prosthion/Basion–Nasion) × 100.

All these indices provide a system for *metrical* description of sizes and proportions of cranial features, in place of subjective impressions. If a given racial group is said to be dolichocephalic, this does not (or should not) imply a vague comparison, but that the index lies within certain numerical limits. It is possible to state that the orbital opening appears rounder in females than males, as it does, but this statement can be quantified and is then far more useful. Again, the jaws project forwards somewhat more in some races than others, a fact which can be detected by inspection alone, when the condition is pronounced; the gnathic index permits a numerical expression of this trait, and comparisons are then possible.

The following measurements are applied to the mandible: (*a*) height of the symphysis, (*b*) length of the body, (*c*) length of the ramus, (*d*) bigonial width (between the angles), (*e*) bicondylar width, and so on. The angle between body and ramus is also often estimated. Since the mandible is often missing from dried skulls and moreover is held to be a less reliable element in assessing racial affinity than the rest of the skull (Morant 1936), its measurements are not so widely used.

Other forms of cranial measurement are also employed. The horizontal circumference of the head and various arcs and contours are sometimes measured. Radiographic studies make it possible to extend the classical series of craniometric dimensions described above and to measure directly the angles between certain of them, for example, the *gnathic angle*, measured between the basion-nasion and basion-prosthion lines. The *craniofacial* or *cranial base angle* is of special interest, representing the degree of cranial flexure. The angle has a value of about 130°, and this is probably achieved by the time of birth, little further change occurring. Its high value in man is sometimes associated with the movement of the tongue towards the pharynx, a change sometimes regarded as essential to speech. (For a review of the literature *see* Schulter 1976.) A radiographic technique for estimation of endocranial volume, or cranial capacity, has also been evolved (Haas 1952). *Cranial capacity*, which is taken as an indication of brain volume, can be assessed directly by filling the cranial cavity with lead shot, millet seed, or other particulate materials suitable for volumetric measurement when poured out again. A number of formulae have also been calculated to yield



cranial capacity from length, breadth and height of the cranium. Examples are:

Males: $0{\cdot}000337\,(L-11)\,(B-11)\,(H-11)+406{\cdot}01$ c.c.
Females: $0{\cdot}000400\,(L-11)\,(B-11)\,(H-11)+206{\cdot}60$ c.c.

In these formulae, L and B are length and breadth, and H is the *auricular height*, which is measured to the vertex from the external acoustic meatus. All measurements are expressed in millimetres. These methods are subject to considerable inaccuracy, and various corrections and allowances do not entirely remove this (Hrdlička 1947, Montagu 1960).

Attempts to establish reliable craniometric differentiation between races are as old as craniometry itself; and although the mandible and cranial capacity are in this connection less dependable, satisfactory characterization has been established for some racial groups and especially for Caucasians and Negroes. Where a number of measurements are treated by discriminant analysis, an accuracy of over 90 per cent can be expected (Giles and Elliot 1960). Multivariate analysis may also elucidate problems of cranial growth (Liebgott 1977). Craniometric methods have a special usefulness in forensic practice where cranial remains can be compared with existing photographic and radiographic records in making an identification (Glaister and Brash 1937). They also play a part in attempts to reconstruct the appearance in life of individuals represented only by skeletal remains (Stewart 1954). Cephalometry has a further application in clinical specialities, such as plastic and oral surgery, concerned with cranio-facial deformity. A recent development in this field is *morphanalysis*, an approach which uses gridded radiographs and photographs that are universally related in three dimensions (**3**.126B). Such standardized records enable diagnostic comparisons to be made between patients and the normal population (Rabey 1977).

Applied Anatomy. Features which tend to prevent fracture of the skull are its elasticity, its rounded shape, and its construction from a number of secondary elastic arches, each made up of a single bone. Moreover, in some places where the bone is thin, overlying muscles may offer some resistance in cushioning blows. Examples are the temporal squama and the inferior occipital

3.126B Combined, accurately superimposed, photographs and radiographs of the kind shown here are currently being used to produce a computerized analysis of metrical relations between a selection of datum points in the skeletal and soft tissue components of human heads and faces. The technique, known as morphanalysis, has been elaborated by Dr. G. P. Rabey, to whom we are indebted for these records. Both photographs and radiographs are produced in the three primary planes, and hence the morphometric analysis is three-dimensional. For further information, *see* Rabey (1968, 1971, 1980).

fossa. A metrical study of the thickness of the calvaria in 28 Caucasians (aged from 15 to 82 years) yielded an average thickness of 5·8 mm. In male specimens, thickness increased with age; in females, the reverse was observed (Lippert and Käfer 1974).

The most common place for fracture of the base to occur is through the middle fossa, and here the fissure usually takes a fairly definite course. Starting from the point struck, usually near the parietal tuber, it runs downwards through the parietal and the squamous temporal and across the petrous portion, frequently traversing and implicating the internal acoustic meatus, to the foramen lacerum. This course explains the symptoms which may arise: thus, if the fissure passes across the internal acoustic meatus, injury to the facial and vestibulocochlear nerves may result, with consequent facial paralysis and deafness; if the fissure extends through the semicircular ducts vertigo will ensue, or the tubular prolongation of the arachnoid around the nerves in the meatus may be torn and thus permit the escape of the cerebrospinal fluid, should there be a communication between the internal ear and the tympanic cavity together with rupture of the tympanic membrane, as is frequently the case.

The bones of the face are sometimes fractured by direct violence. Those most commonly broken are the nasal bones and the mandible; the latter is by far the most frequently fractured of all facial bones. Fracture of the nasal bone is usually transverse, about 1·25 cm from the free margin. The broken portion may be displaced backwards or more generally to one side by the force which produced the lesion. The most common situation for a fracture of the mandible is in the neighbourhood of the canine tooth, as at this spot the bone is weakened by the deep socket for its root; it is next most frequently fractured at the angle. Occasionally a double fracture may occur, one in each half of the bone. Such fractures are usually compound, from laceration of the mucous membrane covering the gums.

THE APPENDICULAR SKELETON

Phylogeny and Functions

The ancestral vertebrates, the *Agnatha*, were not only jawless but also without appendages, like their surviving representatives, such as the lampreys (Young 1962; Romer 1970). It has been hypothecated that two continuous finfolds, ventrolateral in position, were the forerunners of the separated pairs of fins which appear in the fossil remains of the earliest fish which possessed jaws, the *Placoderms* (Westoll 1958). These sometimes displayed more than two pairs of appendages, but in their descendants, the bony and cartilaginous classes of fish, the *Osteicthyes* and *Chondricthyes*, the characteristic vertebrate pattern of four appendages, arranged in pectoral and pelvic pairs, became stabilized—departed from only in such forms as the snakes, which have subsequently lost their limbs. The appendicular skeletons of fossil and extant fish show much variation; but there is a basic division into 'girdle' bones, embedded in the musculature of the body wall, and the rodlike elements radiating into the mobile fin, the two articulating at a joint of approximately ball and socket type. In many orders of bony fish the homologues of the components of the pectoral and pelvic girdles can already be identified, as well as those of the proximal two segments, arm and forearm or thigh and foreleg, of the terrestrial limbs (Bolk *et al.* 1931–9). Distal to this the equivalence is less clear; but in the multiplicity of its small bony units the fin bears at least some resemblance to the extremities, hand and foot, of the land tetrapods.

The terrestrial vertebrates are grouped as the *tetrapods* because their four limbs are an outstanding common feature, even though the pectoral pair may become extensively modified for flight. The tetrapods are widely considered to be derived from a primitive order of bony fish, the *Crossopterygii* ('fringe-finned'), related to another ancient group, the *Dipnoi* or lungfish, several species of which still survive today. The crossopterygians, in contrast, were known only as fossil remains until 1938, when a living representative of a suborder, *Coelacanthus*, was captured off the coast of South Africa; further living coelacanths have been secured subsequently near the Comoro Islands and elsewhere in the Indian Ocean. These forms possess lobed fins, with a narrowed attachment to the body, and it is from such appendages that tetrapod limbs can most plausibly be derived (Gregory and Raven 1944).

In the change to a terrestrial environment, during the evolution of primitive amphibians from crossopterygian fish, two major adaptions commenced. The first, already foreshadowed in their fins, was a change in the positioning of these limb-like paddles to bring them into more effective use for support and propulsion on land. The *fore-limbs* became rotated in a *lateral* direction at their joints with the pectoral girdles, so that the hinge of the elbow, at first pointing outwards away from the body, as it still does in many amphibians and reptiles, finally projected backwards. In contrast, the *hind-limbs* were rotated *medially* at their junction with the pelvic girdle into opposite positions, the knees projecting forwards. These opposite changes in the positioning of the limbs entailed that the *pre-axial* or leading *border*, corresponding with the 'first' digit, pollex or hallux, was rotated from an anterior to a lateral position in the pectoral limb, but from an anterior to a medial position in the pelvic limb. (As described later on p. 352 this change in orientation of the fore-limb necessitates a complementary *pronation* of its radio-ulnar segment to ensure a plantigrade position of the appendage. The compensation is unnecessary in the hind-limb.) Coupled with these growing structural distinctions between the fore and hind extremities was a second major modification—the articulation of the pelvic girdles with the spinal column, a condition not present in any fish, but uniform in tetrapods, except in some early fossil amphibians.

With the evolution of the amphibians, the general skeletal pattern of the tetrapod limb was defined, and apart from relatively minor modifications this has persisted throughout subsequent forms. It is often called the *primitive pentadactyl limb*, since it terminates typically in five digits. Among mammals especially, reduction in the number of these is frequent, but the primates, including mankind, have retained the full number and are in this respect unspecialized.

Of the *limb girdles*, the *pectoral* always consists of a dorsal element, the *scapula*, but displays considerable variation in its ventral components, which are commonly a mixture of endochondral and dermal bones. Of these the *coracoid* and *clavicle* persists in mammals, the former being reduced in size and fused to the scapula. The clavicle, the sole mammalian survivor of a considerable variety of dermal elements, such as the *cleithrum* and *interclavicle*, present in the pectoral girdle of lower vertebrates, is also reduced and frequently lost in mammals, especially in fast-running or bounding types of quadruped. Its persistence in the primates can be associated with the development of the fore-limb for climbing and prehensile activity; the clavicle acts as a mobile strut, at the lateral end of which the rest of the limb can be steadied in a variety of positions (Watson 1917). The *pelvic girdle*, in contrast to the pectoral, contains only endochondral elements; the dermal armour of many primitive fish extended far enough caudally to permit the incorporation of dermal elements into the pectoral but not the pelvic girdle. The latter developed a primitive ventral *symphysis* in fish, and in tetrapods this region is composed of distinguishable pubic and ischial elements. The dorsal component, the ilium, though present in some fish, is not well developed. In land animals the need of larger muscles to support the body's weight and to impart thrust to it through the hind-limbs, is associated with greater size of the ilium and of its articulation with the sacral part of the spinal column. Throughout the tetrapods these three pelvic entities, *pubis*, *ischium* and *ilium*, show a greater uniformity of arrangement than in fish. They also show an increasing tendency to fuse together into an *innominate*

bone, especially in adult mammals. The two innominate bones are jointed together ventrally at a symphysis pubis and each to the sacrum dorsally at sacro-iliac articulations. Thus is established a structural arrangement, the *pelvis*, the primary functions of which are locomotor, in conducting stresses between the axial skeleton and that of the limbs. The term pelvis, meaning a basin, is misleading, for it is more of an irregular ring of bone which, being in the body wall at the caudal end of the body cavity, inevitably surrounds certain viscera. This relationship may, in human anatomy, obscure the essentially appendicular origin and function of the pelvis. Since the cloaca is immediately caudal to it, not only the hindgut, but other tubes, urinary or genital, must pass through the pelvis, even when they achieve separate external openings in the mammals. During birth, offspring must therefore traverse the pelvis, and their comparatively large size in human females entails obstetric considerations (p. 384), which again may overshadow the somatic and locomotor nature of the hind-limb girdle.

In mammals the functional differences between the fore- and hind-limbs, which are accentuated in a primate such as man, are associated with marked structural divergence in their girdles. These major differences are as follows:

	Pectoral Girdle	**Pelvic Girdle**
1.	Dermal and endochondral.	Entirely endochondral.
2.	Two components, clavicle and scapula, which remain separate.	Three components, pubis, ischium and ilium, which fuse into a single innominate bone.
3.	No articulation with vertebral column.	Articulates with sacral vertebrae.
4.	No direct ventral articulation (clavicles connected only by interclavicular ligament).	Direct ventral articulation at symphysis pubis.
5.	Articulations of clavicles with axial skeleton (sternum) are relatively small, mobile, and ventral.	Articulations of innominate bones with axial skeleton (sacrum) are relatively large, capable of little movement, and dorsal.
6.	Comparatively lightly built for mobility.	Massively constructed for resistance to stress rather than for mobility.
7.	Resilient to thrust.	Transmits thrust between vertebral column and leg.
8.	Shallow joint with limb, allowing wide range of movement.	Deep joint with limb, limiting range of movement.

Both girdles articulate with the distal, freely movable parts of the limbs by 'ball and socket' joints, the first segment of each limb containing a single element, *humerus* or *femur*. The shoulder and hip joints are essentially the same in mechanism, allowing some degree of movement in all directions, though usually to a more limited extent in the latter. Even in quadrupedal mammals, where the limbs tend to function as walking props, mainly adapted to fore and aft movement in the long axis of the body, greater mobility is usual at the shoulder, particularly as regards abduction, which permits outward splaying of the fore-limbs. Throughout the tetrapods the shoulder region shows a greater range of structural adaptation with changing function than the hip.
